Tolerance develops to the anticonvulsant and sedative effects of many benzodiazepines. However, tolerance to the anxiolytic effects of these drugs appears less likely to develop (Simpson and Simpson 1996). In contrast, withdrawal can accompany rapid discontinuation of the drug. Thus, doses should be gradually tapered (e.g., 25% per week) as the drug is discontinued (Simpson and Simpson 1996; Overall 1997).

SIDE EFFECTS. In addition to changes in behavior, the benzodiazepines have been associated with a number of side effects in human patients. Reaction may be to the parent drug or a metabolite. Long-term use in human patients has been associated with neutropenia and liver disease. Recently, acute fulminating hepatotoxicity has been reported in cats receiving diazepam orally (Center 1996). Clinical signs include anorexia, vomiting, lethargy, hypothermia, and jaundice. The adversity appears to be dose dependent (and thus may be idiosyncratic), occurring in most animals within 5–11 days after therapy is begun. Mortality is high (8 out of 11 cats in one report) despite intensive therapy. Histology revealed severe acute to subacute lobular to massive hepatic necrosis, suppurative cholangitis, and biliary hyperplasia. Baseline hepatic function data might be collected in cats prior to starting therapy and 3–5 days after therapy is begun in order to minimize the damage induced by diazepam administered to cats at risk. Any evidence of illness (or evidence of prolonged elimination) should lead to discontinuation of the drug.

CLINICAL INDICATIONS. The benzodiazepines are less desirable as behavior-modifying drugs because of their nonspecific nature (Overall 1997). Thus, a notable disadvantage of the long-term use of benzodiazepines is their tendency to interfere with the ability to learn in animals undergoing behavior modification as part of their treatment program (Lindell 1997). An exception can be made for chlordiazepoxide, which appears to facilitate operant conditioning in nervous (Pointer) dogs (Simpson and Simpson 1996). Paradoxical reactions may occur in some animals, including rage, hyperexcitability, and anxiety. In addition, the risk of substance abuse by pet owners should lead to close scrutiny of drug needs and use.

Benzodiazepines are indicated for the treatment of anxiety. Alprazolam and clonazepam may be associated with fewer side effects and might be preferred (Overall 1997); however, fewer reports exist regarding their use in animals. The benzodiazepines are contraindicated in aggressive patients (Overall 1997). Simpson and Simpson (1996) notes that the contraindication may depend on the cause of aggression. If aggression is a manifestation of an underlying fear or anxiety, then the benzodiazepines may reduce aggression. If, however, anxiety or fear is masking aggression, benzodiazepines may increase aggression. Other indications for benzodiazepines include treatment of inappropriate elimination (Overall 1997), noise phobias, and selected anxieties such as visits to the veterinarian (Simpson and Simpson 1996; Overall 1997).

Anxioselective Drugs: Azapirones (Buspirone)

STRUCTURE-ACTIVITY RELATIONSHIP. Buspirone is referred to as a nonspecific anxiolytic. Azapirones were specifically developed for atypical depressions, nonspecific generalized anxiety disorders, and selected obsessive-compulsive disorders. Buspirone is the first nonsedating antianxiety drug to be marketed (Simpson and Simpson 1996). Its effects appear to reflect blockade of 5-HT$_1$ receptors at both pre- and postsynaptic sites. Presynaptic inhibition increases low serotonergic activity, whereas postsynaptic control reduces high (Simpson and Simpson 1996). Buspirone causes downregulation of 5-HT receptors. In addition, it acts as a dopamine agonist throughout the brain (Simpson and Simpson 1996).

SIDE EFFECTS. In contrast to benzodiazepine anxiolytic drugs, buspirone has no sedative, muscle relaxant, or anticonvulsant actions. It does not impair motor performance (Simpson and Simpson 1996). Side effects to buspirone manifested in cats include increased aggressiveness (toward other household cats), increased affection toward owners, mild sedation, and agitation (Cooper 1997). Vomiting and tachycardia also have been reported (Cooper 1997). In contrast to the anxiolytic drugs and TCAs, buspirone is associated with a low abuse potential. Withdrawal following discontinuation of the drug apparently does not occur (Overall 1997).

CLINICAL INDICATIONS. Buspirone has been used to treat canine aggression, canine and feline stereotypic behaviors, self-mutilation, obsessive-compulsive disorders, thunderstorm phobias, and feline spraying (Hart et al. 1993; Overall 1997). Buspirone apparently has been particularly useful for treatment of anxiety associated with social situations such as aggression or marking behaviors (Overall 1997). However, treatment for anxiety is more likely to be successful short term rather than long term, perhaps because of the slow onset of action characterizing the drug.

MISCELLANEOUS (NONSPECIFIC) DRUGS USED TO MODIFY BEHAVIOR

Progestins. Progestin interaction with GABA receptors is 10–50 times more potent than that of barbiturates (Overall 1997). This may account for the nonspecific calming effects of the drugs observed in veterinary medicine. The advent of newer behavior-modifying drugs (e.g., TCAs, SSRIs) and the incidence of side effects largely limit their use to animals that have not responded to other medications and are faced with euthanasia.

Several side effects have been well documented in animals receiving progestins long term. Among the more notable because of their magnitude or life-threatening nature are gynecomastia, mammary gland neoplasia, diabetes mellitus, aplastic anemia, and pyometra (Juarbe-Diaz 1997a). Animals should be frequently monitored for evidence of adversities.

Progestins are most wisely reserved for adjuvant short-term therapy (until the second drug takes affect, i.e., 4–6 weeks), and only the oral form is recommended. The progestins are an alternative for animals for whom euthanasia is being considered; in such cases, a high dose (4 mg/kg orally every 24 hours) has been recommended in order to stimulate a rapid response (Juarbe-Diaz 1997a).

Anticonvulsants. A number of anticonvulsant drugs have been used to treat behavioral abnormalities. The most notable of those used in animals include the barbiturate phenobarbital, its congener primidone, and phenytoin, a hydantoin derivative. They have been somewhat efficacious for treatment of overactive or aggressive behaviors (which actually may have been an expression of psychomotor epilepsy) (Overall 1997). However, efficacy is generally dependent on sedative (and, with long-term use, potentially toxic) effects. They have largely been replaced by the TCAs and SSRIs. The side effects of these drugs (discussed in Chap. 16) limit their long-term use, although monitoring (as with anticonvulsant therapy) may help prevent toxicity.

Phenytoin has been useful for the treatment of explosive aggression in human patients. Phenobarbital may prove useful for controlling excessive feline vocalization during car travel (Overall 1997) and canine aggression (Dodman and Shuster 1994). Carbamazepine (an iminodiabenzyl derivative of imipramine) also has been used to treat explosive aggression in humans. Valproic acid may be useful for treatment of aggression (Dodman and Shuster 1994).

Narcotic Agonists and Antagonists. These drugs are discussed in depth in Chap. 13. The antagonists in particular have proven useful in the treatment of selective obsessive-compulsive disorders in humans. Efficacy also has been reported when used to treat selected self-mutilation disorders in dogs (e.g., acral lick dermatitis or lick granuloma) (Overall 1997; Dodman et al. 1988; Dodman and Shuster 1994; Simpson and Simpson 1996). Pure antagonists, including naloxone and naltrexone (the latter an orally bioavailable product), and mixed agonists/antagonists such as pentazocine appear effective. These drugs block μ and κ receptors. The assumed mechanism of action is blockade of self-reward mediated by endogenous opioid release that may accompany self-destructive behavior. Hydrocodone also has proven effective in selective self-destructive behaviors in both the dog and the cat.

Antihistamines. The mildly sedative (e.g., hydroxyzine) or hypnotic (e.g., diphenhydramine) effects caused by H_1-receptor blockade can be of benefit for treatment of some behavioral disorders. These drugs are discussed in depth in Chap. 51 as antiemetics at the vestibular apparatus. Indications as behavior-modifying drugs might include the treatment of chronic pruritus, late-night activity, problems during car travel, and selected transient behaviors accompanied by pacing and vocalization (Overall 1997).

Beta Blockers. Beta-adrenergic blockers (e.g., propranolol, pindolol) have been used in human medicine for the treatment of aggressive outburst associated with self-mutilation or injury problems, intermittent explosive behaviors, conduct disorders, dementia, and schizophrenia (Overall 1997). However, the use of these drugs for similar disorders in animals has not been very successful (Overall 1997). Nonselective beta blockers also have been used to treat anxiety in human beings. One animal behaviorist reports success with the use of propranolol or pindolol (the latter also affecting serotonin receptors) for the treatment of fear aggression in dogs (Dodman and Shuster 1994).

Stimulants. Stimulants include dextroamphetamine, methylphenidate (Ritalin®), and pemoline. Stimulants are characterized by paradoxical effects in that they cause excitement in the normal patient but have a calming effect on the hyperactive patient. Their indication in human patients is for the treatment of attention deficits. Conditions of hyperactivity are rare in veterinary medicine. Proper diagnosis is imperative for successful therapy with stimulants. They increase sympathomimetic stimulation. Side effects include increased heart and respiratory rate and anorexia. Tremors and hyperthermia may occur. The drugs are contraindicated in patients with cardiovascular disease, glaucoma, and hyperthyroidism. The drugs should not be used in combination with other behavior-modifying drugs (Overall 1997).

EUTHANIZING AGENTS

EUGENE P. STEFFEY

- **Agent Evaluation Criteria**
- **Agent Category and Mode of Action**
  - **Inhaled Vapors and Gases**
    - **Carbon Monoxide**
    - **Carbon Dioxide**
    - **Hydrogen Cyanide**
    - **Inhalation Anesthetics**
    - **Nitrogen**
  - **Injectable Agents**
    - **Barbiturates**
    - **Chloral Hydrate**
    - **Ethanol**
    - **T-61 Euthanasia Solution**
    - **Neuromuscular Blocking Drugs**
    - **Miscellaneous Injectable Drugs**
- **Agents for Aquatic Animals**

Euthanasia (literally a "good death") is the act of inducing humane death. Euthanasia can be performed using physical or chemical means. Information in this chapter is limited to chemical agents of euthanasia. The subject has been reviewed over the past few decades in five published reports by American Veterinary Medical Association (AVMA) Panels on Euthanasia. A new panel will be commissioned soon, and likely a published (the sixth) report of this sixth panel will appear before the next edition of this text. The fourth and fifth AVMA Panel reports (Smith et al. 1986; Andrews et al. 1993) and "Recommendations for Euthanasia of Experimental Animals," parts 1 and 2, prepared by a working party for the European Commission (Close et al. 1996, 1997), serve collectively as an informational focus for this chapter and a source of animal species–specific information. The present review also draws information from an earlier edition of this text (Hatch 1988).

AGENT EVALUATION CRITERIA. Several criteria should be used in evaluating agents for animal euthanasia. These include (1) ability to induce death without causing pain; (2) time required to induce loss of consciousness; (3) time required to produce death; (4) reliability; (5) safety of personnel; (6) potential for minimizing undesirable psychological stress on the animal (i.e., anxiety, apprehension, or distress); (7) nonreversibility; (8) compatibility with requirement and purpose; (9) emotional effect upon observers or operators; (10) economic feasibility; (11) compatibility with histopathologic evaluation; and (12) drug availability and personnel abuse potential. The ideal euthanizing agent should have the following properties:

1. The agent should produce death without causing pain or meet this condition as closely as possible under the circumstances of the moment.
2. The agent should not cause or require restraint that causes undue anxiety, struggling, vocalization, or clinical signs of autonomic activation.
3. The agent should be fast acting; unconsciousness and death should be instantaneous or occur within minutes of agent administration.
4. The agent's effects should be reliably and consistently produced.
5. The agent should be safe for properly trained personnel to use.
6. The agent should be easy to administer and not require complicated administration methods.
7. The agent should not be a drug with potential for abuse by humans.
8. The agent's operation should be aesthetically acceptable to those people observing the event.
9. The agent should be compatible with the overall reason and purpose of euthanizing the animal(s).
10. The agent and its method of delivery should be economical.
11. The agent should not be a threat to the environment or pose a sanitation problem.
12. The agent should not cause tissue changes that complicate necropsy results, including histopathologic inspection of tissues or toxicologic evaluation of body components. There should be no agent or agent-related tissue residues in animals intended for consumption.

AGENT CATEGORY AND MODE OF ACTION. Chemical agents that are used to euthanize animals can be categorized as injectable drugs or inhaled vapors or gases. A list is given in Table 18.1.

Chemical agents ultimately end life by decreasing the delivery of oxygen to cells to a level incompatible with sustained cellular function. The specific mechanism of individual agents varies. Adequate delivery of oxygen is a function of the respiratory and circulatory

TABLE 18.1—Chemical agents currently used as euthanizing agents

Inhalation agents
Carbon monoxide
Carbon dioxide
Inhalation anesthetics (diethyl ether, enflurane, halothane, isoflurane, methoxyflurane)
Nitrogen
Injectable agents
Barbiturates
Chloral hydrate and adjuvants
Ethanol
Miscellaneous injectable general anesthetics (used as adjuvants to other, primary agents in selected circumstances)

TABLE 18.2—Mechanism of action of euthanizing agents

Agent	Action	Comments
Inhalation agents		
Carbon monoxide	Combines with hemoglobin, lowering oxygen content of blood	Unconsciousness occurs rapidly; motor activity may persist after unconsciousness
Carbon dioxide	Direct depression of CNS and other vital organs; anesthetic effects	Unconsciousness occurs rapidly; possible involuntary motor activity after unconsciousness
Hydrogen cyanide	Direct inhibition of cellular utilization of oxygen	Unconsciousness occurs rapidly; involuntary motor activity after unconsciousness; dangerous to personnel; recently removed from lists of acceptable methods of euthanasia
Inhalation anesthetics	Direct depression of CNS and other vital organs	Used largely for individual animals in selected specific circumstances
Nitrogen	Displaces oxygen in the inspired breath; lowers oxygen content of blood	Unconsciousness occurs rapidly; involuntary motor activity may persist after unconsciousness
Injectable agents		
Barbiturates	Direct depression of CNS; anesthetic effects	Unconsciousness occurs rapidly when given by IV route
Chloral hydrate and combinations	Direct depression of CNS; anesthetic effects	Unconsciousness occurs rapidly; generally reserved for large domestic animals
Ethanol	Direct depression of CNS	Use with small laboratory animals only
T61	Direct depression of CNS	Transient struggling may occur before unconsciousness; objectionable tissue damage may occur; recently withdrawn from US market
Neuromuscular blocking drugs	Paralysis of respiratory muscles	Unacceptable for use as a sole agent

Sources: Modified from AVMA Panel reports on euthanasia (Smith et al. 1986; Andrews et al. 1993).

systems and their own associated regulatory mechanisms (central, peripheral, and autonomic nervous systems). Euthanizing agents can and often do influence the process of oxygen delivery at one or multiple stages. Table 18.2 lists the sites of action of frequently used euthanizing agents.

Inhaled Vapors and Gases

CARBON MONOXIDE. Carbon monoxide (CO) comes from natural sources such as forest fires and atmospheric oxidation of methane and from human activity. The greatest source from human activity is as a byproduct of internal combustion engines. It also can be produced chemically (Klaassen 1990). It has a high affinity for hemoglobin—more than 200 times that of oxygen for hemoglobin (Nunn 1987). Its toxicity is largely due to its combination with hemoglobin to form carboxyhemoglobin. This form of hemoglobin cannot carry oxygen. As a result, the partial pressure of oxygen may not change from normal but the oxygen content of blood and therefore the amount of oxygen available to the tissues decrease markedly. By its presence it also accounts for a shift to the left in the dissociation curve of remaining hemoglobin combined with oxygen. This means that it is more difficult to unload oxygen from hemoglobin at the tissue level. Therefore, less oxygen is available to tissues by yet a different mechanism. Carbon monoxide also exerts a direct toxic effect by binding to cellular cytochromes.

Carbon monoxide is odorless, tasteless, nonirritating, and causes no increase in ventilation or cyanosis (blood is cherry red). The tissues most affected by CO and other euthanizing agents that directly influence oxygen delivery are those most sensitive to oxygen deprivation, like the brain and the heart. Unconsciousness occurs without pain or apparent appreciable discomfort. A concentration of 6% or greater is usually desired for purposes of euthanasia. Agitation and vocalization may occur before loss of consciousness, but this can be minimized by pretreatment with tranquilizers (Chalifoux and Dallaire 1983; Dallaire and Chalifoux 1985).

Carbon monoxide used for individual or mass euthanasia is considered acceptable for small animals, including dogs and cats, providing appropriate precautions are taken. These are discussed further in recent panel reports (Smith et al. 1986; Andrews et al. 1993; Close et al. 1996). Because of its insidious nature, personnel safety is of particular concern with its use.

CARBON DIOXIDE. Carbon dioxide (CO_2) has been and continues to be used widely to euthanize small laboratory animals, but there is debate about which method and concentration should be used: i.e., rapid immersion in a gas mixture of high CO_2 concentration versus gradual induction with increasing CO_2 concentrations (Dannemann et al. 1997; Smith and Harrap 1997; Andrews et al. 1993; Close et al. 1996). It has also been used for preslaughter narcosis of some food animals (Smith et al. 1986; Andrews et al. 1993; Gregory et al. 1987), but use for euthanasia of large laboratory animals is not common (Ewbank 1983).

Time to anesthesia and death are inversely related to CO_2 concentration (Dannemann et al. 1997). At low concentrations (5-8%) CO_2 elevates the pain threshold (Stokes et al. 1948), and at higher concentrations (<30%) it has a rapid anesthetic effect (Nunn 1987; Leake and Waters 1929; Mattsson et al. 1972; Klemm 1964; Simonsen et al. 1981; Glen and Scott 1973; Hansen et al. 1991). Eisele et al. (1967) showed in dogs that an arterial CO_2 partial pressure greater than 95 mm Hg (alveolar concentration of about 13% at sea level) is associated with arterial and cerebrospinal fluid pH of less than 7.10 and is increasingly anesthetic; a basal level of general anesthesia (1.0 minimum alveolar concentration) is produced by an arterial CO_2 partial pressure of about 245 mm Hg (an alveolar concentration of about 35%). The major effect of CO_2 on the central nervous system is likely caused by alteration of the intracellular pH with consequent derangements of metabolic processes (Woodbury and Karler 1960). The work of Eisele et al. (1967) showed that the degree of CO_2 narcosis correlated better with cisternal cerebrospinal fluid pH than with arterial CO_2 partial pressure. Adverse reactions such as involuntary muscle activity and convulsions may occur in some animals, but this is usually after the animals are unconscious (Leake and Waters 1929; Hansen et al. 1991; Smith et al. 1986; Forslid 1987). Hemorrhaging from the nose and pulmonary hemorrhage and edema are also observed on histologic examination of some animals (Dannemann et al. 1997).

Carbon dioxide is available as a compressed gas in cylinders. Oxygen can be added in low concentrations (15-20%) if desirable to minimize or prevent hypoxic conditions during CO_2 inhalation (Coenen et al. 1995). Carbon dioxide is nonflammable and nonexplosive and thus represents little hazard to personnel. Additional information on the pharmacologic effects of CO_2 can be found in Chap. 10.

HYDROGEN CYANIDE. Hydrogen cyanide (HC) induces rapid death because it blocks mitochondrial utilization of oxygen. Cellular respiration is thus inhibited and cytotoxicity results (Klaassen 1990). Convulsions may occur, usually following unconsciousness, and are presumably related to cellular hypoxic conditions in the brain. Use poses a substantial risk for harm to animal handlers. Hydrogen cyanide has been removed from the AVMA Panel's list of acceptable methods of euthanasia (AVMA 1992; Andrews et al. 1993). Therefore, its action will not be further discussed here. Additional information can be found in the panel's reports (Smith et al. 1986; Andrews et al. 1993) and elsewhere (Klaassen 1990).

INHALATION ANESTHETICS. The inhalation anesthetics, including diethyl ether, halothane, methoxyflurane, enflurane, isoflurane, and the recently introduced sevoflurane and desflurane, may be used to euthanize animals via overdose. With small animals, any of these agents can be delivered by placing an animal or animals in a closed receptacle containing gauze pledget soaked with the anesthetic liquid. Alternatively, the anesthetic can be delivered under more controlled circumstances by introducing the anesthetic along with carrier gas into a chamber or chambers from a flowmeter-vaporizer assembly, equipment similar to that used in the clinical delivery of inhaled anesthetics to patients. The inhalation anesthetics are generally less desirable than other techniques because the prolonged time to death may be excessive, especially with the more soluble agents such as ether and methoxyflurane. The species is also a factor in this decision (Blackshaw et al. 1988).

The anesthetic potency of nitrous oxide is too low to be used by itself as a euthanizing agent under this category. At inspired concentrations of nitrous oxide greater than 80% (sea level conditions) hypoxemic conditions exist. Human abuse is a potential with this drug.

The long-term adverse effects on health from occupational exposure to trace concentrations of waste anesthetic gases is a controversial subject. Present information indicates that inhaled anesthetics have no more than a low potential for causing long-term toxicity (Baden and Rice 1990). However, until definitive information is available, it is best to consider that all of the inhaled anesthetics are potentially hazardous to personnel who are chronically exposed.

NITROGEN. Nitrogen (N_2) is a colorless, odorless, inert gas that constitutes about 79% of normal atmospheric air. It is readily available commercially as a compressed gas stored in cylinders.

Euthanasia is induced by rapidly replacing the air within a sealed chamber with pure N_2 at ambient pressure. The N_2 displaces oxygen within the chamber and hypoxic conditions result. Unconsciousness occurs rapidly, but gasping, yelping, muscle tremors, or convulsions may precede death. Newborn animals are not euthanized by this method as rapidly as older animals; therefore, N_2 is not recommended for euthanasia of these animals (Smith et al. 1986). Nitrogen gas is considered an acceptable agent for mass euthanasia, but in many situations other methods are considered preferable (Andrews et al. 1993).

Injectable Agents. Noninhalation agents can be administered via a variety of routes. In the past, intravenous, intracardiac, intraperitoneal, intrathecal, intramuscular, intrathoracic, subcutaneous, rectal, and oral routes have been used. Preference is given to the intravenous route because the effect is most rapid and predictable. Contemporary opinion does not support the routine use of intra cardiac, intrathoracic, and intrathecal routes, especially in unsedated healthy animals (Andrews et al. 1993). Administration of drugs for euthanasia via the oral, rectal, or subcutaneous routes is generally inadvisable because of prolonged onset of action (Smith et al. 1986; Grier 1991).

BARBITURATES. The barbiturates are used extensively for euthanasia. They may be administered by a variety of routes but intravenous is preferred for speed of unconsciousness and lack of trauma. There is a rapid progression from unconsciousness to deep general anesthesia, respiratory arrest, and finally cardiac arrest.

Pentobarbital alone or in combination with other depressant drugs is most commonly used to euthanize individual animals. It is not suitable for mass euthanasia because of the technical expertise required and the need to handle individual animals regardless of their temperament or the available facilities. Barbiturates require professional supervision and are listed as Schedule II drugs under current Drug Enforcement Administration (DEA) regulations. Human abuse potential is of concern. Meat from barbiturate-euthanized animals should not be used for animal (or human) consumption.

CHLORAL HYDRATE. This drug, like the barbiturates, causes progressive dose-related central nervous system depression. However, because some of its accompanying actions (e.g., slower onset of action vs. barbiturates, gasping, vocalizations) in otherwise unmedicated animals are considered by some objectionable, it is not recommended by the AVMA Panel for routine use with dogs, cats, and other small animals (Andrews et al. 1993).

Chloral hydrate and mixtures of chloral hydrate, magnesium sulfate, and pentobarbital have long been in use as an anesthetic for large domestic animals, especially horses. Intravenous overdose of these chloral hydrate mixtures is suitable for euthanasia of individual large animals.

Chloral hydrate and its mixtures are classed as Schedule IV drugs under DEA regulations.

ETHANOL. Ethanol is a widely available drug with potent hypnotic and sedative effects. It has recently been advocated as an alternative and effective method of euthanasia for small laboratory animals (e.g., mice) (Prien et al. 1988).

Ethanol is a primary central nervous system depressant. As blood ethanol concentration is increased, general impairment of nervous function occurs followed by general anesthesia and ultimately coma and death via respiratory arrest, conditions not unlike actions related to increasing doses of barbiturates. In one study of mice, 70% ethanol injected intraperitoneally reportedly caused death in 2.68 minutes with no discomfort observable in any individual (Prien et al. 1988).

T-61 EUTHANASIA SOLUTION. T-61 is an injectable drug mixture marketed as a non-DEA-controlled alternative to barbiturate solutions. It is a mixture of an agent with general anesthetic properties (*N*-2-[methoxyphenyl]-2-ethylbutyl-1-hydroxybutyramide), a muscle relaxant (4,4′-methylene *bis*-cyclohexyl-tri-methyl ammonium iodide), and a local anesthetic (tetracaine hydrochloride). Each milliliter of T-61 contains 200, 50, and 5 mg of these components, respectively.

The agent has been recently withdrawn from the market in the US but is available in Canada (Andrews et al. 1993). There is no human abuse potential.

Because it causes discomfort when administered extravascularly, T-61 should only be administered intravenously. The agent is unsuitable in many cases in which postmortem tissue studies are desirable because of widespread undesirable effects on structure and biochemistry of tissues and body fluid (Prien et al. 1988; Hellebrekers et al. 1990; Doughty and Stuart 1995).

NEUROMUSCULAR BLOCKING DRUGS. Neuromuscular blocking drugs, also referred to as curariform or peripheral-acting muscle relaxant drugs, must never be used by themselves for euthanasia. Drugs in this classification include curare (*d*-tubocurarine), succinylcholine, pancuronium, and atracurium. They induce death by immobilizing the respiratory muscles, causing fatal suffocation. There is no central nervous system depression. Animals are immobile but fully conscious and sensitive to their immediate surroundings and body part manipulations. The use of these drugs as sole agents for euthanasia is unacceptable.

MISCELLANEOUS INJECTABLE DRUGS. A wide variety of anesthetic and anesthetic adjuvant drugs (Chap. 9) may be useful in allaying animal apprehension and facilitating control of animals presented for euthanasia. Readers are encouraged to review pharmacological advantages and disadvantages in appropriate sections elsewhere in this text.

A number of drugs have been used alone in the past to euthanize animals but are now considered undesirable. These include strychnine and nicotine (Smith et al. 1986). In addition, drugs such as digitalis and calcium, magnesium, and potassium ions act directly on heart muscle and cause death by stopping the heart. They have no effect on consciousness and are not analgesic. Therefore, they too should not be used alone to purposely end life.

AGENTS FOR AQUATIC ANIMALS. Discussion in this chapter has focused on chemicals for mammals and birds. Some of these agents may also be used for causing humane death in aquatic animals, e.g., pentobarbital via injection. In addition, agents may be placed in the water environment for absorption through the skin and gills (Andrews et al. 1993; Close et al. 1996). For example, inhalation anesthetic agents may be bubbled into the water environment. Benzocaine dissolved in acetone before adding to tank water is an effective and humane method of killing fish and amphibians. Death occurs subsequent to generalized CNS depression. Tricaine methane sulphonate (MS-222), a dose-related CNS depressant, is commonly used as a general anesthetic for fish and like barbiturates may be used in overdose for a euthanasia agent.

Euthanasia of a pet animal is a very sensitive situation for the client-veterinarian relationship (Edney 1989; Cohen and Sawyer 1991; Kay et al. 1988) and must satisfy humane and ethical tests. It is a procedure that is common to varying degrees in most companion animal health care facilities (Gorodetsky 1997) and its conduct requires careful consideration and empathy on the part of the veterinarian (Randolph 1994).

Laboratory animal euthanasia also must satisfy scientific criteria. For example, euthanasia per se might alter cellular architecture (Feldman and Gupta 1976; Port et al. 1978; Prien et al. 1988) or components of host immune defenses (Howard et al. 1990; Lord et al. 1991) or other aspects of laboratory study. Accordingly, agent selection is multifactorial and complex. In many cases, information on which to base a sound decision is lacking.

HISTAMINE. Histamine is a biogenic amine detected in the early 1900s as a common bacterial-source contaminant of ergot extracts (Dale and Laidlaw 1910). Because histamine evoked a contractile response in smooth muscles and also lowered blood pressure, attention was drawn to similarities between its actions and anaphylactic-type reactions. Histamine was discovered in mammalian tissues and found to be released upon cellular trauma, leading to the theory of histamine as an endogenous mediator of cell injury. Subsequent studies have provided a wealth of physiologic and pathophysiologic roles for histamine quite apart from simple cellular trauma (Barnes et al. 1990; Falus and Meretey 1992). This amine is involved in inflammations, anaphylaxis, allergies, and certain types of drug reactions, and it regulates gastric secretion (Obrink 1991; Morris 1992; Mitsuhashi and Payan 1992). Histamine itself is not used therapeutically, but antihistaminic agents are commonly used to inhibit effects of endogenous histamine.

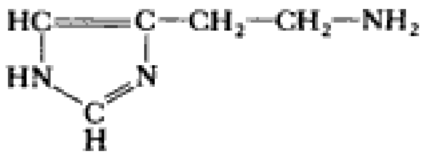
H_1, H_2, and H_3 Histamine Receptors. Histamine contracts several types of smooth muscles, including those of the bronchi, gut, and large blood vessels. In contrast, small arterioles are relaxed by histamine to the extent that peripheral vascular resistance and blood pressure fall. Capillary permeability is increased. Gastric secretion of hydrochloric acid is stimulated, as are secretory activities of other exocrine glands. In humans, flushing of the facial skin and burning and itching sensations also are evoked. With large doses of histamine, blood pressure progressively falls and is accompanied by hemoconcentration caused by extravasation of plasma. "Histamine shock" may terminate in death (Pearce 1991).

Responses to histamine can be explained by activation of specific histamine receptors on various target cells. Analysis of histamine-receptor interactions was advanced by Bovet and Staub (1937), who described the first antihistamine. This type of drug competitively inhibits several biologic effects of histamine and protects guinea pigs from the high lethality of anaphylactic shock. Ash and Schild (1966) subsequently pointed out the likelihood for two types of histamine receptors in mammalian tissue. This theory was based on the knowledge that conventional antihistaminic drugs available at that time, such as pyrilamine and diphenhydramine, blocked only certain actions of histamine. Other activities, most notably stimulation of gastric secretion, were not amenable to inhibition by such drugs and were therefore thought to be mediated by a second type of receptor.

The existence of two general types of histamine receptors was confirmed by Black et al. (1972), who conducted a systematic pharmacologic study of compounds derived from the basic structural components of histamine. Based on this investigation, histamine receptors were designated as histamine type 1 (H_1) and histamine type 2 (H_2). Histamine-induced contraction of bronchial and intestinal smooth muscle is mediated through H_1 receptors and inhibited by pyrilamine and other standard antihistamines (now called H_1 blockers). In contrast, histamine-induced stimulation of gastric secretion is mediated by H_2 receptors and inhibited by the newly available H_2 blockers burimamide, metamide, and cimetidine. Different histamine receptor agonists likewise display preferential action at receptor subtypes. For example, 2-methylhistamine evokes rather selective agonist action at H_1 receptors; whereas, 4-methylhistamine acts preferentially at H_2 receptors.

Studies have also indicated yet a third class of histamine receptors. These H_3 receptors are believed to be linked to inhibition of adenylyl cyclase through an inhibitory G_i protein (Arang et al. 1987). H_3 receptors may be localized to the central nervous system (CNS), and their therapeutic relevance to veterinary medicine remains to be discovered.

Endogenous Histamine. Histamine is 2-(4-imidazolyl) ethylamine (Fig. 19.1); it is derived from the decarboxylation of an amino acid, histidine. Conversion of histidine to histamine is catalyzed in mammalian tissues by a specific enzyme, histidine decarboxylase; this enzyme is present in all cell types that contain histamine.



Histamine

FIG. 19.1

Histamine is widely distributed throughout mammalian tissue, but concentrations vary considerably in different species; e.g., quantities of circulating histamine are relatively high in the goat and rabbit but low in the horse, dog, cat, and human. It is generally accepted that most of the histamine stored within the body is derived locally from enzymatic decarboxylation of histidine. Dietary histamine and histamine produced by enteric bacteria are disposed of rapidly after absorption into the portal circulation and contribute little or nothing to tissue storage sites.

Two general stores of histamine can be identified in mammalian species: the mast cell pool made up of mast cells and basophils and the non-mast cell pool localized in the gastrointestinal (GI) tract, CNS, dermis, and other organs. These two pools differ not only in cellular locale but also in responsiveness to physiologic and pharmacologic stimuli.

The mast cell pool of highly concentrated histamine is distributed in connective tissue throughout the body. Circulating basophils, free counterparts of fixed-tissue mast cells, also contain high concentrations of histamine and are grouped with the mast cell because of basic similarities. Within these two cell types, histamine is synthesized rather slowly and stored tenaciously in secretory granules; hence, turnover rate is low. Experimental drugs such as compound 48/80 have the interesting capability of liberating histamine from storage granules. Because of the slow turnover rate, mast cell stores are replenished slowly after exposure to a histamine-releasing agent. The mast cell pool represents the histamine that participates in inflammatory responses, allergic phenomena, shock, some adverse drug reactions, and other forms of cellular insult.

The precise cellular localizations and physiologic functions of the non-mast cell pool of histamine within the gastric mucosa, brain, and skin are not known with certainty. Histamine in these regions, in contrast to the mast cell pool, undergoes a rapid turnover rate; it is synthesized and released continuously rather than being stored. Functional roles of this newly synthesized or nascent histamine are under considerable investigation. Portions of this histamine are present within neural elements, and neurotransmitter functions have been proposed. In the gastric mucosa, a "local hormone" action of histamine controls gastric secretion. Interestingly, non-mast cell histamine is generally resistant to the histamine-releasing drugs such as compound 48/80.

Histamine Release. Histamine is highly concentrated in mast cell granules, where it is stored with a heparin-protein complex, proteolytic enzymes, and other autacoids. Release of histamine basically is a two-step process: sudden exocytotic extrusion of granules from the cell and release of histamine from the granules into the interstitial milieu. The latter occurs as an ionic exchange reaction between extracellular cations and molecules of granular histamine. Release can be initiated by a variety of stressful stimuli, including anaphylaxis-allergy, different drugs and chemicals, and physical injury.

ANAPHYLAXIS AND ALLERGY. Hypersensitivity phenomena associated with antigen-antibody reactions evoke active release of histamine from the mast cell pool. Free histamine then plays an important role in mediating physiologic manifestations of such reactions as vasodilation, itching, smooth muscle contraction, and edema. Other autacoids also participate in tissue responses to hypersensitivity reactions. Signs of histamine involvement in systemic anaphylaxis vary in different species. In carnivores, histamine and anaphylaxis produce pronounced hypotension and hepatomegaly. In rabbits, pulmonary arterioles constrict and the right heart dilates in response to either histamine injection or exposure of a sensitized individual to the appropriate antigen. In guinea pigs, dominant manifestations are bronchial constriction and death by asphyxiation. Humans seem to respond like guinea pigs and dogs in that severe hypotension, bronchial constriction, and laryngeal edema are principal signs of anaphylaxis.

The mast cell pool of histamine represents a major target for acute types of hypersensitivity-allergy reactions. Expulsion of the granular contents of mast cells and basophils is initiated by interaction of specific antigen and cell-bound reaginic (IgE) antibody. This interaction increases permeability of the cell to calcium ions (Ca^{++}). The resulting influx of Ca^{++} from the interstitium then evokes release of histamine in a manner basically analogous to the secretory responses of various endocrine and exocrine cells to their respective secretagogues (Douglas 1974). Release is an active process, requiring metabolic energy as well as Ca^{++}, and should be distinguished from simple release secondary to cell destruction and cytolysis.

The ubiquitous cyclic adenosine 3′,5′-monophosphate (cAMP) system may be involved in histamine release evoked by antigen-antibody interactions. Studies indicate that an increase in cAMP concentration suppresses histamine release (Lichtenstein and Margolis 1968). Agents that activate adenylyl cyclase (e.g., catecholamines) or inhibit phosphodiesterase (e.g., xanthines) can be anticipated to inhibit the release of histamine. The beneficial effects of drugs widely used in treating allergic disorders, such as the catecholamines and theophylline, may therefore involve inhibition of histamine release in addition to their well-known and more important physiologic antagonism of histamine actions on target cells.

DRUGS AND CHEMICALS. Many drugs and chemicals produce direct degranulation of mast cells with release of histamine independently from development of allergy. This characteristic action represents an untoward side effect associated either with intravenous (IV) administration of a relatively large dose or direct intradermal injection. Conversely, certain chemicals have as their dominant property the ability to release histamine from the mast cell pool.

The curare-alkaloids are used clinically as neuromuscular blocking agents (Chap. 8), but they also are notorious for releasing histamine as an adverse side effect; in some species, IV injection of these agents can be followed by histamine-induced bronchospasm and hypotension. Other clinically used drugs that may release histamine include morphine, codeine, papaverine, meperidine, polypeptide antibiotics (polymyxin), atropine, and, under some conditions, even sympathomimetic amines. Histamine release usually is significant with most of these agents only when large doses are used.

Certain other chemicals have been classified simply as histamine-releasing agents because this particular activity supersedes their other pharmacologic properties. The best known and most active is an organic base called compound 48/80, a condensation product of *p*-methoxyphenylethylmethylamine with formaldehyde (Goth and Johnson 1975). Injection of compound 48/80 or other similar agents evokes classic pharmacologic signs of histamine release that are susceptible to blockade by antihistaminic drugs. Tachyphylaxis to repeated injections is characteristic of these chemicals, presumably because of decreased availability of releasable stores of histamine. Other substances such as dextran, ovomucoid (from egg white), histones, and lysosomal enzymes also can release histamine, depending upon the species. Endogenous substances that provoke histamine release and may be involved in physiologic release mechanisms include bradykinin, kallidin, and substance P. Cellular reactions to many venoms and toxins also involve histamine release.

The basis for species-dependent actions of different releasing agents has not been clarified, and little is known about cellular mechanisms of drug-induced histamine release phenomena. Compound 48/80 not only elicits release of histamine but causes complete discharge of all the granular contents of mast cells. This process is Ca^{++} and energy dependent, but it is not known if such drugs act like pseudoantigens at cell membranes or directly mobilize cellular calcium instead (Douglas 1974; Goth and Johnson 1975).

PHYSICAL INJURY. When the skin is scratched or pricked, the characteristic redness and urtication that result are due to histamine. This response is quite pronounced in humans. Dermal reactions to severe cold or heat stress likewise depend on histamine liberated by local mast cells. Physical injury of virtually any type sufficiently intense to damage the cells will also evoke release of histamine.

Role in Health and Disease

GASTRIC SECRETION. Histamine is a potent stimulant of hydrochloric acid secretion by the gastric mucosa. This finding led early investigators to portray endogenous histamine as the final common mediator of gastric secretion, irrespective of whether stimulation arises from chemical, mechanical, or nervous elements. Full acceptance of this theory was delayed for over 50 years because conventional antihistaminic drugs available at the time (i.e., the H_1 blockers) failed to prevent gastric effects of histamine. This impediment was surmounted when Black et al. (1972) reported that the new H_2-blocking agents are quite efficacious in inhibiting gastric stimulant activities of histamine and its congeners. H_2-blocking drugs also reduce the gastric secretory response evoked by ingestion of a meal or administration of either the gastric hormone gastrin or its synthetic derivative pentagastrin.

NEURONS. Locally released or injected histamine stimulates sensory nerve endings, thereby evoking the classic symptoms of itching and pain. Histamine also is present in the brain, where it is concentrated in the hypothalamus; subcellular distribution studies have localized histamine to some nerve endings. These and related studies, in conjunction with the obvious CNS effects of histamine blockers, have prompted the suggestion that histaminergic neurons are present in the brain and that histamine released from these fibers functions as a neurotransmitter. Some investigators have proposed the existence of peripheral efferent histaminergic nerves; these fibers are envisioned as subserving vasodilation and participating as active components of reflex vasodilation in conjunction with the passive withdrawal of sympathetic vasoconstrictor tone in this reflex.

OTHERS. A variety of biologic roles have been proposed for endogenous histamine in addition to those previously addressed, including local regulation of the microcirculatory response to injury and inflammation, some type of anabolic activity in rapidly growing or repairing tissues, systemic signs associated with excessive numbers of mast cells or basophils, and involvement in different types of headaches in humans. In domestic animals, histamine released from damaged tissue has been suggested as a mediator in several pathologic states, including allergic reactions to drugs, venoms, and other antigens; ruminant bloating; overeating and other GI disorders of ruminants; laminitis; azoturia; retained placenta; pneumonia; gut edema of the pig; and various types of circulatory shock syndromes (e.g., septic shock). Except for allergic phenomena, however, the role of histamine in these conditions usually is more empirically based than experimentally founded.

Pharmacologic Effects. Histamine administered orally has essentially no effect because it is destroyed rapidly by the GI tract and liver. When injected intravenously, histamine produces a spectrum of characteristic effects. These activities include smooth muscle contraction, hypotension, increased gastric secretion, dermal reactions, and others.

Difficulties are encountered when attempts are made to designate H_1- or H_2-receptor responsibility for each action of histamine. In some tissues, H_1 and H_2 receptors are complementary and subserve similar tissue responses. In contrast, distinct and even opposing functions of the two receptor types have been identified in some tissues. Species differences are formidable and in most cases await further study for classification. In the following paragraphs, only the more representative examples of H_1- or H_2-receptor involvement, when known, are discussed.

CARDIOVASCULAR SYSTEM. The principal circulatory effects of histamine are dilation of terminal arterioles and other vessels of the microcirculation, edema formation caused by increased capillary permeability, and contraction of large arteries and veins. Relative dominance of the different actions varies in different species so that net circulatory response to histamine changes as the zoologic scale is ascended; e.g., arterioles are contracted strongly by histamine in rodents, less so in cats, and actually are dilated in dogs, nonhuman primates, and humans.

In rabbits, histamine is a pressor agent as a result of pronounced constriction of large blood vessels. This constrictor activity is feeble in carnivores where vasodilation of the microcirculation dominates instead. Thus the blood pressure response to histamine in cats, dogs, and primates is hypotension caused by a sharp fall in peripheral vascular resistance. The fall in blood pressure is dose dependent but is usually short-lived because of compensatory reflexes and inactivation of histamine.

The striking effects of histamine on the microcirculation can be demonstrated quite convincingly in the human subject. When this agent is administered intradermally, a characteristic triple response is produced, which includes localized redness at the injection site, developing within a few seconds and attaining maximal hue within a minute; localized edema fluid, forming a wheal in about 90 seconds; and diffuse redness or "flare," extending about 1 cm from the original red spot. The central redness and edema are from the dilation and increased permeability of local microcirculatory vessels (terminal arterioles, capillaries, and venules). The surrounding flush, which is accompanied by itching and perhaps pain, is due to dilation of neighboring arterioles brought about by a poorly understood axonal reflex mechanism. The triple response of human skin may be similar to manifestations of urticaria in animals.

Vascular actions of histamine formerly were believed to be mediated solely by H_1 receptors; however, it now seems that both types of histamine receptors are involved. The vasodilator response to H_1-receptor activation occurs at low doses of histamine and is rapid in onset and of brief duration. The H_2-receptor vasodilator response is evoked with larger doses and is slower in onset and of longer duration. The small-vessel permeability changes evoked by histamine are clearly mediated by H_1 receptors, while the role of H_2 events is uncertain. The precise ratio of H_1- and H_2-receptor involvement in vascular responses to histamine varies in domestic animal species; some of the more important species differences were reviewed by Hirschowitz (1979).

Cardiac effects of histamine are minimal when compared to vascular actions. In the intact animal, slight tachycardia is a common finding. This response is mainly secondary to baroreceptor reflexes activated by the depressor effect. In isolated heart muscle, histamine can elicit positive inotropic and chronotropic effects that are due partly to release of norepinephrine from nerve endings and also to direct activation of H_2 receptors in the heart muscle. There is some evidence that in vivo cardiac responses to histamine injection may partially reflect activation of cardiac H_2 receptors (Hirschowitz 1979).

NONVASCULAR SMOOTH MUSCLE. Histamine contracts bronchial smooth muscle via H_1 receptors in numerous mammals including the guinea pig, rabbit, dog, goat, calf, pig, horse, and human (Chand and Eyre 1975). Guinea pigs are exceptionally sensitive, and even minute doses of histamine can evoke bronchoconstriction leading to death. Humans with bronchial asthma likewise demonstrate increased sensitivity to bronchial effects of histamine and other bronchial smooth muscle stimulants. In contrast, histamine can mediate relaxation of respiratory smooth muscle in some species. Histamine-induced tracheal relaxation in cats involves both H_1 and H_2 receptors, while bronchial relaxation in sheep seems to be mediated by H_2 receptors (Hirschowitz 1979).

Relaxation of the rat uterus by histamine is mediated by H_2 receptors, but uterine muscle of other species is generally contracted by histamine. Responses of intestinal muscle also vary with species and region, but the classic effect is a contractile response caused by H_1 receptors. Although an indirect component mediated by neural elements may be involved, smooth muscle effects of histamine chiefly involve direct actions on the muscle itself.

EXOCRINE GLANDS. The following exocrine glands are listed in descending order of response to histamine: gastric, salivary, pancreatic, bronchial, and lacrimal. Gastric secretion of hydrochloric acid and, to a lesser degree, pepsinogen is unquestionably the most important; this response is mediated by H_2 receptors.

MECHANISM OF ACTION. The H_1 receptors in some cell types are linked to activation of phospholipase C and the resulting increase in inositol triphosphate and intracellular Ca^{++}. This process most likely involves a G protein, as discussed in Chap. 5 (Lambert 1993). The H_2 receptors also utilize G proteins linked to activation of adenylyl cyclase and its increased synthesis of cAMP, culminating in activation of the latter's intracellular receptor, protein kinase A. Interestingly, the vasodilator response elicited by endothelial H_1 receptors involves activation of nitric oxide synthase and release of endothelium-derived nitric oxide. The vasodilatory H_2 receptors, on the other hand, are localized on the vascular smooth muscle itself.

Biotransformation. Histamine administered orally is poorly absorbed, but absorption is virtually complete after parenteral injection. Pharmacologic actions are brief because of rapid metabolism and distribution into tissues. Exogenous histamine can be incorporated into storage granules to some extent; however, this pathway is probably unimportant to endogenous storage pools of the amine.

Biotransformation of histamine involves methylation and oxidation, as shown in Fig. 19.2. Histamine is acted upon by the enzyme histamine-*N*-methyltransferase (imidazole-*N*-methyltransferase) to form methylhistamine; most of this metabolite is oxidized to methylimidazole acetic acid by the enzyme monoamine oxidase (>50%). The second pathway is oxidative deamination catalyzed by the enzyme diamine oxidase (histaminase) to form imidazoleacetic acid, which is conjugated with ribose as riboside (>25%). Only a small percentage of the primary amine can be acetylated in the GI tract, absorbed, and excreted in urine (1%). Some free histamine is also excreted in urine (2-3%).

Medical Use. Clinical applications in humans involve use of histamine as a test agent for achlorhydria, in diagnosis of pheochromocytoma, and for production of the triple response to evaluate the integrity of sensory innervations and circulatory competency. The polypeptide pentagastrin and histamine analogs such as the H_2-selective agonist impromidine have been used as alternative means of evaluating gastric secretory function because of less objectionable H_1-mediated side effects. Repeated injections of histamine in an attempt to desensitize patients with allergies has not met with general acceptance.

Cromolyn is an interesting drug used in human medicine as a prophylactic treatment of bronchial asthma. Cromolyn exerts this activity by inhibiting the release of histamine and other autacoids that participate in the asthmatic syndrome. The application of cromolyn to animal medicine remains untested.

ANTIHISTAMINES. Although the pharmacologic effects of histamine can be antagonized by several types of drugs, the term antihistamine should be restricted to agents that act on histamine receptors. The receptors are not activated by such interaction, but their occupancy by the antihistamine limits accessibility to

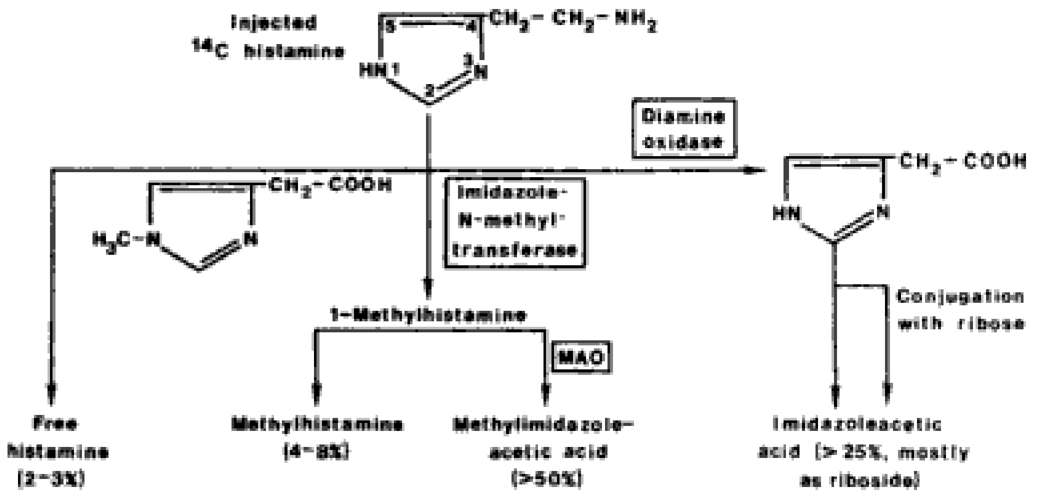


FIG. 19.2—Synthesis, metabolism, and urinary metabolites of histamine recovered in 12 hours following intradermal injection of ^{14}C-histamine in a human male (% values from Schayer and Cooper 1956).

histamine and thereby prevents the latter from exerting its cellular actions. Other agents such as catecholamines and xanthines exhibit pharmacologic activities that are, among other things, antagonistic to actions of histamine. However, these opposing actions are mediated by different receptors and cellular pathways; they represent physiologic antagonism.

Development. Bovet and Staub (1937) of the Pasteur Institute in Paris first demonstrated that two phenolic esters possessed antihistaminic activity. One of these compounds, 929F (thymoxyethyldiethylamine), protected guinea pigs against several lethal doses of histamine. Although the original drugs were too toxic for therapeutic use, their discovery led to development of many modern antihistaminic agents. Such compounds are now referred to as H_1 and H_2 antihistamines, based on the previously described differentiation of histamine receptors into H_1 and H_2 subtypes (Ash and Schild 1966; Black et al. 1972).

Chemistry. Some of the more frequently used H_1 antihistamines are listed in Table 19.1. The chemical structure of nearly all the H_1 antihistaminic drugs can be depicted by the structural formula shown in Fig. 19.3. The nucleus of the structure is ethylamine (CH_2CH_2N), which is also present in histamine. This moiety is thought to be the molecular component necessary for competition with histamine for specific cell receptors.

Three types of H_1 antihistaminics are known in which the element X (as depicted in Fig. 19.3) is nitrogen, oxygen, or carbon. The X represents a nitrogen for the ethylenediamine class (e.g., pyrilamine, Neoantergan), oxygen for the ethanolamine class (e.g., diphenhydramine, Benadryl), and carbon for the alkylamine class (e.g., Teldrin). The fourth class of antihistaminics contains a piperazine in place of the conventional ethylenediamine linkage (e.g., cyclizine, Marezine). The representative of the fifth class (e.g., promethazine, Phenergan) is not related directly to the previous drugs, since it is a phenothiazine derivative. The sixth class comprises the peperidines terfenadine and astemizole; these agents have aromatic ring moieties on either end of the ethylamine chain. These different chemical substitutions influence the potency of H_1-antihistaminic action as well as producing a variety of side effects.

The H_2 antihistamines differ from the H_1 blockers in their chemistry, pharmacokinetics, and pharmacodynamics. The imidazole ring structure of histamine is modified extensively or replaced by other substituents in the H_1 antagonists. In the H_2-blocking agents, however, the side chain is modified extensively, while the imidazole moiety is preserved. In contrast to the H_1 antihistaminics, the H_2 antagonists are somewhat less lipid soluble and do not effectively penetrate the blood-brain barrier. Hence the H_2 antagonists do not cause sedation, a prominent side effect of most of their H_1 counterparts.

Burimamide was the first H_2 antagonist, but it was absorbed too poorly to be effective after oral administration. Metiamide was subsequently synthesized; it was absorbed effectively from the GI tract, but several human patients treated with the drug developed agranulocytosis. A newer H_2 blocker, cimetidine, was then introduced into clinical medicine and so far has not been associated with hematologic toxicity. Ranitidine, famotidine, and nizatidine are some of the newer H_2 blockers.

Pharmacologic Effects. Antihistaminics of the H_1 subtype are absorbed satisfactorily after oral administration in monogastic animals but not in ruminants. Effects are usually expected within 20-45 minutes after oral administration, and the duration of action ranges from 3 to 12 hours (Table 19.1). IV administration elicits immediate effects, but this route is not often recommended because of resulting stimulation of the CNS and other side effects. The intramuscular

TABLE 19.1—Preparations and doses of some H_1 antihistamines in veterinary use

Generic name	Trade name	Single dose and route (in mg/kg unless indicated otherwise)	Preparation	Special properties
Diphenhydramine Hydrochloride, USP	Benadryl, Caladryl (lotion)	LA: 0.5–1 SA: 1–2 PO, IV/12 hr	Inj. 10, 25, 50 mg/mL Elix. 10 mg/4 mL	Marked sedation; anti-motion sickness
Pyrilamine Maleate, NF	Histosol,[a] Neoantergan	LA, SA: 1–2 IM, IV, SC	Inj. 20–25 mg/mL Tab. 25–50 mg	Prominent sedation
Tripelennamine Hydrochloride, USP	Pyribenzamine	LA: 1–2 PO, IV SA: 1–1.5 PO, q8h	Inj. 20 mg/mL Tab. 25–50 mg Bolus 500 mg	Sedation; if overdose, ataxia; convulsions
Chlorpheniramine Maleate, NF	Telodron,[b] Teldrin	SA: 1 span. for dogs >3.6–18 kg/12 hr 2 span. for dogs >18 kg/12 hr	Span. 8 mg., sustained-release form	Moderate sedation
Dimenhydrinate, USP	Dramamine	LA, SA: 1–1.5 PO, IM, SC	Inj. 50 mg/mL Tab. 50mg Liquid 12.5 mg/4 mL	Prominent anti-motion sickness
Promethazine Hydrochloride, USP	Phenergan	LA, SA: 0.2–1 IM, IV, PO, q8h	Inj. 25–50 mg/mL Tab. 25, and 50 mg Also available as cream for topical use	Long acting, marked sedation; anti-motion sickness
Clemastine	Tavist 1	SA: 0.5–1 PO, q12h	Tab.	Few side effects
Hydroxyzine	Atarax	SA: 2 PO, q8h	Tab.	Sedation
Trimeprazine	Temaril	SA: 0.5–2 PO, q12h	Tab.	Sedation
Astemizole	Hismanal	SA: 2.5–10 PO, q24h	Tab.	Nonsedative
Terfenadine	Seldane		Tab.	Nonsedative
Amitriptyline	Eleva	SA:1.0–2 PO, q12h	Tab.	Tricyclic

Abbreviations: LA = large animal, SA = small animal, PO = oral, SC = subcutaneous, IM = intramuscular, IV = intravenous, inj. = injection, elix. = elixer, tab. = tablet, span. = spansule, q8h = every 8 hr.

[a] Also available: Pyrazine with ephedrine (injectable and oral); Antiphrine with ephedrine (injectable and granules to administer in feed); Novahistine with phenylephrine hydrochloride.

[b] Metrevet and Predmaton with prednisone for oral use in dogs and cats.

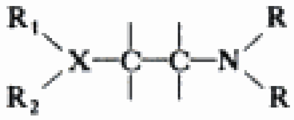

FIG. 19.3—General formula of most H_1 antihistaminic agents.

route rarely gives rise to side effects and is commonly used. Topical application may be suitable in certain skin conditions.

Antihistamines act as competitive antagonists for specific histamine receptors in the tissue cells; their binding to the cell receptors evokes no direct cellular action. This mechanism of action is based on quantitative considerations; therefore, histamine in excess may displace antihistaminics. Generally, antihistaminics are more effective against exogenously administered histamine than against endogenously released histamine. They are also more effective in preventing actions of histamine than in reversing them.

H_1 antihistaminics are useful in countering action of histamine on bronchial, intestinal, uterine, and vascular smooth muscle. They antagonize both the vasoconstrictor effects of histamine and the more important vasodilator effects as well as the increase in capillary permeability produced by this agent. These antihistaminic effects counteract urticaria, whealing, and other types of edema formation in response to injury, antigens, allergens, or histamine-liberating drugs in many species. H_1 antihistaminics also suppress itching and flare in humans and greatly reduce itching associated with allergic reaction.

H_1 antihistaminics only partially antagonize histamine-induced arterial hypotension because portions of this response are associated with H_2 receptors. Similarly, H_1 antagonists do not block the stimulant effect of histamine on gastric secretion, which is an H_2-dependent function. Importantly, neither H_1 nor H_2 antihistamines prevent histamine release; some antihistaminics possess histamine-liberating properties. This latter action may be of clinical significance in therapeutic use of these drugs.

H_2 antagonists block the gastric stimulating effects of histamine as well as other actions of histamine that have been defined as H_2 receptor dependent (e.g., stimulation of rat uterus, cardiac excitatory effects, and some vascular effects).

Side Effects and Interactions. Each antihistaminic produces certain side effects. Those of clinical importance for the H_1 blockers include sedation or CNS excitement, GI disturbances, parasympatholytic action, local anesthetic properties, allergenic properties, and teratogenic effects.

In therapeutic doses, H_1 antihistaminics elicit a sedative effect, which is expressed by drowsiness or ataxia. In higher doses they produce irritability, convulsions, hyperpyrexia, and even death. Intestinal disorders involve anorexia, nausea, vomiting, constipation, or diarrhea when antihistamines are administered orally for a prolonged period. The anticholinergic effects are expressed by a dry mouth, pupillary dilation, blurred vision, and tachycardia. Local anesthetic properties are of value when these agents are used as antipruritic drugs in topical application. Paradoxically, antihistaminics also can be allergenic when applied to the skin. The teratogenic effects of certain of these agents suggest caution in their use during pregnancy. These drugs possess antiserotonin properties as well as cocainelike effects on catecholamine uptake. The newer H_1-antihistamines terfenadine and astemizole are largely excluded from the CNS when given in therapeutic doses (Janssens and Howart 1993). Their lack of sedation as a side effect is a distinct advantage in human medicine. Study is needed in veterinary medicine to determine their clinical efficacy and whether lack of sedation is an important attribute in animals (Miller et al. 1989).

Toxicity. In recommended doses H_1 antihistaminics are relatively nontoxic; however, overdosage or combinations with the above potentiating agents can elicit toxic effects, which are expressed by hyperexcitability and even convulsions. Treatment of acute toxicity is symptomatic; sedative or ultrashort-acting barbiturates may be of value, but caution is indicated because additive effects are possible.

Therapeutic Uses. Clinically, H_1 antagonists are used to prevent participation of endogenous histamine in the body's reaction to certain allergic disorders and anaphylactic syndromes. However, the clinician must be aware that autacoids other than histamine also play important roles in allergy-anaphylaxis disorders. Eyre and Burka (1978) reviewed this field and listed the following compounds as primary or secondary mediators of hypersensitivity reactions: histamine, serotonin, dopamine, kinins, slow-reacting substance of anaphylaxis, platelet activating factor, eosinophil chemotactic factor of anaphylaxis, prostaglandins, complement, and lymphokines. Thus it is not surprising that antihistamines alone are often ineffective in treating allergic-type reactions in animals.

Clinical signs of allergy vary with different species. The most frequently observed signs are restlessness, anorexia, yawning, salivation, lacrimation, nasal discharge, coughing, edema, urticaria, eczema, necrosis, hemorrhage, inflammation of the mucous membranes and eyes, contraction of smooth muscle (bronchoconstriction), and cardiovascular disturbances. In acute or delayed anaphylaxis, clinical signs occur quickly and, if not treated, are followed by collapse and death in minutes.

Diagnosis is dependent on anamnesis, specific signs, feed tests, eosinophil count, and skin tests; in large animals, skin tests are of questionable value. Eosinophilia is evident in several allergic conditions; some authorities believe that in parasitic diseases it may also be allergy related.

Treatment consists of further avoidance of allergens, emergency measures, administration of antihistaminics, and prophylactic desensitization. Anaphylactic syndrome requires emergency treatment because it progresses rapidly to irreversible cardiovascular collapse. The drug of choice is epinephrine; this catecholamine does not directly inhibit mediators of anaphylaxis but reverses their effects. Thus epinephrine acts as a physiologic antagonist (Chap. 6). Other sympathomimetic drugs (ephedrine and isoproterenol) have been used in a variety of acute and chronic allergic reactions. Aminophylline may be beneficial (especially in small animals) as a smooth muscle relaxant in bronchoconstriction and in edema of the bronchial mucosa. Other emergency treatment may include oxygen or even tracheotomy in the presence of laryngeal edema. Corticosteroids are used as suppressants of allergic inflammation, especially in pruritus in dogs. Although corticosteroids have less indication in emergency treatment, their use may prevent late development of skin reactions.

Nonallergic but suspected histamine-related phenomena, which in empirical experience respond to antihistaminic therapy in animals, include many pathologic conditions. Those in which H_1 antihistaminics are reported to be of therapeutic value are pruritus, urticaria, various types of dermatitis, moist eczema, acute eczematous otitis, insect stings, nutritional types of laminitis, pregnancy laminitis, paroxysmal myoglobinuria or azoturia, periodic ophthalmia, and pulmonary emphysema in horses. Antihistamines also are considered to be of value in treatment of bovine asthma (pulmonary emphysema), some types of bloat and acetonemia in ruminants, acute septic and gangrenous mastitis, septic metritis and retained placenta, pregnancy toxemia, and gut edema of pigs. These agents are also helpful in some types of asthma and motion sickness.

The action of antihistaminics is symptomatic in character, and the important involvement of other autacoids in the pathologic conditions and allergic phenomena limit the effectiveness of antihistamines. These drugs are not a panacea, and removal of etiologic factors must be a primary goal of therapy. H_1 antihistaminics frequently used in animals and representative doses are given in Table 19.1.

H_2 antagonists are used extensively in treatment of gastric ulceration and other gastric hypersecretory states in humans. H_2 blockers also are utilized commonly in animal patients when suppression of gastric hyperacidity and prevention of gastric mucosal ulceration are indicated. H_2 antagonists should not be used indiscriminately in an attempt to provide complete protection from histamine release and hypersensitivity reactions.

SEROTONIN. Rapport et al. (1948) isolated a vasoconstrictor substance from serum and gave it the name serotonin. These investigators discovered that, chemically, serotonin was 5-hydroxytryptamine (5-HT). Independently, another group of researchers studying histochemical properties of the intestinal mucosa discovered an active agent in enterochromaffin cells and gave it the name enteramine (Erspamer and Asero 1952). After discovery of 5-HT in blood, it was soon confirmed that enteramine had the same chemical structure.

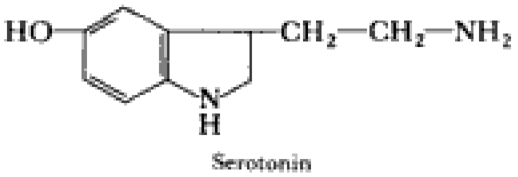
Chemistry. 5-HT is synthesized from dietary tryptophan in a two-stage chemical reaction. First, tryptophan is hydroxylated by the enzyme tryptophan 5-hydroxylase to give 5-hydroxytryptophan (5-HTP). The latter is then decarboxylated to yield 5-HT, as shown in Fig. 19.4.

Like histamine, 5-HT is widely distributed in animals and plants. It occurs in high concentration in some fruits such as bananas, pineapples, and plums; it also is present in stings (common stinging nettle) and venoms. Endogenous 5-HT is synthesized from about 1% of the dietary tryptophan. It is formed and localized in three essential pools; enterochromaffin cells of the intestine (about 90%), a small number of neurons in the CNS, and mast cells of rodents (rats, mice, hamsters) along with histamine and heparin. Although 5-HT is concentrated in blood platelets, it is not synthesized there because of lack of decarboxylase. It appears to be bound within cytoplasmic granules and is also continually produced and destroyed in the pool of the intestine and brain. In platelets it appears to be released only upon their destruction.

Most 5-HT is metabolized by oxidative deamination to form 5-hydroxyindoleacetic acid (5-HIAA); the enzyme catalyzing this reaction is monoamine oxidase. The end product of metabolism, 5-HIAA, is excreted in urine. However, in the pineal gland, *N*-acetylation and 5-methylation of 5-HT form the hormone melatonin.

Pharmacologic Effects. 5-HT exerts multiple actions with great variation in different species. Its essential effects are on smooth muscle and central and peripheral nerves, including afferent nerve endings. Given orally, it is quickly degraded and produces no effect.

Rapid IV injection of 5-HT produces a triphasic response: an initial fall of systemic arterial pressure accompanied by paradoxical bradycardia, caused mainly by reflex chemoreceptor stimulation (Bezold-Jarisch effect); a short period of pressor effect (similar to epinephrine effect); and a prolonged fall in systemic blood pressure attributed to a vasodilator effect in the vascular bed of skeletal muscle. 5-HT also causes a fall in pulmonary arterial pressure (pulmonary depressor reflex). A continuous infusion of 5-HT, which most closely resembles endogenous release of this agent, causes a prolonged fall in arterial pressure as a result of vascular bed dilation. Only in rodents does this agent increase small vessel permeability similar to effects of histamine.



Serotonin

FIG. 19.4

The nonvascular smooth muscle of the bronchi and intestines is stimulated by 5-HT. Intestinal effects are both direct and indirect; the latter is mediated via excitation of ganglion cells in the myenteric plexus. In some species, it causes contraction of the ureter and uterus (rodent). After repeated doses, tachyphylaxis is a common phenomenon.

When 5-HT is injected, it has no effect on the brain or spinal cord because it is strongly polar and cannot effectively cross the blood-brain barrier. However, 5-HTP can penetrate into the brain and be decarboxylated to 5-HT; this may produce behavioral changes. 5-HT can also stimulate afferent nerve endings, ganglion cells, and adrenal medullary cells.

Role in Physiologic and Pathologic Processes. The finding that 5-HT is present in the CNS, the hypothalamus, and other areas and that reserpine releases it from these areas led to the hypothesis of its role as a central neurotransmitter. 5-HT influences sleep, intestinal motility, and temperature regulation and affects the mood and behavior of humans. It seems that an excess of this agent brings about stimulation and that a deficiency produces depression. Its role in platelets is related to the mechanism of hemostasis via vasoconstriction and platelet aggregation.

Evidence exists that 5-HT exerts an inhibitory effect on a variety of behaviors (Green and Harvey 1974) and plays a role in some mental disorders of humans. The only disease in which 5-HT probably plays an important role is the carcinoid syndrome, which is characterized by widespread development of a serotonin-producing tumor in the GI tract. Symptoms are related to action on smooth muscle of the blood vessels and digestive and respiratory tracts. The 5-HT in the blood of a carcinoid subject is 0.5-2.7 μg/mL, while the normal amount is 0.1-0.3 μg/mL. The urinary metabolite has significant diagnostic value; excretion of 5-HIAA has been reported as 76-850 mg in 24 hours (normal is 2-8 mg). This results in 60% of the dietary intake of tryptophan being converted to 5-HT. Consequently, a deficiency may develop, producing symptoms of pellagra and negative nitrogen balance.

Antagonists. Different types of 5-HT receptors have been identified (Derkach et al. 1989). Actions of 5-HT are countered by two general groups of antagonists. Neural effects in smooth muscle of the digestive tract are antagonized by morphine, atropine, and cocaine; the direct effects on smooth muscle are antagonized by phenoxybenzamine and two derivatives of ergot alkaloids, LSD and methysergide. An antihistamine, cyproheptadine, is also a powerful antiserotonin agent. Chlorpromazine and phenoxybenzamine are weak blocking agents. Reserpine and compound 48/80 are examples of drugs that deplete serotonin in the brain. Another antagonist frequently used experimentally is *p*-chlorphenylamine, but this agent acts by inhibition of serotonin synthesis. For clinical use in humans, methysergide (oral dose 2-4 mg 3 times daily) and cyproheptadine (oral dose 4 mg 3 times daily) are the available effective antagonists. Ketanserin is a new 5-HT antagonist that acts preferentially at the 5-HT_2 receptor subtype without significant action at the 5-HT_1 receptors. The relevance of 5-HT receptor subtypes and 5-HT antagonists to clinical veterinary medicine is unknown.

ANGIOTENSIN. Discovery of angiotensin has its origins in the old observation that renal extracts contain a pressor substance that early investigators named renin (Tigerstedt and Bergman 1898). Subsequent researchers found that systemic hypertension could be produced by constriction of the renal artery, and they suggested that a circulating pressor agent released by the ischemic kidney acted as the mediator of the hypertensive response (Goldblatt et al. 1934). The pressor substance, identified as renin, is an enzyme that acts on a plasma substrate, resulting in formation of a peptide with exceptional vasoconstrictor potency. The peptide was called "hypertensin" and "angiotonin" until 1958 when the compromise term angiotensin was adopted (Braun-Menendez and Page 1958).

Angiotensin is a blood-borne polypeptide that serves as a circulating link between the kidney and systemic hemodynamic control systems (Matsusaka and Ichikawa 1997). This peptide is not manufactured directly by the kidney but is formed within the blood by a complex series of reactions initiated by the renal enzyme renin. Release of renin by the kidney is accelerated when this organ is subjected to physiologic stimuli associated with hypovolemia and hypotension (Bernstein 1993).

The renin-angiotensin relationship was complicated by the discovery that, after entering the bloodstream, renin and its substrate (angiotensinogen) yielded an inactive precursor, the decapeptide angiotensin I, which was then converted by other enzymes to the active octapeptide angiotensin II. The latter is an exceptionally potent vasoconstrictor agent and a stimulant of aldosterone secretion. Angiotensin II evokes an increase in peripheral vascular resistance and a reduction of urine and salt output, thereby tending to restore blood pressure and blood volume to more normal values. Pharmacologic manipulation of this system has recently gained considerable importance in clinical medicine. The angiotensin-converting enzyme inhibitors are now one of the most commonly used drugs to treat heart failure and hypertension (Dietz et al. 1993; Holtz 1993). Because angiotensin modulates cardiac cellular growth and hypertrophy, angiotensin-converting enzyme inhibitors are also being evaluated in treatment of cardiac hypertrophic states (Matsusaka and Ichikawa 1997).

The biologic half-life of angiotensin II was found to be quite brief because of the presence in plasma and tissues of proteolytic enzymes, collectively referred to as angiotensinases. A heptapeptide fragment of angiotensin II, originally thought to be an inactive metabolite, was found to possess considerable pharmacologic activity. The active fragment is now referred to as angiotensin III. In the following discussion, the term angiotensin is used to refer to angiotensin II unless otherwise noted.

Endogenous Renin-Angiotensin System

RENIN RELEASE. Renin is a proteolytic enzyme synthesized and stored within cytoplasmic granules of modified smooth muscle cells that line the afferent arteriole of the glomerulus. Both the afferent and efferent arterioles are associated anatomically and functionally with the macula densa, a group of specialized cells localized at the origin of the distal tubule of the nephron. The entire structure is referred to as the juxtaglomerular apparatus (Oparil and Haber 1974; Johnston 1992).

Renin is released from the juxtaglomerular apparatus in response to several stimuli associated with hypotension, hypovolemia, or both. Factors that reduce blood volume, renal perfusion pressure, or plasma sodium concentration tend to stimulate release of renin, while factors that increase these parameters tend to lower it (Gibbons et al. 1984; Bernstein 1993). Actual secretion of renin is regulated by an intrarenal baroreceptor mechanism of the afferent arteriole, an intrarenal chemoreceptor mechanism of the macula densa, the renal sympathetic nerves, and several humoral agents. These factors often interact with each other, resulting in considerable complexity. Basic aspects are summarized below and in Fig. 20.1.

An intrarenal baroreceptor mechanism detects and responds to changes in wall tension or transmural

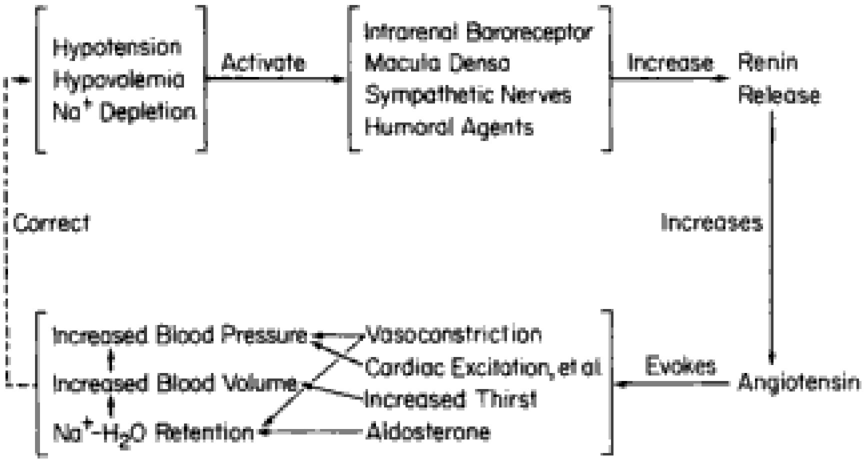

FIG. 20.1—Hemodynamic interrelationships of the renin-angiotensin system.

pressure gradients in the afferent arteriole of the glomerulus. Renin release from the juxtaglomerular apparatus is increased when renal blood flow and, especially, renal blood pressure are decreased. There is evidence that intrarenal prostaglandins serve as a chemical link between pressure changes and the resulting increase in renin secretion, at least within the autoregulatory range of renal blood flow (Schror 1992; Schwieler and Hjemdahl 1992).

The macula densa serves as a Na^+-sensitive and perhaps Cl^- sensitive chemoreceptor that detects these ions in renal tubular fluid. If Na^+ and/or Cl^- concentrations are reduced, renin release is increased.

Activation of the renal sympathetic nerves evokes release of renin. This response is mediated by an intrarenal β-adrenergic receptor. An α-adrenergic receptor that subserves an inhibitory effect on renin release seems to be present within the kidney, but its importance is not known.

Several circulating humoral agents and electrolytes influence renin release. Angiotensin itself can feed back to inhibit renin release; vasopressin is also inhibitory. Since angiotensin acts on the brain to increase release of vasopressin, there seems to be a vasopressin-angiotensin feedback loop. Other agents that can influence renin release include catecholamines, prostaglandins, cyclic nucleotides, K^+, Mg^{++}, Ca^{++}, serotonin, adenosine, and others. The importance of all these factors to normal control of renin release has not been determined (Keeton and Campbell 1981). There may be species differences in which scheme is dominant.

ANGIOTENSIN FORMATION. The known amino acid sequence of renin substrate, angiotensinogen, is limited to a 14 amino acid segment at the amino terminus of a larger protein. Once in the blood, renin cleaves the bond that joins the *N*-terminal 10 amino acid sequence to the remainder of angiotensinogen. The released decapeptide is angiotensin I; it can be considered as a circulating and essentially inactive prohormone to angiotensin II (Ardaillou 1997).

After the decapeptide angiotensin I is formed, two amino acids are removed from its *C*-terminus by converting enzyme to yield the octapeptide angiotensin II. The sequential formation of angiotensin is summarized in Fig. 20.2. Converting enzymes are present in endothelial cells throughout the body, but especially the lungs. Virtually all the circulating angiotensin I can be converted to angiotensin II by a single passage through the pulmonary vascular circuit. The angiotensin-converting enzyme is also known as kininase II, the enzyme responsible for inactivating bradykinin.

Angiotensin II is metabolized rapidly by plasma and tissue angiotensinases. The best characterized of the plasma enzymes are an aminopeptidase (angiotensinase A) and a less important endopeptidase (angiotensinase B). A heptapeptide fragment of angiotensin II is des-Asp^1 angiotensin II or, as it is now named, angiotensin III. This peptide shares many of the pharmacologic actions of its parent molecule, especially the ability to stimulate aldosterone secretion. However, the physiologic significance of angiotensin III in the intact animal is not known.

CARDIOVASCULAR EFFECTS. Angiotensin II exerts a wide spectrum of effects that are directed toward maintenance of blood pressure and volume (Cody 1997; Matsusaka and Ichikawa 1997). First and foremost, angiotensin produces a pronounced vasoconstriction as a result of direct stimulation of vascular smooth muscle cells (Berk and Corson 1997). This effect is most prominent on arteries and, especially, small arterioles, with less influence on veins. The vasoconstrictor action of angiotensin is most pronounced in the kidney, skin, and splanchnic tissues and less pronounced in the brain, heart, and skeletal muscle. The net result is an increase in peripheral vascular resistance and hence in blood pressure (Griendling and Alexander 1990).

FIG. 20.2—Sequential formation of angiotensins I, II, and III. The structure of angiotensin shown is that found in the rat, pig, horse, and human. Bovine angiotensin contains valine in position 5.

Angiotensin also increases cardiac output by direct stimulation of the heart and action on the sympathetic nervous system. By an effect on the brain, angiotensin elicits an increase in sympathetic discharge to the heart and blood vessels. This contributes further to increases in cardiac output and vascular resistance. Angiotensin also provokes release of norepinephrine and epinephrine from the adrenal medulla, facilitates release of norepinephrine from postganglionic sympathetic neurons, stimulates sympathetic ganglia, and decreases uptake of norepinephrine into adrenergic axons. Thus angiotensin produces a state of cardiovascular excitation through several pathways (Peart 1975; Cody 1997; Matsusaka and Ichikawa 1997).

Aside from its direct cardiovascular effects, angiotensin accelerates steroidogenesis in the adrenal cortex. This action results in increased synthesis and release of the mineralocorticoid aldosterone, which acts in turn on the distal tubule of the kidney to increase reabsorption of Na$^+$ and, subsequently, water (Vecsei et al. 1978). Angiotensin also releases vasopressin (antidiuretic hormone) from the brain and produces a marked dipsogenic effect. All these actions help to expand or restore blood volume and hence assist in maintaining normal blood pressure and circulatory function.

From the above description, it is obvious that the renin-angiotensin system can play an important role in electrolyte-water balance and hemodynamics. Disruptions of this system contribute to certain pathophysiologic states such as renovascular hypertension and aldosteronism. In states of low cardiac output, angiotensin is believed to contribute to maintenance of blood pressure. The physiologic functions of extrarenal renins (the "isorenins" found in blood vessels, the brain, and other tissues) are under considerable study (Ganong 1984; Lee et al. 1993).

Pharmacology of the Renin-Angiotensin System. Several drugs interact with the renin, angiotensin, and associated enzyme system (Keeton and Campbell 1981; Csajka et al. 1997). The amide of angiotensin II (1-*l*-asparaginyl-5-*l*-valyl angiotensin octapeptide, Hypertensin) activates angiotensin receptors throughout the body. This drug is diluted and administered by slow intravenous infusion for its pressor actions; blood pressure should be monitored continuously.

Different types of angiotensin receptors have been identified, e.g., angiotensin-1 (AT$_1$) and angiotensin-2 receptors (Matsusaka and Ichikawa 1997), but the clinical value of such differentiation is unknown. Saralasin acetate (1-sar-8-ala angiotensin II, Sarenin) is the prototype for drugs defined as angiotensin receptor blockers. These agents interact with the receptors, thereby preventing angiotensin from eliciting its physiologic-pharmacologic actions. Saralasin and other angiotensin receptor blockers are used experimentally in attempts to define biologic roles of angiotensin, and clinically in humans as antihypertensive agents (Csajka et al. 1997).

The proline derivative captopril (Capoten) and the related drug enalapril (Vasotec) are inhibitors of angiotensin-converting enzyme. They prevent transformation of angiotensin I to angiotensin II. They also inhibit the inactivation of bradykinin and kallidin. Converting enzyme inhibitors are used to diagnose and treat certain forms of hypertension in humans. Converting enzyme inhibitors also are being used increasingly in human and veterinary medicine to relieve vasoconstriction and lessen fluid retention in patients with congestive heart failure (Knowlen et al. 1983; Dietz et al. 1993; Holtz 1993). An important part of the endogenous compensatory attempt in heart failure syndrome involves increased formation of angiotensin and aldosterone, leading in turn to peripheral vasoconstriction and enhanced urinary reabsorption of salt and water respectively. By inhibiting angiotensin formation, converting enzyme inhibitors evoke vasodilation and reduced cardiac workload as well as lessen aldosterone-mediated fluid retention and the propensity for edema formation (Cody 1997; Matsusaka and Ichikawa 1997; Berk and Corson 1997).

A large number of drugs used for other therapeutic purposes also influence the renin-angiotensin system; e.g., vasodilators indirectly cause renin release resulting from a reflex increase in sympathetic nervous system discharge to the kidney. General anesthetics also provoke nonspecific increase in renin release. Propranolol inhibits renin secretion by blocking the intrarenal β-adrenergic receptors that subserve release of renin from the juxtaglomerular apparatus (Schwieler and Hjemdahl 1992).

KININS. Discovery of the mammalian kallikrein-kinin system can be traced to the old observation that urine produces a fall in blood pressure when injected intravenously. The urinary principle responsible for the hypotensive activity is an enzyme called kallikrein. However, kallikrein itself does not affect blood pressure directly but converts an inactive α-2 globulin in the plasma, kininogen, into bradykinin, the active depressor substance. Bradykinin and other related polypeptide kinins such as kallidin are exceptionally potent vasodilators. The kinins also increase permeability of the microcirculation, cause contraction of several nonvascular smooth muscles, and evoke pain.

Because the kallikrein enzymes are present in various glandular tissues and bodily fluids of mammals, the kinins have been proposed as endogenous mediators of cellular responses to certain types of physiologic and pathophysiologic stimuli. Many aspects remain unresolved, however, and pharmacologic control of the kallikrein-kinin system is still in its infancy.

Early studies of kinins were carried out independently by two groups of scientists. The resulting terminology was confusing because of the development of different nomenclatures. One group called their plasma enzyme kallikrein; it formed the active peptide kallidin from the inactive precursor kallidinogen. Other workers reported that trypsin released an active peptide (bradykinin) from a plasma globulin substrate (bradykininogen) (Rocha e Silva et al. 1949).

Similarities between the trypsin-bradykininogen-bradykinin system and the kallikrein-kallidinogen-kallidin system soon became apparent. Schachter and Thain (1954) subsequently introduced the generic term kinin to encompass both bradykinin and kallidin, since these two polypeptides exert essentially identical pharmacologic actions. Bradykinin and kallidin are now recognized as members of a group of closely related kinin peptides occurring naturally in wasp, hornet, and other venoms or released from mammalian plasma substrate by kallikreins, trypsin, and certain snake venoms.

Current terminology for the kinin system uses kallikrein-kininogen-kinin as general terms for designating the enzymes, the inactive precursors (substrates), and the active polypeptides respectively (Schachter 1980).

Kinin Formation: Components and Chemistry. A schematic representation of the contributions of kallikrein, kininogen, and other factors to kinin formation is depicted in Fig. 20.3.

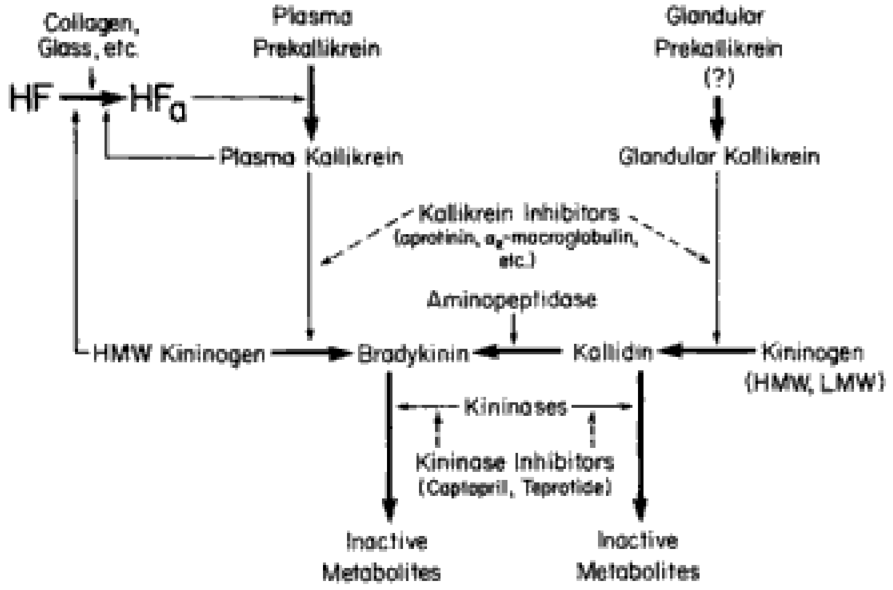

FIG. 20.3—Formation and inactivation of kinins. HF = Hageman factor, HF_a = activated HF, HMW and LMW = high and low molecular weight. Wide solid lines represent conversion of substrate to product. Narrow solid lines represent enzyme acceleration of substrate conversion to product. Dashed lines represent sites of inhibitory actions.

KALLIKREINS, PREKALLIKREINS, AND KALLIKREIN INHIBITORS

KALLIKREINS. The term kallikreins denotes the endogenous serine protease enzymes that liberate kinins from specific kininogen substrates by limited proteolysis. The term kininogenase encompasses the kallikreins and other serine proteases such as trypsin, some snake venoms, thrombin, fibrinolysin, and other enzymes that share the common property of releasing kinins from kininogen (Schachter 1980).

Mammals have two basic kallikrein types: plasma and glandular. The latter is localized in exocrine glands and their secretions and has been isolated from porcine pancreas; guinea pig coagulation gland; intestine of the rat, pig, dog, and human; urine from the horse, rat, and human; and saliva from humans. Structurally, the kallikreins are glycoproteins with molecular weights between 24,000 and 43,000 for those of glandular origin and at least 100,000 for the plasma form.

In general, the glandular kallikreins yield kallidin, from which bradykinin is formed rapidly by aminopeptidase activity in plasma and tissue (Erdös 1976). Bradykinin is formed directly by plasma kallikrein and also by trypsin, fibrinolysin, and snake venom (Fig. 20.3).

PREKALLIKREINS. Kallikrein is present in some tissues (especially the pancreas, intestines, and plasma) in inactive or prekallikrein forms (referred to formerly as kallikreinogens). Prekallikreins are converted to the active mode by various factors that disrupt plasma homeostasis (Fig. 20.3). These include pH changes; organic solvents; trypsin; and contact with glass, collagen, skin, or damaged tissue. The major plasma activators of prekallikreins are the Hageman factor and its fragments, i.e., blood clotting factor XII.

KALLIKREIN INHIBITORS. Once kallikrein is activated, its capability to form kinins is short-lived because of rapid inhibition by several plasma protease inhibitors. These include α_2 macroglobulin, α_1 antitrypsin, antithrombin III, and C,1 esterase inhibitor (Fig. 20.3).

In addition, a polyvalent kallikrein-trypsin inhibitor called aprotinin has been isolated from bovine tissues where it is localized in mast cells (Fritz et al. 1979). This inhibitor is a low molecular weight protein; it is prepared commercially as Trasylol. Aprotinin has been used outside the USA with varying success in treatment of acute pancreatitis and the carcinoid syndrome in humans.

KININOGENS. The kinin precursors, kininogens, are acidic glycoproteins of the α-2 globulin fraction of plasma; they have been isolated from human, bovine, equine, and rabbit blood.

At least two plasma kininogens have been identified, the high-molecular-weight (HMW) and the low-molecular-weight (LMW) forms. Both types have been isolated from different species, and the HMW and LMW kininogens of bovine origin have molecular weights of 76,000 and 48,000 respectively. The HMW form, also referred to as substrate 1, is a good substrate for both plasma and glandular kallikrein. Substrate 2, the LMW type, is a good substrate for glandular kallikrein only (Fig. 20.3).

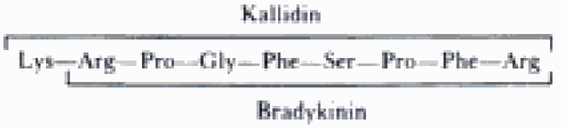

FIG. 20.4—Amino acid sequence of bradykinin and kallidin

KININS AND KININ INHIBITORS

KININS. The amino acid sequence of the two most important plasma kinins, bradykinin and kallidin, is shown in Fig. 20.4. Bradykinin is a nonapeptide, whereas kallidin is a decapeptide identical to the former except for the addition of an *N*-terminal lysine. Thus kallidin also is referred to as lysylbradykinin. Addition of methionine to the *N*-terminal lysine of kallidin yields a third biologically active kinin called methionyl-kallidin or methionyl-lysylbradykinin.

KININ INHIBITORS. Specific inhibitors or antagonists of kinin actions on effector cells have not yet been satisfactorily identified. Accordingly, little is known about kinin-specific receptors, although they have been divided into a series of subtypes (Drouin et al. 1979; Burch et al. 1990; Farmer et al. 1989). Analgesic and anti-inflammatory drugs such as aspirin and indomethacin reduce pain and inflammatory responses to kinins. However, these drugs probably act by blocking synthesis of prostaglandins, which mediate or modulate certain activities of kinins (Marceau et al. 1983).

KININASES AND KININASE INHIBITORS

KININASES. Plasma and other tissues contain enzymes, collectively called kininases, that rapidly inactivate kinins (Fig. 20.3). The most important kininases have been named simply kininase I and II.

Kininase I is a carboxypeptidase probably synthesized by the liver, but it can be recovered from the lungs and, possibly, the skin. More attention has been directed to kininase II, a peptidyl dipeptide hydrolase. Kininase II also converts angiotensin I to angiotensin II and in this context is commonly referred to as angiotensin-converting enzyme. It is present in many tissues but is extremely active in the lungs (Erdös 1975).

KININASE INHIBITORS. Captopril and teprotide are new drugs that inhibit kininase activity, thereby retarding inactivation of bradykinin. As discussed earlier in this chapter, the kininase inhibitors also reduce the conversion of angiotensin I to angiotensin II (Erdös 1976).

Although captopril and teprotide are increasingly being used to diagnose and treat forms of hypertension in humans, the importance of the kininases to normal and abnormal circulatory function remains uncertain (Mills 1979; Bhoola et al. 1992).

Pharmacologic Effects of Kinins. Kinins are extremely potent vasodilators, being about 10 times as active as histamine. They act directly on vascular smooth muscle, but the net effect in different vascular beds varies with species and dose. Smooth muscle of the microcirculation (i.e., of terminal arterioles and small venules) is relaxed by the kinins, yielding a marked decrease in systemic vascular resistance. Blood pressure falls accordingly, but a reflex increase in heart rate and cardiac output may occur. Large arteries and veins, in contrast to the microcirculatory vessels, tend to contract upon exposure to kinins. Permeability of the microcirculation is increased by the kinins, resulting in edema formation similar to the wheal and flare response seen with histamine (Chap. 19). Bradykinin is believed to act in part through activation of the phospholipase C-inositol trisphosphate-Ca^{++} triad (Fasolato et al. 1988).

Intestinal and uterine smooth muscle generally is contracted by kinins, but the duodenum in the rat is relaxed. Bronchoconstriction by kinins is prominent in the guinea pig and in some asthmatic humans but is generally unremarkable in other species.

Kinins are potent algesic substances, and they evoke pain when applied topically to exposed blisters or when injected intra-arterially. These responses are thought to be associated with stimulation of sensory nerve endings. Since aspirin and other inhibitors of prostaglandin synthesis reduce kinin-induced pain, prostaglandins may mediate or modulate the algesic activities of the kinins (Marceau et al. 1983). Kinins also can stimulate autonomic ganglia and release catecholamines from the adrenal medulla.

Role of Endogenous Kinins. Considerable speculation has centered on the possible roles of kinins in physiologic and pathophysiologic processes. Pathologic conditions in which kinins may participate include acute inflammations, arthritic states, carcinoid syndrome, pancreatitis, migraine headache, allergic reactions, endotoxin shock, and anaphylactic shock. Kinins most likely interact with other autacoids in some of these pathologic states, but their precise involvement remains speculative in most cases (Schror 1992).

The physiologic roles of the kallikreins-kinins, even in tissues where they exist in large concentrations (e.g., pancreas, plasma, and parotid gland), also remain uncertain. There is evidence that kallikreins-kinins influence blood flow in exocrine glands and even participate in reproductive activities and cell proliferation (Schachter 1980).

Studies have focused on the roles of plasma kallikrein and HMW kininogen in blood coagulation independently from their involvement in kinin formation. There is considerable evidence that plasma kallikrein activates the Hageman factor (factor XII). Activated Hageman factor and its fragments in turn accelerate conversion of prekallikrein to kallikrein. This establishes a local positive feedback system for sustained activation of clotting factor XII for the coagulation cascade (Fig. 20.3). In addition, the HMW kininogen may participate in the coagulation process by increasing the activation of factor XII, prekallikrein, factor XI, and plasminogen activator. Since plasma kallikrein and plasminogen activator are chemotactic for leukocytes, there seem to be functional interactions between blood coagulation, kallikreins and other kininogenases, and inflammation (Cochrane et al. 1973; Mandle et al. 1976; Ratnoff and Saito 1979).

Studies also have suggested that renal kallikrein may be of significance in regulating fluid and electrolyte balance and, perhaps, renal hemodynamics. In contrast to the renin-angiotensin system, however, kallikrein and bradykinin are diuretic and natriuretic agents; i.e., they increase urine volume and salt excretion. Part of the physiologic actions of the kinins seems to be mediated or modulated by prostaglandins and other autacoids (Busse and Fleming 1996), but the contribution of kinins to the regulation of renal blood flow and nephron function remains speculative (Margolius 1978; Mills 1979). The exact physiologic roles of the kinins probably will not be delineated until specific blockers of kinin receptors are identified (Regoli et al. 1996).

OTHER PEPTIDES. Several other vasoactive peptides, of which the actions in pathophysiologic states are less known, are substance P, vasoactive intestinal polypeptide (VIP), eledoisin, physalaemin, coerulein, colostrokinin, urokinin, and the kinins of wasp and hornet venoms. VIP is present in the small intestine and also widely distributed in peripheral nerves and the central nervous system. Although VIP exerts multiple pharmacologic actions in different tissues, its physiologic relevance remains questionable. Substance P was first extracted from horse intestine and brain; it is an endecapeptide structurally similar to eledoisin and physalamin. Substance P has some bradykininlike action and is a potent stimulant of the gut. Eledoisin (from the octopus) and physalamin (from the skin of an amphibian) are endecapeptides with bradykinin-like activity. Coerulein, a related decapeptide, is an extremely potent stimulator of pancreatic and other exocrine secretions.

Atrial natriuretic factor is released from the right atrial musculature of the heart in response to blood volume overload and cardiac stretch. This peptide promotes sodium excretion and diuresis and may have future application in the therapy of congestive heart failure.

Other vasoactive peptides such as oxytocin and vasopressin are discussed in the chapters on hormones, and the cytokines are addressed in Chap. 21 along with the eicosanoids.

Prostaglandins, thromboxanes, and leukotrienes are principal members of a diverse family of endogenous fatty acid derivatives synthesized from cell membrane phospholipids by virtually all types of mammalian cells. These compounds and their relatives are referred to collectively as the eicosanoids, because their fatty acid precursors share "eicosa" as the prefix in their chemical nomenclatures. Eicosanoids and other related fatty acid derivatives such as platelet-activating factor (PAF) have a remarkable spectrum of biologic activities. These substances represent some of the most important autacoids involved in homeostatic regulation. The breadth of biologic effects of the eicosanoids is believed to encompass practically every bodily activity, including various reproductive functions, blood pressure control, renal function, thrombus formation, inflammation, and many more. Interaction with the prostaglandin system is now recognized as an important mechanism of pharmacologic action of certain therapeutic agents such as aspirin and other nonsteroidal anti-inflammatory drugs (Masferrer and Kulkarni 1997; de Brum-Fernandes 1997; Donnelly and Hawkey 1997).

In addition to eicosanoids and PAF, this chapter briefly addresses another group of endogenous proinflammatory mediators, the cytokines. These agents are not chemically related to the eicosanoids or other fatty acid derivatives; rather, the cytokines are proteins secreted by a variety of cell types in response to inflammation and other stimuli that often concomitantly promote increased synthesis of the eicosanoids.

HISTORY. Recognition of the eicosanoids can be traced to the early 1930s. Two American gynecologists reported that human semen contained a substance affecting the contractile activity of human uterine strips (Kurzrok and Lieb 1930). Extracts of seminal fluid and accessory reproductive glands affected systemic blood pressure and smooth muscle contractile function. The active substance was distinct from the then known autacoids and was identified as a lipid-soluble acid and was named prostaglandin (PG).

Continuing investigations revealed that PG actually comprised a large family of closely related acidic lipids with unique chemical structure. The basic structural unit of the PG compounds proved to be a 20-carbon unsaturated carboxylic acid (Bergström and Samuelsson 1968); the initial PGs were named according to chemical structure and were designated by the letters A-F. $PGF_{2\alpha}$ continues to receive the most attention relative to animal reproductive problems, which represent the most important clinical uses of PG compounds in veterinary medicine (Schultz 1980; Seguin 1980). Recent advancements have shifted emphasis away from the classic PGs (i.e., PGA-PGF) and toward newer compounds such as the cyclic endoperoxides PGG_2 and PGH_2, prostacyclin, thromboxane A_2, leukotrienes, other eicosanoids, and the related PAF (Campbell 1990; Baird and Morrison 1993).

CHEMISTRY AND TERMINOLOGY OF PROSTAGLANDINS. Common to the structure of naturally occurring PGs is the unnatural fatty acid named prostanoic acid; this compound is a 20-carbon carboxylic acid with a cyclopentane ring (Fig. 21.1). The primary or classic PGs are individually named according to substituents on the cyclopentane ring; these are PGA, PGB, PGC, PGD, PGE, and PGF, as shown in Fig. 21.1. This figure also pictures the ring moieties of the newer PG-related compounds: PGG, PGH, prostacyclin (PGI), and thromboxane (Fig. 21.1).

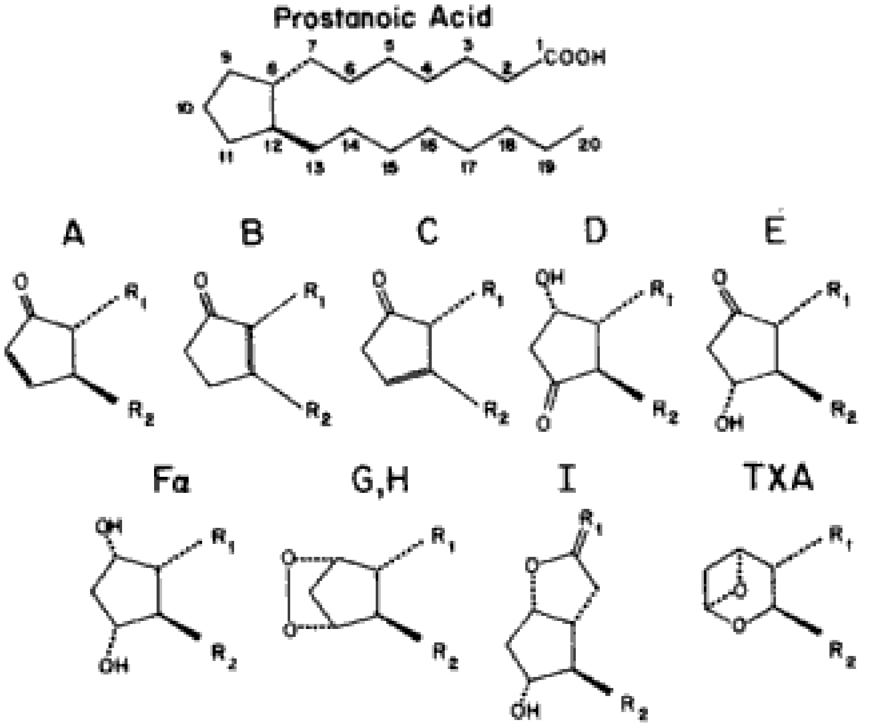

FIG. 21.1—Structures of prostanoic acid and the ring moieties of the six primary PGs (A-F), the cyclic endoperoxides (G, H), prostacyclin (I), and thromboxane A (TxA). In the stereochemical convention used in this and subsequent illustrations, the substituents indicated by the triangle lie in front of the plane of the ring structure, whereas those indicated by the dashed line lie behind it.

The PGs and related substances are further categorized as mono-, di-, or triunsaturated depending on the number of carbon-carbon double bonds in the side chains. This classification appears as a subscript to the letter; e.g., a PG$_1$ has one double bond between C-13 and C-14, a PG$_2$ has an additional double bond between C-5 and C-6, and a PG$_3$ has an additional double bond between C-17 and C-18. As an example, the structural formulas of PGE$_1$, PGE$_2$, and PGE$_3$ are compared in Fig. 21.2.

Biosynthetically, the PGs are derived from 20-carbon polyunsaturated fatty acids that contain a total of three, four, or five double bonds. These acids are 8, 11, 14-eicosatrienoic acid (dihomo-γ-linolenic acid); 5, 8, 11, 14-eicosatetraenoic acid (arachidonic acid); and 5, 8, 11, 14, 17-eicosapentaenoic acid respectively (Fig. 21.3). These essential fatty acids yield PGs with one, two, or three double bonds remaining in the side chains respectively, which account for the previously described classification as mono- (PG$_1$), bis- (PG$_2$), or trienoic (PG$_3$) PGs (see Fig. 21.3) (Wolfe 1982).

BIOSYNTHESIS OF EICOSANOIDS. The eicosanoids, in contrast to many other autacoids, are not localized or stored in tissue pools. Instead, release of these compounds from cellular components reflects increased rate of their synthesis from available fatty acid precursors. Arachidonic acid, the precursor of the bisenoic PGs, is believed to be the most important

source of the PG compounds found in higher mammalian species. The trienoic PGs may be important in marine animals, where the eicosapentaenoic acid seems to be the predominant fatty acid precursor.

Arachidonic acid is an essential fatty acid. It is incorporated by ester linkage into phospholipids of cell membranes and may be contained in other complex lipids such as the triglycerides. Cellular phospholipids release arachidonic acid in response to phospholipase A_2. This enzyme is activated by a wide array of physiologic, pharmacologic, and pathologic stimuli. Hormones, neurohormones, and other autacoids can participate in initiation of this process; e.g., potent, vasoactive kinins and angiotensin activate tissue phospholipase A_2 and thereby accelerate PG synthesis. This activity in turn results in changes in intensity and range of action of bradykinin and angiotensin, since PG can also modulate the biologic effects of these polypeptides (McGiff 1979). Thus complex feedback systems exist, which regulate PG synthesis relative to the physiologic status of the animal and the resulting activities of other biologically active compounds. Even simple mechanical agitation or trauma of tissues can result in phospholipase activation with release of arachidonic acid (Moncada and Vane 1978).

After its liberation from phospholipids, arachidonic acid is subject to rapid oxidative catabolism by two separate enzymatic pathways involving a cyclooxygenase and a lipoxygenase. Transformation of arachidonic acid to some of its more important PG derivatives is illustrated in Fig. 21.4 and summarized below.

Cyclooxygenase. Synthesis of PG compounds begins with the oxygenation and cyclization of arachidonic acid; these events are catalyzed by the enzyme known as fatty acid cyclooxygenase (Fig. 21.4). This enzyme is widely distributed in mammals, and arachidonic acid can be metabolized to its PG derivatives by virtually all tissue types that have been tested. The immediate product of cyclooxygenase and arachidonic acid is the cyclic endoperoxide PGG_2, which is transformed to the closely related cyclic endoperoxide PGH_2 (Fig. 21.4).

Endoperoxides PGG_2 and PGH_2 are quite unstable, with biologic half-lives of 5 minutes at physiologic pH and body temperature. The endoperoxides undergo enzymatic or nonenzymatic transformation, yielding different PG products (i.e., PGD_2, PGE_2, and $PGF_{2\alpha}$) (Fig. 21.4). PGA, PGB, and PGC compounds are formed from the corresponding PGE during chemical extraction procedures and may not occur biologically. $PGF_{2\alpha}$ can be transformed from PGE_2 in some tissues by a 9-keto-reductase enzyme, but the presence of this enzyme under biologic conditions is somewhat debatable. In addition, enzymelike activity called PG endoperoxide $F_{2\alpha}$ reductase, which can form $PGF_{2\alpha}$ from the endoperoxides, has been detected in the bovine uterus (Kindahl 1980).

In addition to yielding PGs of the D, E, and F series, endoperoxide PGH_2 also is metabolized into two other compounds called thromboxane A_2 and prostacyclin. These substances are highly active but possess structures that differ somewhat from those of the primary PGs (Fig. 21.4).

Studies have shown that there are two major isoforms of cyclooxygenase: cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). The former enzyme is constitutively expressed in most cells under basal conditions, and it serves to synthesize the small amounts of PGs that participate in normal physiologic functions. COX-1 is especially important in producing those eicosanoids that have protective actions on gastrointestinal mucosa. Inhibition of COX-1 activity can therefore be detrimental to the patient because of loss of gastrointestinal protection of mucosal epithelial cells (Masferrer and Kulkarni 1997).

The other isoform of cyclooxygenase, COX-2, is not constitutively present; it is nondetectable under basal nonstimulated conditions. However, when cells are exposed to bacterial lipopolysaccharide and certain inflammatory cytokines and growth factors, the synthesis of COX-2 is induced. The inducible COX-2 results in increased concentrations of PGs that participate in inflammatory reactions (de Brum-Fernandes 1997).

THROMBOXANE A_2. An enzyme first isolated from equine and human thrombocytes was found to convert PGH_2 into a compound containing an oxane ring instead of the cyclopentane ring of the PGs. This substance was named thromboxane A_2 (TxA_2), and the responsible enzyme was named thromboxane synthase (Fig. 21.4).

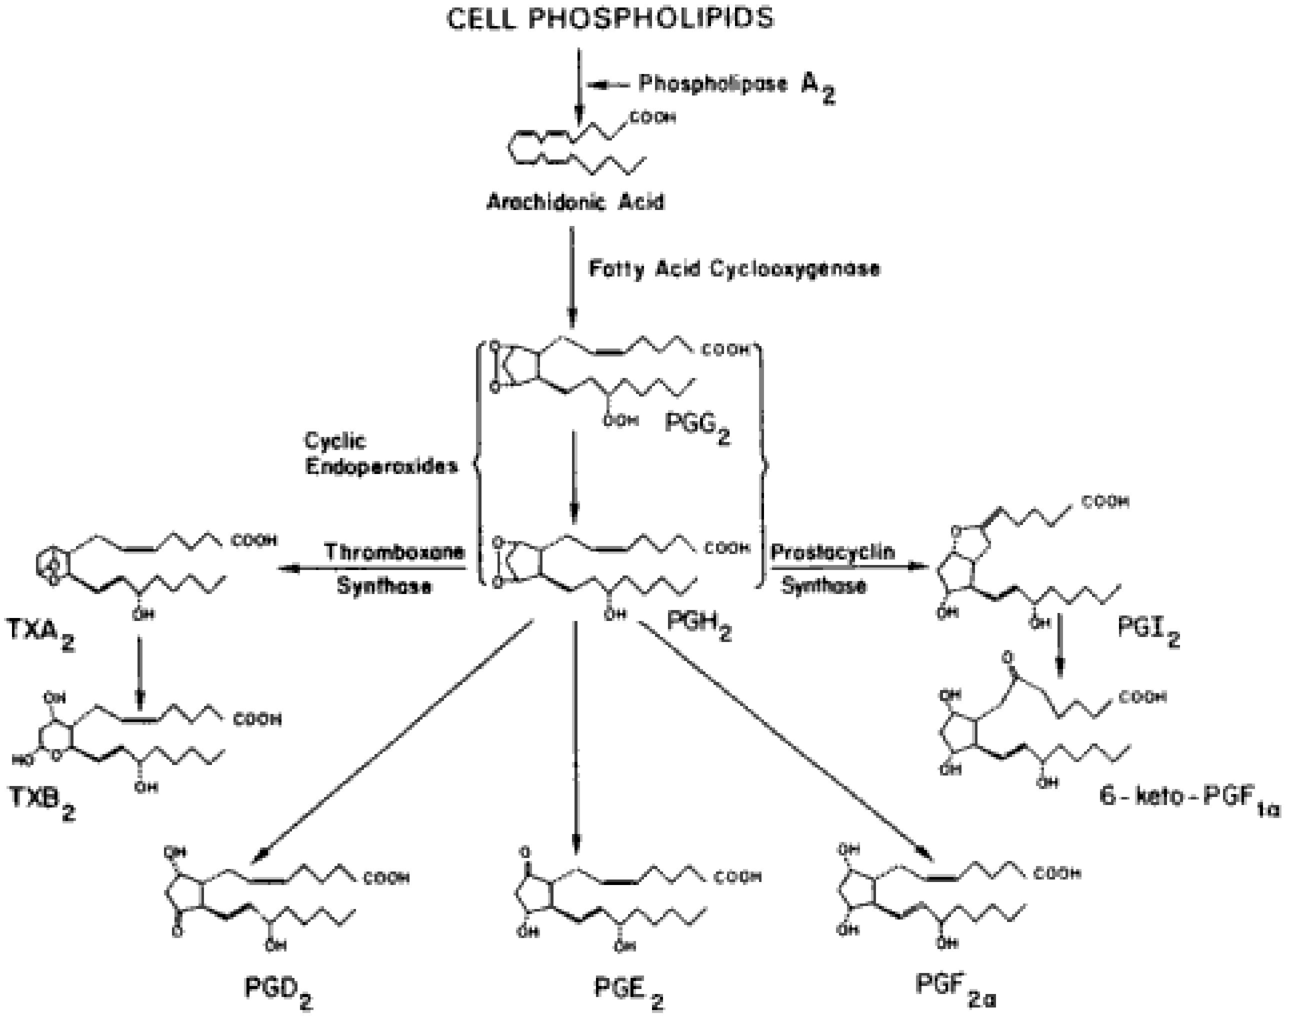

FIG. 21.4—Cyclooxygenase-catalyzed conversion of arachidonic acid to major PG compounds.

TxA_2 has a brief half-life of about 30 seconds under physiologic conditions, and it degrades into the stable compound thromboxane B_2 (Fig. 21.4). As will be discussed subsequently, TxA_2 plays an important physiologic role as a vasoconstrictor and proaggregate in thrombus formation (see Chap. 28).

PROSTACYCLIN. An enzyme localized in vascular tissue was found to convert PGH_2 into yet another highly active metabolite called prostacyclin or PGI_2 (Fig. 21.4). The enzyme was named prostacyclin synthase (Fig. 21.4).

PGI_2 has a double-ring component rather than the single cyclopentane ring (Figs. 21.1, 21.4). The biologic half-life of PGI_2 is quite short, between 2 and 3 minutes; it is converted nonenzymatically into a relatively inactive but stable product, 6-keto-$PGF_{1\alpha}$ (Fig. 21.4). PGI_2 is a potent vasodilator and exerts antiaggregatory activity on blood platelets (see below and Chap. 28).

Lipoxygenase. Although fatty acid cyclooxygenase is widely distributed, lipoxygenases have so far been found mainly in lung, platelets, and white blood cells. Metabolism of arachidonic acid via lipoxygenase pathways yields unstable hydroperoxides, which then break down to the stable hydroxyacids or are further transformed into other derivatives such as the leukotrienes. Selected products of lipoxygenases are shown in Fig. 21.5; these include 12-hydroperoxyarachidonic acid (HPETE) and its stable metabolite 12-hydroxyarachidonic acid (HETE). The breadth of physiologic actions of these compounds remains uncertain, but they are chemotactic for leukocytes and participate in inflammatory responses.

The name leukotriene has been proposed for a group of noncyclized, 20-carbon, carboxylic acid products of arachidonic acid formed by 5-lipoxygenase activity (Fig. 21.5). The trivial name leukotriene was chosen because these compounds were discovered in leukocytes and shared a common structural feature as conjugated trienes (Samuelsson 1983). The initial reaction of the 5-lipoxygenase pathway is the formation of 5-HPETE (Fig. 21.5); 5-HPETE is converted either to 5-HETE or to leukotriene A_4, a 5,6 epoxide. Leukotriene A_4 is converted in turn either to leukotriene B_4 or C_4. The latter is a glutathionyl derivative, formed by the

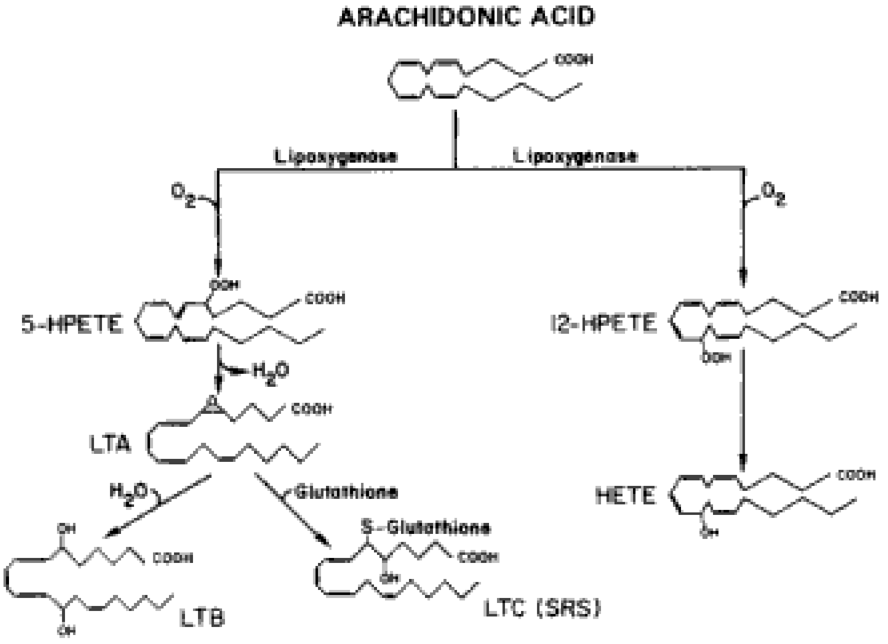

FIG. 21.5—Lipoxygenase-catalyzed conversion of arachidonic acid to hydroperoxyarachidonic acids (HPETE), hydroxyarachidonic acid (HETE), and leukotriene (LT) A_4, B_4, and C_4. SRS = slow-reacting substance of anaphylaxis.

enzyme glutathione-*S*-transferase (Fig. 21.5). Leukotriene D_4 is formed via the cleavage of the glycine moiety from leukotriene C_4, while E_4 is synthesized by the subsequent removal of glycine. The biologic importance of the leukotrienes is under intensive investigation; there is considerable evidence that these substances participate in inflammatory reactions, and a combination of the cysteine-containing leukotrienes (i.e., C_4, D_4, and E_4) is now believed to compose the slow-reacting substance of anaphylaxis (Samuelsson 1983; Samuelsson et al. 1980). As a general rule, the dihydroxy acids are chemotactic for leukocytes but have minimal smooth muscle-stimulating properties, whereas the sulfur linkage and amino acid residues at C-6 are required for smooth muscle-stimulating properties (Piper 1983).

INHIBITION OF BIOSYNTHESIS OF EICOSANOIDS. Tissue distribution of the different enzymes involved in PG biosynthesis is important to medicine. These enzymes currently represent the most vulnerable targets for pharmacologic manipulation of the PG system.

Cyclooxygenase seems to be rather ubiquitous, because most tissues are able to convert arachidonic acid to the intermediate endoperoxides PGG_2 and PGH_2. However, the fate of the latter compounds varies considerably in different tissues.

Reproductive organs of several species are able to synthesize PGE_2 and $PGH_{2\alpha}$, whereas the spleen and lung can produce the whole range of PG compounds. The major PG formed by blood vessel endothelial cells is PGI_2; hence, prostacyclin synthase is of major importance in this tissue. On the other hand, thromboxane synthase is dominant in blood platelets; TxA_2 is a primary PG product of this cell type. Various drugs have been studied in attempts to regulate the PG system via effects on the participating enzymes.

Starting with Vane's work in 1971, the rather pronounced influence of aspirin-like drugs on the PG system became apparent. Aspirin and other anti-inflammatory agents of the nonsteroidal type disrupt the cellular release of PGs by interfering with their biosynthesis. The site of inhibitory action of these drugs is localized high in the PG cascade, at the cyclooxygenase level (Fig. 21.4). By inhibiting cyclooxygenase, aspirin prevents conversion of arachidonic acid to the endoperoxides PGG_2 and PGH_2. Accordingly, the formation of PG products below PGG_2 and PGH_2 in the metabolic pathway is likewise retarded by the action of aspirin (Vane 1971).

Other nonsteroidal anti-inflammatory agents that inhibit cyclooxygenase include other salicylates, indomethacin, phenylbutazone, naproxen, flunixin, and meclofenamic acid (see Chap. 22). The anti-inflammatory, antipyretic, and analgesic actions of such drugs are mediated principally by inhibition of PG biosynthesis at the cyclooxygenase level (Moncada and Vane 1978). The side effects of this group of drugs also depend on inhibition of PG synthesis (see Chap. 22). Aspirin-like drugs are not inhibitors of the lipoxygenase enzymes that participate in other metabolic pathways of arachidonic acid.

Traditional nonsteroidal anti-inflammatory agents are nonselective inhibitors of both the constitutive COX-1 and the inducible COX-2 isoenzymes. Inhibition of COX-2 results in therapeutically useful reductions in the synthesis of proinflammatory eicosanoids, but inhibition of COX-1 would at the same time result in loss of protective and other physiologic functions of PGs necessary for normal cellular functions (de Brum-Fernandes 1997; Donnelly and Hawkey 1997). Drugs with greater inhibitory action on COX-2 than on COX-1 would be therapeutically beneficial because they would selectively reduce synthesis of inflammatory PGs while sparing cellular protective actions of COX-1 products. Newer nonsteroidal anti-inflammatory agents with selective COX-2 inhibitory actions are addressed in Chap. 22.

Corticosteroids interfere with PG biosynthesis by inducing the synthesis of a protein inhibitor of phospholipase activity, thereby retarding release of arachidonic acid from cellular phospholipids (Wolfe 1982). Corticosteroids also modulate expression of the inducible COX-2 enzyme, thereby decreasing its formation (Masferrer and Kulkarni 1997; de Brum-Fernandes 1997; Donnelly and Hawkey 1997).

Considerable interest is directed toward characterization of selective inhibitors of the PG-synthesizing enzymes; e.g., imidazole and certain of its analogs preferentially inhibit thromboxane synthase. Certain analogs of PGG_2 and PGH_2 also exert selective inhibitory actions on this enzyme. Conversely, prostacyclin synthase is inhibited by lipid peroxides such as 15-HPETE. Clinical application of the above enzyme inhibitors is unproven, but potential advantages over the aspirin-like cyclooxygenase inhibitors reside in the possibility of selectively reducing production of one PG derivative without affecting others.

PHYSIOLOGIC-PHARMACOLOGIC ASPECTS OF EICOSANOIDS. Although a multitude of biologic activities has been assigned to the different eicosanoids, the physiologic value of all such effects and relative importance of individual derivatives undergo almost continual reappraisal as new discoveries are unfolded. Artifactual conversion of one PG to another during tissue isolation has delayed attempts to designate biologic responsibility. In addition, data obtained from one animal species may not apply to others because there are formidable species differences in responsiveness to many members of the eicosanoid complex. In the following paragraphs, some of the better defined physiologic and pharmacologic aspects of the biologic activities of this system are summarized.

Reproductive System. The involvement of PGs in reproductive physiology is covered later in this volume. Briefly, PG compounds have been associated with luteolysis, abortion, and parturition.

Interest is focused mainly on $PGF_{2\alpha}$, which is believed to be the long-sought luteolytic hormone produced by the uterus in some nonprimate species (e.g., mare, cow, sow, ewe, and guinea pig). This factor is believed to control the life span of the corpus luteum; e.g., in nonpregnant cows the luteolytic hormone or $PGF_{2\alpha}$ is released about day 14 or 15 of the estrous cycle. The corpus luteum degenerates, which evokes the return of estrus. Pregnancy inhibits release of the luteolytic factor, hence the corpus luteum persists and the fetus develops.

In addition to producing luteolysis, $PGF_{2\alpha}$ also causes contraction of uterine smooth muscle. Since blood concentrations of PG increase during labor, $PGF_{2\alpha}$ release is viewed as important for prepartum lysis of the corpus luteum, which removes the progesterone block, and for evoking uterine contractions during parturition. Increased PG production has also been associated with abortion and premature labor. In support of these concepts, aspirin was found to delay parturition, reduce uterine contractions during labor, retard premature labor, and delay abortion. The participation of PG in reproductive events has been reviewed by Schultz (1980), Seguin (1980), and Stabenfeldt et al. (1980).

Cardiovascular System. Systemic administration of PGs can evoke pronounced hemodynamic responses, depending upon the individual compound and animal species tested (Camu et al. 1992). Blood pressure effects of all the PG derivatives mainly reflect changes in peripheral vascular resistance; these agents affect smooth muscle contractile activity in large arteries, arterioles, precapillaries, venules, and large veins. Primary PGs of the E and A series, particularly PGE_2, are potent vasodilators in most species. Conversely, vascular smooth muscle is generally contracted by $PGF_{2\alpha}$. Vasodilator effects of the latter and vasoconstrictor effects of PGE_2 have been seen in certain vascular beds (McGiff 1979).

TxA_2 is a potent stimulant of vascular smooth muscle and has produced vasoconstriction in all blood vessel systems yet tested. TxA_2 was originally detected as rabbit aorta-contracting substance released from guinea pig lungs during anaphylaxis (Piper and Vane 1969). As opposed to TxA_2, PGI_2 is an exceptional vasodilator. It is several times more potent than PGE_2. Pronounced vasodilator effects of PGI_2 have been demonstrated in several regions, including the coronary, renal, skeletal muscle, and omental vascular beds.

A systemic depressor response is evoked by the vasodilators PGI_2, PGE_2, and PGE_1, whereas a pressor response is produced by the vasoconstrictors $PGF_{2\alpha}$ and TxA_2. Interestingly, PGI_2 is equipotent as a vasodilator whether administered intravenously or intra-arterially. This is an important difference from PGE_1 or PGE_2, which are much less active when given intravenously. These differences were explained when it was discovered that PGE_1 and PGE_2 undergo almost complete metabolism during a single passage through the pulmonary vascular circuit, whereas PGI_2 is not metabolized rapidly by the lungs. In fact, the lungs seem able to release PGI_2 into the circulation. Persistence of PGI_2 in the blood contributed to the suggestion that this agent may be a circulating PG with more hemodynamic responsibility than the rapidly inactivated PGE_2 (Moncada and Vane 1978).

The intermediate endoperoxides PGG_2 and PGH_2 exert variable effects on vascular smooth muscle; both vasoconstriction and vasodilation have been reported. This scope of activity reflects some intrinsic vasoconstrictor actions of the endoperoxides as well as their rapid conversion to other potent agents such as PGI_2. Similarly, injection of arachidonic acid can elicit circulatory effects that are mediated by its metabolites; such effects are inhibited by aspirin.

Cardiac output is increased slightly by PGs of the A, E, and F series, but cardiac responses to PG in intact subjects are mainly a result of reflex adjustment to systemic blood pressure changes. Only weak inotropic effects are seen with isolated heart muscle preparations. The heart can release endogenously produced PGI_2 upon exposure to certain stimuli, but this activity reflects PG synthesis by the coronary vasculature and not by the cardiac muscle cell (Sivakoff et al. 1979).

There is increasing evidence that different eicosanoids participate in the pathogenicity of circulatory depressant effects associated with gram-negative endotoxicosis. Most studies have focused on TxA_2 and PGI_2, and the concentrations of both increase during endotoxin shock in dogs and horses (Moore et al. 1986).

Although leukotrienes C_4 and D_4 exert potent cardiovascular effects, differences exist relative to animal species and to route of administration. Both agents cause an initial hypertensive response followed by long-lasting hypotension when injected intravenously. When given arterially, the pressor phase is reduced, while the depressor response is prolonged. Interestingly, at least a portion of the cardiovascular response to the leukotrienes may be secondary to release of PGs, because cyclooxygenase inhibitors attenuate the prolonged hypotensive response to the leukotrienes. Piper (1983) has reviewed the cardiovascular profile of the leukotrienes.

Since certain fetal and maternal blood vessels can synthesize PGI_2, this agent may participate in circulatory adjustments to pregnancy and parturition (Terragno and Terragno 1979). Locally synthesized PGI_2 has been implicated in maintenance of the patency of the ductus arteriosus. This concept was based in part on the observation that aspirin could produce closure of the ductus in neonates. Indomethacin has proven superior to aspirin in this respect, but mixed results have been seen in clinical trials.

Blood. Compared to most cell types, erythrocytes lack the capacity to generate significant amounts of PG. In contrast, blood platelets are prolific producers of the endoperoxides PGG_2 and PGH_2 and of TxA_2. These compounds, especially the more active TxA_2, are potent aggregating agents; their involvement in thrombus formation is contrasted with the antiaggregating action of PGI_2 in Fig. 28.1.

Briefly, the platelet-aggregating effects of TxA_2 are believed to be important to the thrombus-forming and thus hemostatic mechanisms provoked by damage to blood and blood vessels. Conversely, the antiaggregating action of PGI_2 may serve to modulate thrombus formation. Indeed, PGI_2 is the most potent endogenous inhibitor of platelet aggregation yet discovered. It is 1000 times more potent than adenosine and 30-40 times more active than PGE_1. Also, PGI_2 disaggregates platelets in vitro, in vivo in the circulatory system, and in extracorporeal circuits where platelet clumping has occurred.

It has been suggested that small amounts of PGI_2 are present in the circulation, circulating PGI_2 is responsible for lack of aggregation of normal platelets, locally produced PGI_2 is involved in providing vascular endothelium with its smooth-surfaced characteristics, and vascular endothelium may even scavenge endoperoxides from platelets for use in production of PGI_2. The latter activity is envisioned to serve as a control mechanism to prevent spread of thrombi onto normal vascular endothelium when adjacent injuries have evoked TxA_2 formation and platelet aggregation. Thus platelet TxA_2 and vascular PGI_2 serve as biologically opposite regulators of interactions between platelets and blood vessels (Gorman 1979; Moncada and Vane 1978).

The antiaggregating action of PGI_2, PGE_1, and PGD_2 has been associated with an increase in the concentration of cyclic adenosine monophosphate (cAMP). Although different PG receptors may be involved, it seems that adenylyl cyclase is activated by each of the antiaggregating PG compounds. Conversely, the endoperoxides and TxA_2 inhibit the stimulatory effect of PGI_2 on adenylyl cyclase, thereby lowering cAMP concentration. Drugs that increase cAMP concentration, such as the phosphodiesterase inhibitor dipyridamole (Persantine), enhance the antiaggregating effects of PGI and antagonize the proaggregating effects of TxA_2.

Kidney. Although cyclooxygenase is present in various regions of the kidney, the major products of arachidonic acid metabolism are thought to be tissue-specific in this organ (McGiff and Wong 1979). PGI_2 is synthesized within the kidney primarily by the vascular smooth muscle compartment. Small quantities of this PG cause renal vasodilation and thereby lower vascular resistance and increase blood flow in the kidney. Urinary excretion of sodium, potassium, chloride, and water is increased by PGI_2; these changes may reflect direct effects on tubular transport mechanisms or secondary effects caused by redistribution of blood flow. There is increasing evidence that PGI_2 also regulates release of renin through actions exerted at the vascular pole of the glomerulus, and PG formation may be involved in certain types of hypertension (Oates et al. 1979).

The major PG derivative of renal medullary interstitial cells seems to be PGE_2. Collecting ducts also are capable of generating PGE_2. This PG can increase salt and water excretion independently of blood flow changes, an effect caused in part by inhibition of the action of antidiuretic hormone on permeability of collecting ducts. There is increasing evidence that effects of PGE_2 and also $PGF_{2\alpha}$ on salt and water excretion involve interaction with the kallikrein-kinin system within the renal urinary compartment (McGiff and Wong 1979; Moncada and Vane 1978).

TxA_2 is believed to be synthesized by the kidney only under pathologic conditions, e.g., after ligation or other obstructions of the ureter. Pathophysiologic stimuli such as hemorrhage or laparotomy can also increase synthesis of renal PG, especially PGE_2, which then contributes to maintenance of renal blood flow. The physiologic value of PG to renal blood flow in normal nonstressed animals remains unclear.

Inflammation. PGs and other eicosanoids are released from soft tissues in response to a variety of noxious stimuli such as infection and mechanical, thermal, and chemical trauma. Once liberated from irritated or damaged cells, PG contributes importantly to different phases of the local inflammatory reaction. Large concentrations of PG elicit pain by direct stimulation of sensory nerve endings. More typically, PGs in quite small concentrations sensitize sensory nerve endings to other pain-provoking stimuli such as bradykinin, histamine, and other mediators of inflammation. Edema-inducing and hyperemic effects of kinins and other autacoids are likewise enhanced by certain PGs, e.g., PGE_2 and PGI_2. These PGs do not seem to directly affect vascular permeability but facilitate leukocyte infiltration and edema formation through vasodilation-induced increase in blood flow. Metabolites of the lipoxygenase pathway also contribute to the inflammatory process, and increasing evidence has linked these compounds and certain PG derivatives with immunologic phenomena.

The peptide leukotrienes increase vascular permeability and contribute further to inflammation by their chemotactic effect on leukocytes. Leukotriene B_4 is especially active as a chemoattractant for polymorphonuclear leukocytes. Other lipoxygenase products such as 5-HPETE and 5-HETE may facilitate the release of histamine and other inflammatory autacoids from mast cells.

Others. PGs affect contractile activity of several smooth muscles besides those of the reproductive and vascular systems. Many species differences exist, and the net effect in each tissue is influenced by the age, health, sex, and endocrine status of the test subject. PGs of the F series, especially $PGF_{2\alpha}$, generally contract tracheal and bronchial smooth muscle in several species. Members of the E series generally relax respiratory muscle. In asthmatic humans, $PGF_{2\alpha}$ has induced intense bronchospasm, while PGE_1 and PGE_2 are potent bronchodilators. TxA_2, PGG_2, and PGH_2 contract tracheal muscle and induce bronchospasm.

PGI_2 affects smooth muscle motility and fluid transport mechanisms in the intestine, where it exerts an antidiarrheal effect. In contrast, PGE_2 produces diarrhea, which is an important limitation to therapeutic use of this agent.

PGI_2 is a major product of the gastric mucosa of several species. It is a potent vasodilator in this tissue, where it also inhibits the acid secretion evoked by pentagastrin. Thus PGI_2 may serve as a suppressant modulator of gastric acid secretion and as a participant in functional hyperemia of the stomach. The untoward ability of aspirin-like drugs to induce gastric irritation and ulceration has been attributed to inhibition of PGI_2 synthesis.

Numerous central nervous system effects have been attributed to PG, but large concentrations are generally needed to demonstrate such actions. Several PG derivatives depress release of norepinephrine from adrenergic neurons of the autonomic nervous system, but physiologic significance remains questionable.

Mechanism of Action. Membrane receptors for PG have been identified in certain tissues, and smooth muscle-stimulating effects of PG have been associated with alterations in calcium movement induced by cell membrane depolarization. Changes in cellular metabolism of calcium may also be involved in other actions of PG, secondary to changes in various enzyme activities. Certain of the PGs increase cAMP concentrations by stimulating adenylyl cyclase activity, e.g., PGI_2 in platelets. Others are inhibitory to such relationships, e.g., TxA_2 in platelets. In certain tissues, however, cAMP can inhibit PG biosynthesis.

The biological complexity of the eicosanoids is exemplified by the complexity of PG receptors and their associated signal-transduction mechanisms. The G-protein-adenylyl cyclase-cAMP system is linked with some PG receptors (Smith 1992), whereas the phospholipase C-inositol trisphospate-Ca^{++} system is linked with others (Mitchell and Trautman 1993). This area was reviewed by Campbell (1990), and Table 21.1 summarizes some of the PG receptor types and their affiliated receptor mechanisms. Although antagonists for PG receptors are under intense investigation, inhibition of biosynthetic enzymes in the eicosanoid cascades (Figs. 21.4 and 21.5) is the most viable therapeutic mechanism for altering eicosanoid actions.

Clinical Aspects. Bell et al. (1980) compiled lengthy lists of possible therapeutic uses of different members of the PG group in veterinary medicine. Disorders that were listed as potentially responsive to PG or to anti-PG treatment varied from such diverse disorders as equine laminitis and feline cardiomyopathies to paralytic ileus and porcine gastric ulceration. Use of PG in treating such pathophysiologic states may well prove to have clinical value in the future. Currently, pharmacologic manipulation of the PG complex involves mainly the cardiovascular system, reproductive functions, and inflammation.

The capability of $PGF_{2\alpha}$ and synthetic analogs to influence reproductive performance represents the most important clinical application of PG compounds in veterinary medicine. Use of aspirin-like cyclooxygenase inhibitors for analgesic, anti-inflammatory, and antipyretic effects is discussed elsewhere in this volume.

TABLE 21.1—Classification of some eicosanoid receptors and their affiliated signal-transduction pathways in vascular smooth muscle and platelets

Receptor type	Endogenous agonist	Transduction mechanism	Vascular effect	Platelet aggregation
DP	PGD_2	cAMP	—	Inhibit
EP_1	PGE_2; $PGF_{2\alpha}$	IP_3–Ca^{++}	Vasoconstrict	—
EP_2	PGE_2; PGE_1	cAMP	Vasodilate	Inhibit
FP	$PGF_{2\alpha}$	IP_3–Ca^{++}	Vasoconstrict	—
IP	PGI_2; PGE	cAMP	Vasodilate	Inhibit
TP	TxA_2; PGH_2	IP_3–Ca^{++}	Vasoconstrict	Enhance

Source: Campbell 1990; Smith 1992; Mitchell and Trautman 1993.

Note: P = prostaglandin; cAMP = the $G_s$protein-adenylyl cyclase-cAMP-protein kinase A pathway; IP_3-Ca^{++} = the phospholipase C-IP_3-diacylglycerol–protein kinase C–Ca^{++} pathway. The — designates unknown or vasoconstriction and vasodilation depending on tissues. cAMP = cyclic adenosine monophosphate.

Pharmacologic manipulation of the PG system also has application in treating or preventing disorders of the cardiovascular system, but such uses are mainly experimental; e.g., PGI_2 has been used to retard platelet aggregation and thromboembolism in several systems of extracorporeal circulation such as renal dialysis and cardiopulmonary bypass. PGI_2 and its analogs may also become important in controlling thromboembolism in the intact circulation. Intra-arterial infusions of the vasodilators PGE_2 and PGI_2 were reported to increase blood flow, reduce pain, and accelerate healing of ulcers in human patients with peripheral vascular disease (Szczeklik et al. 1979).

Platelet cyclooxygenase is more sensitive to the inhibitory action of aspirin than the cyclooxygenase of blood vessels. Aspirin irreversibly inhibits cyclooxygenase by acetylating its active site. Since platelets cannot synthesize new protein during their sojourn in the bloodstream, the inhibitory effect of aspirin persists for several days, i.e., until new platelets are produced by the bone marrow. Thus small doses of aspirin preferentially inhibit platelet production of the proaggregating TxA_2 without marked reduction of vascular production of the antiaggregating PGI_2. The net result is expressed as an antithrombotic effect with increased bleeding time. Aspirin therefore is an antithrombotic agent used for prevention of conditions characterized by excessive platelet aggregation. However, large doses also inhibit vascular cyclooxygenase, resulting in loss of preferential block of TxA_2 synthesis. The clinical application of such interrelationships in animals remains to be clearly defined.

PLATELET-ACTIVATING FACTOR. Platelet-activating factor (PAF) is another autacoid derived from membrane phospholipids rich in arachidonic acid and other precursors of polyunsaturated fatty acids, and is therefore chemically related to the ubiquitous eicosanoid family. Whereas the eicosanoids are formed from a wide variety of cell types, PAF is synthesized principally by platelets, endothelial cells, and circulating leukocytes. The wide distribution of these cells throughout the body ensures PAF the opportunity to affect a host of tissue and cellular functions.

PAF not only provokes platelet aggregation, as its name implies, but it also modulates smooth muscle activity in blood vessel walls and promotes leakage of vascular fluid across endothelial surfaces. Although PAF lowers blood pressure due to its relaxing effect on vascular smooth muscle, it markedly contracts smooth muscle of the gut, stomach, uterus, and peripheral airways of the lungs. PAF can promote the synthesis and release of thromboxane A_2 and therefore exerts both direct and indirect effects on blood pressure. Since some of the smooth muscle and proinflammatory effects of PAF can be prevented by cyclooxygenase inhibitors, PAF is considered to be one of the most active endogenous activators of prostaglandins and related eicosanoids. In this regard, PAF and cyclooxygenase products are commonly activated concomitantly in response to inflammatory stimuli such as bacterial infection. This type of cohort relationship is exemplified in Fig. 21.6, wherein the response of a mammalian cell membrane to bacterial lipopolysaccharide (endotoxin) is schematized. Endotoxin lipopolysaccharide interacts with cellular constituents, culminating in activation of the cell membrane enzyme phospholipase A_2. Not only does the latter release arachidonic acid for eicosanoid biosynthesis through the cyclooxygenase (Fig. 21.4) and lipoxygenase pathways (Fig. 21.5), but this same reaction also yields a lysophospholipid that can be formed into PAF (Fig. 21.6). Thus, biological roles for PAF are often linked to those exhibited by the eicosanoid family. Despite the wealth of physiologic and pathophysiologic activities proposed for PAF (Campbell 1990), pharmacologic manipulation of PAF synthesis and receptors is at a preliminary stage. The clinical significance of PAF antagonists is currently unknown for veterinary medicine.

CYTOKINES. In response to certain inflammatory and immunologic stimuli, many types of mammalian cells produce one or more of a variety of small proteins termed cytokines. Cytokines include tumor necrosis factor-α (TNF-α), gamma interferon, and the interleukins (IL). Currently, monoclonal antibodies raised against these specific proteins represent the primary pharmacotherapeutic intervention relevant to the area

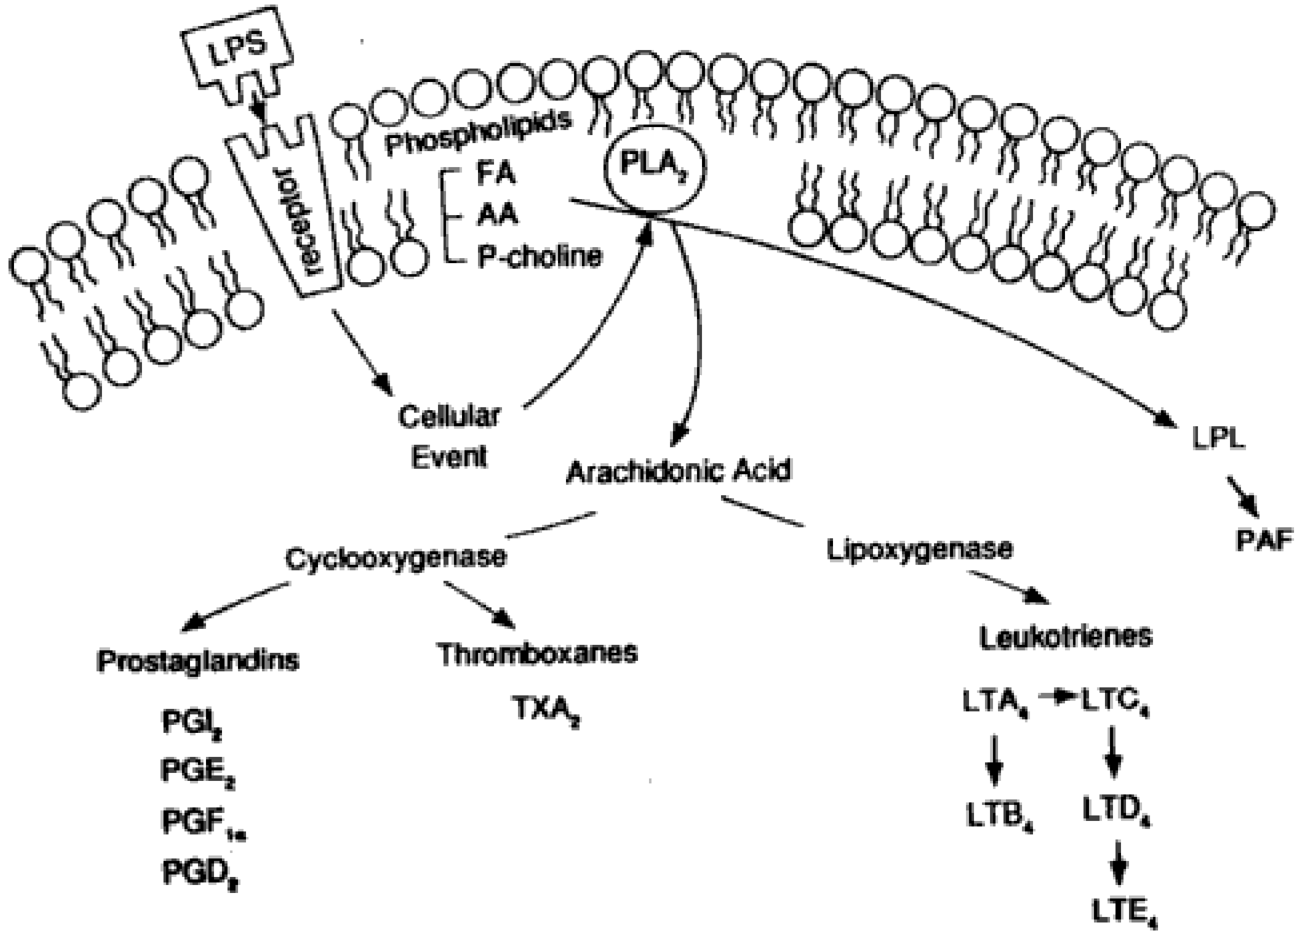

FIG. 21.6—Schematic diagram of endotoxin (lipopolysaccharide, LPS)-induced activation of phospholipase A$_2$ (PLA$_2$). Activated PLA$_2$ results in the release of arachidonic acid from the 2-acyl position of membrane phospholipids, leaving a lysophospholipid (LPL) that can be used to form platelet-activating factor (PAF). Arachidonic acid is metabolized to prostaglandins (PG), thromboxanes (TX), and leukotrienes (LT). FA = fatty acid; AA = arachidonic acid; and P-choline = phosphatidylcholine. (Source: Bottoms and Adams 1992.)

of cytokines. However, because of the likely future importance of cytokines to pharmacologic management of bacterial invasion and other inflammatory conditions, the following discussion briefly summarizes key aspects about TNF-α and the interleukins.

Tumor Necrosis Factor-α. The polypeptide cytokine TNF-α occupies a prominent and perhaps central role as proximal mediator of endotoxic shock (Tracey et al. 1989; Morris et al. 1990). Macrophages exposed to endotoxin and related stimuli release large quantities of TNF-α. On reaching the circulation, TNF-α binds to high-affinity receptors in normal tissues and triggers a wide array of biological effects. The infusion of recombinant TNF-α from human beings can induce lethal shock and tissue injury in animals, closely simulating key elements of the pathophysiologic derangements characteristic of endotoxemia (Tracey et al. 1986; Tracey et al. 1987a,b).

The production and release of other cytokines, eicosanoids, and humoral factors are elicited by TNF-α (Fig. 21.7). In addition to induction of IL-1, IL-4, and IL-6 synthesis, other biological activities attributed to TNF-α include T-cell activation, endogenous pyrogen activity, induction of eicosanoid synthesis, activation of osteoclastic bone resorption, inhibition of bone collagen synthesis, induction of acute-phase reactant synthesis and granulocyte/monocyte colony-stimulating factor, and inhibition of lipoprotein lipase and other enzymes of lipid metabolism (Grunfield and Palladino 1990; Beutler and Cerami 1989; Rosonblum and Donato 1989). In neutrophils, TNF-α stimulates activation, respiratory burst, degranulation, and adherence to the vascular endothelium.

At low concentrations, TNF-α exerts its primary effects locally as a paracrine and autocrine regulator of leukocytes and endothelial cells. These actions are critical for the containment of infection. However, when TNF-α gains access to the systemic circulation, signs of septicemia develop and high concentrations of TNF-α can be lethal. Cyclooxygenase inhibitors can block the rapid-onset monophasic fever that is induced by TNF-α. Lethal effects of endotoxin and TNF-α can be reduced under certain conditions by the administration

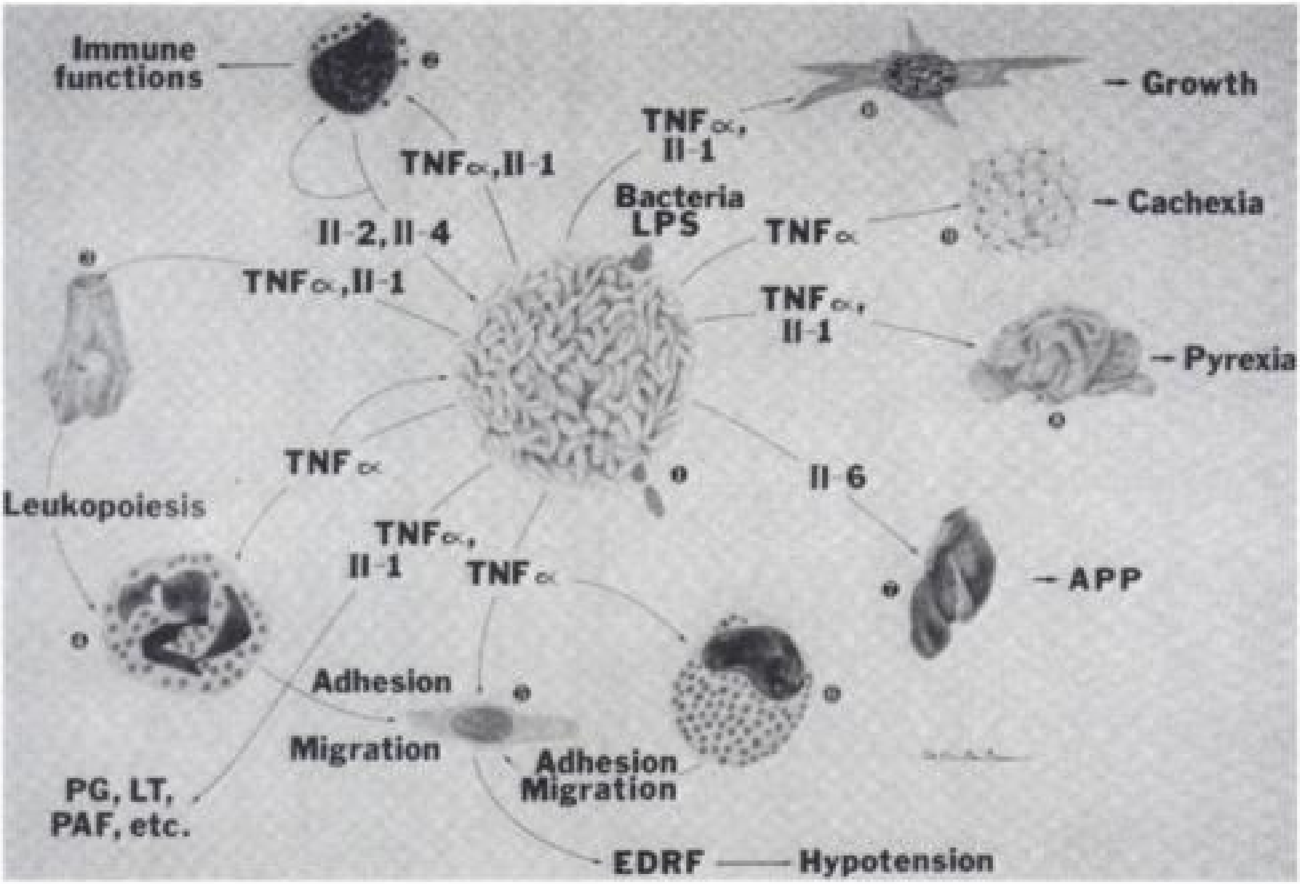

FIG. 21.7—Reaction of macrophage to gram-negative bacteria and endotoxin and representative responses of tissues to liberation of tumor necrosis factor-α (TNF-α) and interleukin (IL) cytokines from macrophages. The following numbered items refer to corresponding numbers in the figure: (1) macrophage: recognizes and assimilates bacteria and endotoxin (lipopolysaccharide, LPS), resulting in macrophage activation and release of cytokine mediators such as TNF-α and IL-1; (2) T and B lymphocytes: TNF-α and IL-1 enhance immunoregulatory functions, and lymphocytes release IL-4 and IL-2, which can affect macrophage function in an autocrine manner; (3) bone marrow: cytokines increase leukopoiesis; (4) neutrophils: activated by TNF-α to enhance migration and adhesion to vascular endothelium; (5) endothelium: TNF-α enhances adhesion and modulates release of hypotensive agents such as endothelium-derived relaxing factor (EDRF); (6) eosinophils: TNF-α promotes migration and adhesion; (7) liver: cytokines promote synthesis of acute-phase proteins (APP); (8) brain: cytokines modulate thermoregulatory functions, resulting in pyrexia; (9) adipocytes: TNF-α modulates metabolic regulatory enzymes, yielding cachexia; and (10) fibroblasts: cytokines enhance proliferation and growth. Cytokines also modulate the release of other mediators, such as prostaglandins (PG), leukotrienes (LT), and platelet-activating factor (PAF). (This figure was modeled after the illustration in Old 1988 and was drawn by Dr. Gheorghe M. Constantinescu, Department of Veterinary Biomedical Sciences, University of Missouri, Columbia. Source: Green and Adams 1992.)

of neutralizing TNF-α antiserum (Tracey et al. 1987a,b; Shimamoto et al. 1988). Long-term exposure to TNF-α results in cachexia, which accounts for its synonym, cachectin.

Interleukin-1. The polypeptide IL-1 has been termed lymphocyte activating factor, because it enhances T-cell responses during antigen presentation, and endogenous pyrogen, because it induces fever. Production of IL-1, primarily by mononuclear phagocytes (Fig. 21.7), is stimulated by endotoxin, other macrophage-derived cytokines such as TNF-α, other microbial products, and antigens. Although they are structurally distinct, IL-1 performs many of the same biological activities as TNF-α (Dinarello 1985). The principal biological function of IL-1 is believed to be mediation of the host response in natural immunity; IL-1 interacts with antigen-stimulated T cells to induce the release of IL-2 by T cells and synthesis of IL-2 receptors. By direct effect on B cells, IL-1 invokes B-cell activation, proliferation, and antibody synthesis. Natural killer cell activity is enhanced by synergism of IL-1 with other cytokines. Arachidonic acid metabolism, secretion of inflammatory proteins, neutrophil chemoattraction, and fibroblast proliferation are stimulated by IL-1. With TNF-α and IL-6, IL-1 participates in the acute-phase response, which is characterized by fever, hepatic production of acute-phase proteins, neutrophilia, procoagulant activity, and hypoferremia. Endothelial cells are stimulated by IL-1 to synthesize prostacyclin, procoagulant activity, PAF, and neutrophil adherence protein. Evidence suggests that IL-1 and TNF-α interact synergistically to induce many of the tissue reactions associated with endotoxemia.

Interleukin-6. The phosphoglycoprotein IL-6 is produced and secreted by macrophages, monocytes, fibroblasts, vascular endothelial cells, T lymphocytes, and mast cells (Kishimoto 1989). Cells are stimulated to produce IL-6 by various inflammatory stimuli, including IL-1 and, to a lesser extent, endotoxin, TNF-α, platelet-derived growth factor, and viral infection. The primary inflammatory action of IL-6 is the induction of hepatic production of acute-phase proteins (Fig. 21.7), such as fibrinogen, C-reactive protein, serum amyloid A, haptoglobin, ferroxidase, α-1-antitrypsin, and complement. Growth and differentiation of B cells are enhanced by IL-6, and IL-6 serves as a costimulator of T cells. High concentrations of IL-6 have been measured in serum and body fluids in human beings after the administration of endotoxin, TNF-α, and IL-1, and during acute bacterial infection and sepsis. Whereas the effects of TNF-α and IL-1 may be detrimental, IL-6 appears to be beneficial. Acute-phase reactants protect the host nonspecifically against microorganisms, and IL-6 does not cause tissue injury and vascular thrombosis characteristic of endotoxin and TNF-α.

The wide spectrum of biological actions of TNF-α and IL-1 are illustrated in Fig. 21.7. Despite the wealth of physiologic activities ascribed to cytokines, the clinical significance of their pharmacologic manipulation remains unclear (Green and Adams 1992).

THE PATHOPHYSIOLOGY OF INFLAMMATION. Inflammation can occur in any vascularized tissue in the body. The sequelae of inflammation are manifested as five cardinal signs: redness, heat, swelling or edema, pain, and loss of function. Vasoconstriction of small vessels in the area of injury is the initial vascular response to damage. Vascular occlusion serves to control hemorrhage. However, within 5-10 minutes, vasodilation and increased vascular permeability of small venules occur. Leukocytes, platelets, and erythrocytes in the injured vessels become "sticky" and adhere to the endothelium. Leakage of cells and of plasma-derived protein-rich fluid is followed by platelet aggregation and fibrin formation. Initially, the predominant cell type infiltrating damaged tissues is the polymorphonuclear leukocyte (PMN)—in part, because it predominates in circulation. As the short-lived PMNs die, macrophages become the predominant cell type. The migration to and concentration of PMNs at the site of injury are facilitated by chemical mediators that act as chemotactic agents. As PMNs die, the contents of the lysed cells accumulate to form the component of inflammatory exudate commonly referred to as pus.

The Role of Chemical Mediators in the Inflammatory Response. The mediators released during the inflammatory process perpetuate the inflammatory response and are responsible for the clinical signs associated with inflammation, including pain and fever (Vane and Botting 1987). Mediators of inflammation (Table 22.1) are derived from both the cells and the fluid which reach the site of tissue damage from blood. Although there are quantitative differences between species, and tissue concentrations of the mediators vary, the effect of each mediator and its role in the pathophysiology of inflammation are predominantly the same in all species. Leukocytes are a rich source of a variety of chemical mediators of inflammation (Fig. 22.1). These cells, as well as cells of other tissues that are injured and dying following either the initial damage or subsequent inflammation, perpetuate the inflammatory response. Mediators include lysosomal and other enzymes, granular mediators such as histamine and serotonin, eicosanoids (products of arachidonic acid metabolism: prostaglandins, leukotrienes, and related compounds), platelet-activating factor, oxygen radicals, and cytokines. The role of each of these mediators in the perpetuation of the inflammatory response varies, in part, according to the phase of inflammation during which the mediator is released.

Plasma-derived mediators are also important contributors to the inflammatory process. Examples include kinins (e.g., bradykinin), released from their precursor form following appropriate physiologic or pathologic stimulation; complement and complement-derived peptides, released following activation of either the classic or an alternative pathway; and fibrinopeptides, released during the conversion of fibrinogen to fibrin during the clotting process and subsequent proteolysis of fibrin by plasmin.

Pharmacological control of inflammation is oriented toward preventing the release of various chemical or plasma mediators, inhibiting their actions, and/or treating pathophysiological responses to them. Drugs useful for modulating the activity of chemical

TABLE 22.1—Mediators important in the course of inflammation

Mediator	Source	Action	Pharmacologic modulator
Lysosomal contents	Phagocytes	Vessel permeability Membrane degradation Chemotactic factors Collagen, fibrin, cartilage, etc., degradation	Glucocorticoids Dimethylsulfoxide Organic gold compounds
Histamine	Granulocytes	Vasodilation Capillary permeability Pain	Antihistamines (particularly H_1 and possibly H_2 blockers)
Serotonin	Platelets	Vasodilation/constriction Capillary permeability Pain	
Eicosanoids Prostaglandins Leukotrienes Lipoxygenases	All cells	Chemotaxis Vascular permeability Vasodilation Pain	Glucocorticoids Nonsteroidal anti-inflammatory drugs
Platelet-activating factor	Platelets	Platelet aggregation Chemotaxis Oxygen radical production	Glucocorticoids
Oxygen radicals	Damaged tissues Leukocytes	Destruction of a number of cellular constituents, particularly lipid membranes	Superoxide dismutase Vitamine E Ascorbic acid Dimethylsulfoxide Xanthine oxidase inhibitors
Kinins	Plasma	Vasodilation Capillary permeability Pain	Nonsteroidal anti-inflammatory drugs
Complement	Plasma	Lysis of cells Histamine release Vascular permeability Release of lysosomal contents Chemotaxis	Glucocorticoids Dimethylsulfoxide Antihistamine
Fibrinopeptides	Plasma	Enhancement of kinins Vascular permeability Chemotaxis	Nonsteroidal anti-inflammatory drugs

mediators derived from cells and plasma are summarized in Table 22.2.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Chemistry. Although nonsteroidal anti-inflammatory drugs (NSAIDs) have been variably defined, the term is used here to describe compounds that are not steroidal and that suppress inflammation. Generally, the classification is restricted to those drugs that inhibit one or more steps in the metabolism of arachidonic acid (AA) (Boynton et al. 1988). The NSAIDs vary in their ability to influence inflammation. The mechanism of action of some of these drugs is not limited to inhibition of AA metabolism (Hochberg 1989).

Aspirin, one of the earliest components of herbal therapy, is the progenitor NSAID, and terms such as "aspirin-like" and "aspirin and related drugs" are commonly used to refer to this group of drugs (Boynton et al. 1988). Structurally, NSAIDs can be broadly classified into salicylate or carboxylic acid derivatives, including the indoles (indomethacin), propionic acids (ibuprofen and naproxen), fenamates (meclofenamic acid), oxicams (piroxicam), or the pyrazolones or enolic acids (phenylbutazone and dipyrone) (Boynton et al. 1988).

Mechanism of Action. Eicosanoids, such as prostaglandins and leukotrienes, are 20-carbon-chain derivatives of cell membranes. These compounds are synthesized when oxygen reacts with the polyunsaturated fatty acids of cell membrane phospholipids (Fig. 22.1). The most important of these fatty acids is AA, which is released into the cell from damaged cell membranes. Once inside the cell, AA serves as a substrate for enzymes which generate intermediate and end (eicosanoid) products (Fig. 22.1) (Weissmann 1991; D. R. Robinson 1989). Cyclooxygenases (prostaglandin synthase or prostaglandin H synthase), located in all cells except mature red blood cells, add oxygen to AA, generating unstable prostaglandin endoperoxides (PGG_2). Subsequent peroxidase reactions convert PGG_2 to PGH_2, the precursor of all other prostaglandins and thromboxane. The final prostaglandin product depends on the presence of specific isomerase enzymes (D. R. Robinson 1989). While all tissues have the capacity to produce cyclooxygenase end products, the concentration varies with the type

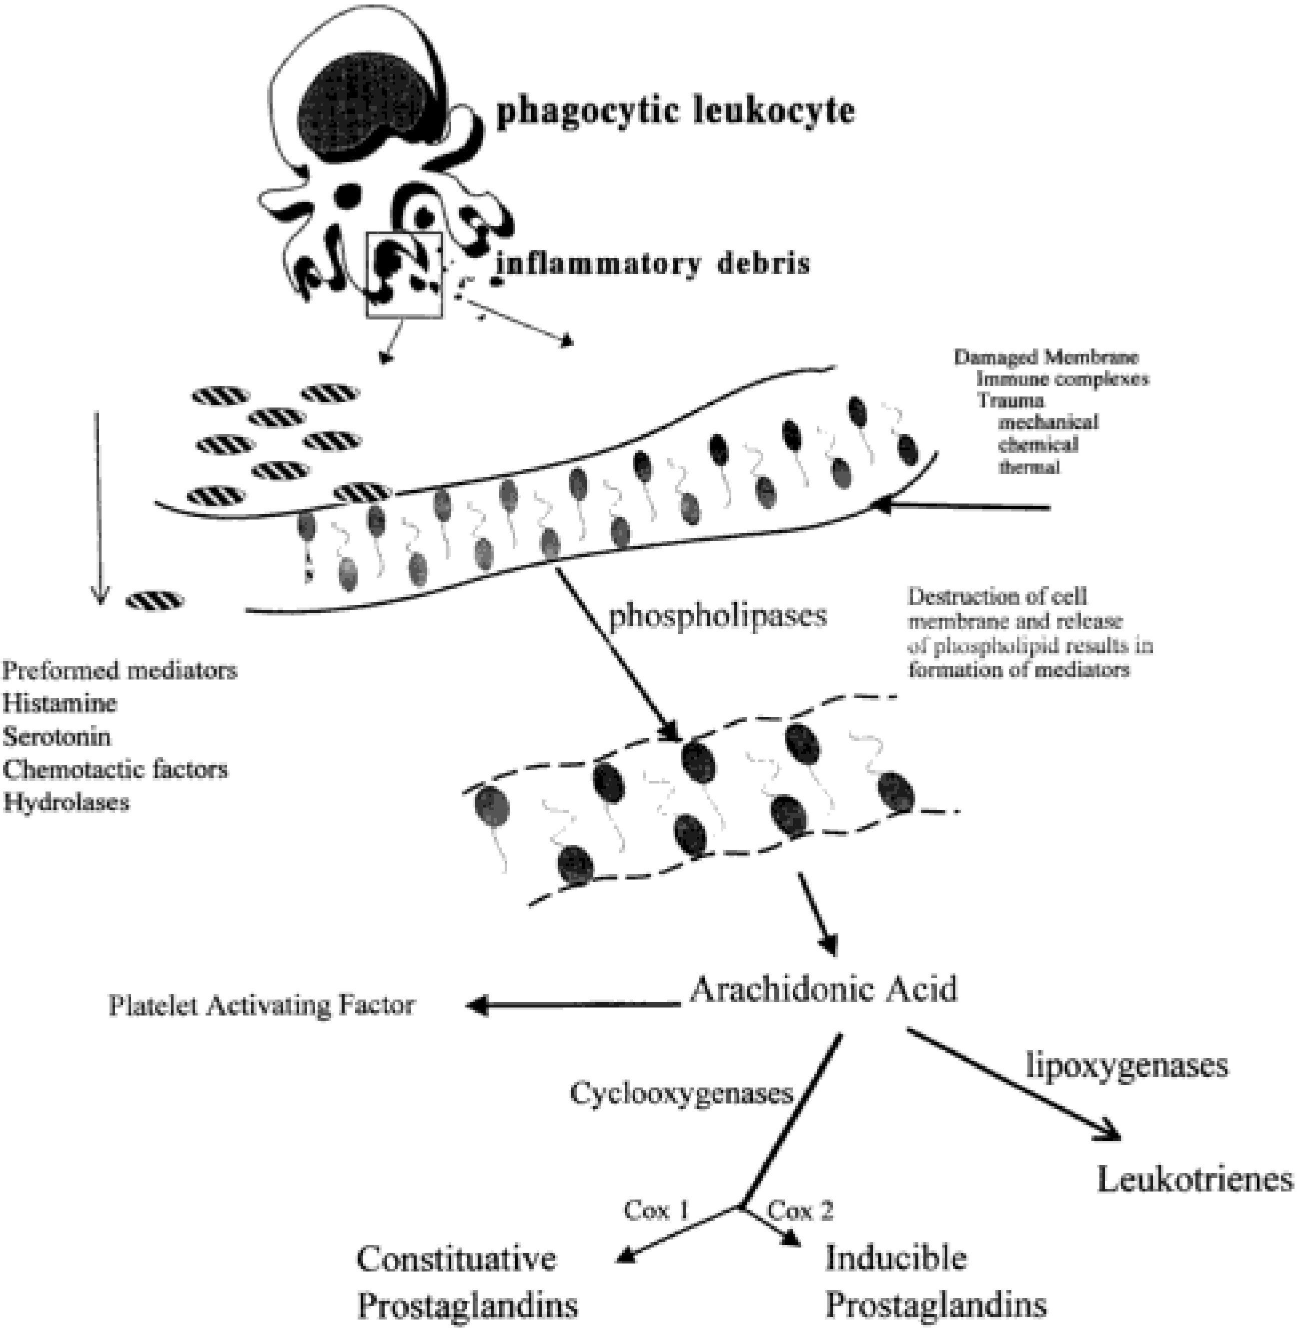

FIG. 22.1—Leukocytes are an important source of inflammatory mediators that perpetuate the inflammatory response. Cellular mediators of inflammation include those preformed in granules or lysosomes and those formed in situ from arachidonic acid released by phospholipases in the cell membrane. Although the phagocytic cell is intimately involved in the inflammatory reaction, it is not the only cell type capable of generating mediators of inflammation. The mediators of cellular origin interact with plasma-derived mediators, further compounding the response. Drugs used to control inflammation target specific mediators (Table 22.1).

and amount of the individual isomerases (D. R. Robinson 1989).

Prostaglandins have important roles in normal physiology that might best be described as protective in nature. Prostaglandin formation is mediated by either one of two isoforms of cyclooxygenase (Fig. 22.1) (Williams 1996; Griswold and Adams 1996; Vane et al. 1998; Pairet and Engelhardt 1996). Cyclooxygenases 1 (COX 1) mediate the formation of constitutive prostaglandins produced by many tissues, including gastrointestinal (GI) cells, platelets, endothelial cells, and renal cells. Prostaglandins generated from COX 1 are constantly present and impart a variety of normal physiologic effects. These include protection of the GI mucosa, hemostasis, and the kidney when subjected to hypotensive insults. Cyclooxygenases 2 (COX 2)

TABLE 22.2—Doses for analgesic, antipyretic, and anti-inflammatory drugs

Aspirin		
	Cows	100 mg/kg PO 12 hr
	Dogs	10 mg/kg PO 8–24 hr
		10 mg/kg PO 24 hr (endarteritis)
		10 mg/kg 12 hr (antipyresis)
		25-35 mg/kg PO 8 to 12 hr (autoimmune diseases)
		25-35 mg/kg PO 24 hr (preoperative ocular surgery)
		40 mg/kg PO every 18 hr (anti-inflammatory)
		3 mg/kg every 6 days (antithrombotic)
	Cats	10 mg/kg PO 48 hr
		75 mg/kg 48 hr (antithrombotic)
Carprofen		
	Dogs	2.2 mg/kg PO 12 hr
Dimethylsulfoxide		
	Horses	0.25-1.0 g/kg IV 6–24 hr
		90% gel solution topical 8–12 hr
Dipyrone		
	Dogs	25 mg/kg IM, SQ 8–12 hr
	Cats	10–25 mg/kg IM, SQ 24 hr
Flunixin meglumine		
	Cows	2.2 mg/kg, then 1.1 mg/kg 8 hr (limited analgesia, effective PG inhibition)
	Dogs	0.5-1.0 mg/kg IV 24 hr; IM × 1-3 hr (analgesic)
		0.25 mg/kg IV 24 hr × 5 days (uveitis)
Ketoprofen		
	Horses	2.2 mg/kg IV 24 hr
	Dogs	1.1 mg/kg [D] IV, PO 24 hr
		0.5 mg/kg [C] PO 24 hr
Naproxen		
	Horses	10 mg/kg PO 12 hr
	Dogs	1–2 mg/kg PO 24-48 hr
Phenylbutazone		
	Cows	10-20 mg/kg PO, then 2.5-5.0 mg/kg 24 hr
	Bulls	24 mg/kg, then 6 mg/kg 48 hr
	Horses	4 g/450 kg PO 24 hr
		2 g/horse maximum IV
		15 mg/kg IV, then 10 mg/kg at 6 and 12 hr
		8.8 mg/kg maximum
	Dogs	10 mg/kg PO 8-12 hr
		10-15 mg/kg IV 12 hr (not to exceed 4 doses)
		22 mg/kg PO 8 hr (not to exceed 800 mg)
Piroxicam		
	Dogs	0.3 mg/kg 48 hr
Meclofenamic acid		
	Cows	2 mg/kg IV
		10 mg/kg intraruminal (oral) or 20 mg/kg IM
Acetaminophen		10-15 mg/kg PO 6-8 hr
Hyaluronic acid		
	Horses	20-40 mg intra-articular (remove equal volume of synovial fluid)

Note: IV = intravenous; IM = intramuscular; PO = per os.

catalyze the formation of inducible prostaglandins, which are needed only intermittently (Williams 1996; Griswold and Adams 1996; Vane et al. 1998; Pairet and Engelhardt 1996; Cashman 1996; Donnelly and Hawkey 1997). Prostaglandins that mediate inflammation are an example. Inflammation is mediated or perpetuated by inducing vasodilation, changes in capillary permeability, and chemotaxis, all of which can be caused by inflammatory prostaglandins. They also potentiate the effects of other chemical mediators of inflammation such as histamine and bradykinin and are capable of inducing a state of hyperalgesia. Although specific points remain controversial, the role of prostaglandins in the inflammatory process have been described (D. R. Robinson 1989). Prostaglandins (PGE) also modify both T- and B-cell function, in part by inhibition of interleukin-2 secretion (D. R. Robinson 1989).

Eicosanoids are potent mediators of inflammation and are particularly important in the later stages (D. R. Robinson 1989). NSAIDs block the first step of prostaglandin synthesis by binding to and inhibiting cyclooxygenase (D. R. Robinson 1989). This action is both dose and drug dependent. The precise site at which cyclooxygenase is inhibited is not known. The planar form that characterizes these drugs is thought to facilitate their binding to cyclooxygenase (Boynton et al. 1988; Higgins 1985). Several investigators have shown that some NSAIDs (e.g., phenylbutazone and flunixin meglumine) also reduce formation of prostaglandin E_2 in inflammatory exudate at therapeutic doses (Lees et al. 1986). The major therapeutic and toxic effects of NSAIDs have been correlated extensively to their ability to inhibit prostaglandin synthesis (D. R. Robinson 1989). Their potency as anti-inflammatory agents relates to their relative potency of inhibition of prostaglandin synthesis (D. R. Robinson 1989).

The differential effect of NSAIDs on the isoforms of cyclooxygenase offers some insight as to the differential pharmacologic and toxic effect of this class of drugs. As a class, NSAIDs appear to inhibit both COX 1 and COX 2. The amount of drug necessary to inhibit each of the two isoforms provides a basis for assessing the relative safety and efficacy of each drug. The ratio of COX 2 to COX 1 describes the amount of drug necessary to inhibit the respective isoforms of the cyclooxygenase enzyme. A drug that inhibits COX 2 at a lower concentration than that necessary to inhibit COX 1 is probably safer since COX 2 prostaglandins (inducible) are inhibited at lower drug concentrations than COX 1 (constitutive) prostaglandins. A COX 2/COX 1 ratio of less than 1 (which indicates that COX 2 is inhibited by less drug than COX 1) is desirable (Griswold and Adams 1996; Williams and DuBois 1996; Cashman 1996; Donnelly and Hawkey 1997). Carprofen, etodolac, and meloxicam appear to be NSAIDs with a favorable COX 2/COX 1 ratio because they preferentially inhibit COX 2.

Lipoxygenase enzymes located within cells can also metabolize AA to inflammatory mediators (Hochberg 1989; Newcombe 1988). Among these enzymes, 5-lipoxygenase appears to be the most important (D. R. Robinson 1989). This enzyme adds oxygen to AA to form 5-hydroperoxyeicosatetraenoic acid (HPETE). Leukotriene (LT) C_4, LTD_4, and LTE_4 result from addition of glutathione to LTA_4 by glutathione-*S*-transferase. These are potent mediators of inflammation. In addition, LTA_4 can also be converted to LTB_4, a potent chemotactic agent (D. R. Robinson 1989). Leukotrienes and other selected lipoxygenase products modulate lymphocyte function (D. R. Robinson 1989). Lipoxygenases are not as ubiquitous as prostaglandins and are found predominantly in the lungs, white blood cells, platelets, and liver. Although lipoxygenases are formed primarily by leukocytes, the end products of lipoxygenase activity, leukotrienes and lipoxins, are also potent mediators of local inflammation (Hochberg 1989). Originally, studies indicated that NSAIDs were not capable of inhibiting leukotriene synthesis. A potential consequence of cyclooxygenase blockade by NSAIDs is increased production of leukotrienes from AA, which would otherwise have been metabolized to prostaglandin products (D. R. Robinson 1989). Aspirin hypersensitivity is associated with the diversion of AA from the prostaglandin to the leukotriene (5-lipoxygenase) pathway and the production of mediators that are more inflammatory than the products of prostaglandin H synthase (Weissmann 1991). Thus, NSAIDs may cause undesirable effects by augmenting leukotriene synthesis (D. R. Robinson 1989). More recently, the anti-inflammatory efficacy of some of these drugs has been ascribed to inhibition of lipoxygenases and thus prevention of leukotriene formation (Boynton et al. 1988), but their ability to inhibit 5-lipoxygenase is controversial (D. R. Robinson 1989).

Inhibition of cyclooxygenase as the sole anti-inflammatory mechanism of action of NSAIDs has recently been scrutinized and criticized. These drugs also appear to alter cellular and humoral immune responses and may suppress inflammatory mediators other than prostaglandins (Hochberg 1989). Connective tissue metabolism may also be affected (Hochberg 1989). As a group, all NSAIDs are planar and anionic and are able to partition into lipid environments, including neutrophil cell membranes. As a result, cell membrane viscosity is altered, even at low concentrations (Weissmann 1991). At higher concentrations, NSAIDs appear to uncouple protein-protein interactions within the plasma membrane and thus interfere with a variety of cell membrane processes such as oxidative phosphorylation and cellular adhesion (Weissmann 1991). The drugs appear to disrupt the response of inflammatory cells to extracellular signals by affecting signal-transduction proteins (G proteins) (Weissmann 1991). Thus, at low doses, prostaglandin H synthase appears to be the target of NSAIDs, whereas membrane-bound signal-processing complexes appear to be the target at higher doses (Weissmann 1991).

Studies using in vitro systems have shown that NSAIDs alter the inflammatory response by inhibiting activation of neutrophils and thus the subsequent release of inflammatory cellular enzymes such as collagenase, elastase, hyaluronidase, and others (Hochberg 1989). NSAIDs interfere with multiple aspects of neutrophil function, including adherence. Some NSAIDs inhibit several neutrophil functions, while others inhibit few. The extent of inhibited neutrophil activation varies with the individual drug. For example, piroxicam inhibits both the generation of superoxide ions and the release of lysosomal enzymes, whereas ibuprofen does neither (Weissmann 1991). All NSAIDs appear to inhibit adhesion. Several NSAIDs, including phenylbutazone, oxyphenylbutazone, and flunixin, inhibit leukocyte cell movement. Of these drugs, flunixin is the most potent inhibitor in vitro at concentrations achieved in equine plasma and inflammatory exudate (Dawson and Sedgwick 1987).

NSAIDs are also capable of immunomodulation. Several prostaglandins and leukotrienes are important immunomodulators (D. R. Robinson 1989). NSAIDs indirectly influence lymphocyte activity through altered prostaglandin formation (Hochberg 1989). Certain NSAIDs appear to enhance cellular immunity by inhibiting prostaglandin E_2, a mediator which dampens the immune response (Hochberg 1989). This effect appears to be more important in the immunosuppressed animal.

NSAIDs have been shown to inhibit proteoglycan synthesis in vitro, and for the salicylates, this is supported by in vivo studies (Brandt 1991). This effect has been attributed to inhibition of uridine diphosphate-glycose dehydrogenase, an enzyme important in proteoglycan synthesis (Brandt 1991). However, hyaluronic acid synthesis, which is also dependent on this enzyme, does not appear to be affected. The effects of NSAIDs on cartilage are controversial. More recent evidence indicates that they may, in fact, favorably modify the metabolism of proteoglycans, collagen, and matrix and may decrease the release of proteases or toxic oxygen metabolites (Brandt 1991).

Pharmacokinetics. The NSAIDs share a number of pharmacokinetic properties. As weak acids, the NSAIDs tend to be well absorbed following oral administration. Bioavailability can vary between animals but has not been established for many NSAIDs because of the lack of intravenous (IV) preparations (Brater 1988). Food can impair the oral absorption of some NSAIDs, or contribute to drug interactions for others (e.g., phenylbutazone in the horse) (Tobin et al. 1986; Munsiff et al. 1988). Solutions of injectable preparations tend to be alkaline and can cause necrosis or pain if perivascular leakage occurs. The drugs are lipid soluble but are characterized by a small volume of distribution (approximately 10%) due to binding to serum albumin, which can exceed 99% in some species. Unbound drug is distributed to extracellular fluid. Only a small portion of pharmacologically active drug reaches peripheral tissues. Displacement from albumin due to competition with other substrates for binding sites or due to decreased serum albumin concentrations initially can result in higher than expected concentrations of pharmacologically active drug and thus predispose the patient to drug-induced adverse effects. This increase, however, is only transient due to increased clearance of unbound drug (Brater 1988).

Clearance of the NSAIDs is variable, differing among drugs and species. Differences in clearance rates are largely responsible for differences in drug half-life among animals (Brater 1988). Most NSAIDs are eliminated primarily by hepatic metabolism. Both phase I and phase II hepatic drug-metabolizing enzymes are important. Conjugated metabolites are predominantly eliminated through the urine, although several drugs undergo extensive enterohepatic circulation in some species (e.g., naproxen and meclofenamic acid in dogs) (Aitken and Sanford 1975). For some drugs, a portion may be eliminated unchanged from the kidneys by active tubular secretion. Age and species differences in drug clearance should lead to caution when extrapolating doses from one animal to another. Although most pharmacokinetic studies measure total, rather than unbound, drug, clearance of unbound drug is substantially less in geriatric patients, whereas clearance of bound drug does not differ. The volume of distribution of unbound drug in adult animals is half that of pediatric patients. Because of these differences in NSAID disposition, geriatric and pediatric patients may require much smaller doses of the NSAIDs (Brater 1988). Species differences in the elimination of the NSAIDs have been well documented and are responsible for some of the adverse reactions commonly associated with the use of these drugs. Recently, stereoselective metabolism has become an additional important consideration when extrapolating doses in human beings (Brater 1988).

Pharmacologic Effects. The pharmacologic effects of this class of drugs include analgesia, antipyresis, and control of inflammation. The mechanisms by which NSAIDs inhibit (interact with) cyclooxygenase are responsible, in part, for the variable anti-inflammatory effect of these drugs. Aspirin binds reversibly to the cyclooxygenase activity site on prostaglandin H synthase and then inactivates the enzyme irreversibly by acetylating a serine residue (Weissmann 1991). The effects of aspirin on platelet activity remain for the life of the platelet because the platelet apparently cannot produce additional thromboxane synthase enzyme. In contrast, endothelial cells are able to synthesize more prostacyclin synthase and are less susceptible to the inhibitory effects of low doses of aspirin (Weissmann 1991). In contrast to irreversible binders of cyclooxygenase, ibuprofen binds reversibly with cyclooxygenase and thus competes with AA. In laboratory animals and humans, relative potency has been established for the NSAIDs: meclofenamic acid > indomethacin > naproxen > phenylbutazone > aspirin (Lee and Higgins 1985). A similar pattern occurs in domestic animals: the relative potency of the NSAIDs in horses has been reported to be flunixin meglumine > meclofenamic acid > phenylbutazone > naproxen > aspirin (Lee and Higgins 1985). However, potency does not necessarily confer therapeutic advantage. Rather, these compounds may be equally effective simply by adjusting the dose appropriately.

Along with inhibition of prostaglandins, disruption of cellular signaling is responsible for all the pharmacologic effects of all NSAIDs. These effects are dose and drug dependent and are antithrombosis, occurring at the lowest doses; analgesia and antipyresis; and control of inflammation, which occurs at the highest doses (Weissmann 1991). Although several NSAIDs are characterized by a short plasma elimination half-life, the clinical response may last for over 24 hours following a single dose or up to 72 hours following multiple doses. Irreversible binding to cyclooxygenase has been postulated as an explanation for the discrepancy between plasma half-life and biological response (Lee and Higgins 1985). Alternatively, prolonged elimination of NSAIDs from inflammatory exudate compared to plasma has also been suggested (Lee and Higgins 1985; Tobin et al. 1986).

Drug Interactions. The NSAIDs can be involved in a variety of drug interactions during any phase of drug disposition. Displacement of only a small percentage of bound drug from albumin can increase the concentration of pharmacologically active drug in tissues. Few, if any, adverse reactions resulting from drug displacement have been reported, in part because the increase in pharmacologically active drug is only transient: clearance of the unbound drug by both the liver and kidneys will increase (Bater 1988). Several NSAIDs can induce or inhibit drug-metabolizing enzymes and thus the clearance and half-life of other drugs cleared by the liver (Bater 1988). Phenylbutazone can both increase and inhibit certain drug-metabolizing enzymes, whereas salicylates increase metabolism (Bater 1988). Renal competition with other organic acids for active renal tubular secretion in the proximal tubule has been documented for aspirin and other drugs.

Adverse Reactions. All NSAIDs induce undesirable and potentially life-threatening side effects. The most commonly consumed NSAIDs in accidental poisoning include ibuprofen, acetaminophen, aspirin, and indomethacin (Jonnes et al. 1992). The most common clinical signs of toxicosis in one study were vomiting, diarrhea, CNS depression, and circulatory manifestations (Jonnes et al. 1992). The majority of adverse reactions reflect the inhibitory effects of NSAIDs on prostaglandin activity. In addition, acute intoxication by several drugs can be fatal. The major toxicities associated with NSAIDs affect the GI, hematopoietic, and renal systems. Miscellaneous side effects associated with use of NSAIDs include hepatotoxicity (Lewis 1984), aseptic meningitis (Clemmons and Meyers 1984; Berliner et al. 1985; Syvlia et al. 1988), diarrhea, and CNS depression (Jonnes et al. 1992).

GASTROINTESTINAL. GI damage is the most common and serious side effect of the NSAIDs. Although not completely understood, several mechanisms have been hypothesized (McCormack and Brune 1987). Gastroduodenal erosion and ulceration reflect inhibition of prostaglandin E_2-mediated bicarbonate and mucus secretion, epithelization, and blood flow (Chastain 1987). Control of gastric acid secretion is consequently decreased as is mucus and bicarbonate secretion, epithelization of the mucosa, and mucosal blood flow. Breakdown of small blood vessels due to a deficiency of mucus may be the initiating lesion (Mazué et al. 1983). Direct irritation by acidic drugs may be important (Chastain 1987). In addition, salicylates cause local damage due to "back-diffusion" of acid, which causes injury to mucosal cells and submucosal capillaries. Impaired platelet activity may contribute to mucosal bleeding. Oral ulceration has been reported in horses receiving oral phenylbutazone (Tobin et al. 1986). There appears to be no chemical characteristic that can be used to predict the likelihood of GI toxicity by a particular NSAID (Chastain 1987; Mazué et al. 1983). Drugs that undergo enterohepatic circulation may be associated with a greater incidence of GI upset. Treatment for GI toxicity should include prostaglandin (PGE) replacement (i.e., misoprostol) and a cytoprotectant such as sucralfate (Collins and Tyler 1985).

HEMATOPOIETIC. All NSAIDs are able to impair platelet activity due to impaired thromboxane synthesis. At pharmacologic doses, aspirin selectively and irreversibly acetylates a serine residue of a platelet cyclooxgenase (Jackson 1987). The platelet form of this enzyme is up to 250 times more sensitive to acetylation by aspirin compared to cyclooxygenases (prostacyclin synthase) in vascular endothelial cells. Although platelets cannot regenerate more cyclooxygenase, endothelial cells apparently are able to rapidly synthesize and replace impaired cyclooxygenase (Jackson 1987). Platelet aggregation defects caused by aspirin can last up to 1 week. In addition to their antiplatelet effects, some NSAIDs (e.g., phenylbutazone) have also been associated with bone marrow dyscrasias (Martin et al. 1984; Carlisle et al. 1968; Watson et al. 1980; Markel 1986).

RENAL. Analgesic nephropathy is a relatively common adverse effect of NSAIDs in human beings (Dunn et al. 1988). However, it does not occur as frequently in domestic animals, in part because the drugs are not used as chronically. In the kidney, vasodilatory prostaglandins are protective, ensuring that medullary vasodilation and urinary output continue during states of renal arterial vasoconstriction. The loss of this protective effect becomes important in patients with compromised renal function (Dunn et al. 1988). Patients who are predisposed to analgesic nephropathy include geriatric patients, patients suffering from cardiac, renal, or liver disease, patients in hypovolemic states such as shock and dehydration, and patients receiving nephrotoxic (i.e., aminoglycosides, amphotericin B, or other antiprostaglandin drugs) or nephroactive (e.g., diuretics) drugs.

Aspirin. Aspirin, the salicylic acid ester of acetic acid, is the prototype of the salicylate drugs, which include sodium salicylate and bismuth subsalicylate. In addition to inhibition of cyclooxygenase enzyme activity, salicylates inhibit the formation and release of kinins, stabilize lysosomes, and remove energy necessary for inflammation by uncoupling oxidative phosphorylation. Aspirin is available in a variety of different preparations, including plain, film coated, buffered, time-release, and enteric coated tablets. Capsules and suppositories are also available (Chastain 1987).

Oral bioavailability of aspirin products may vary due to differences in disintegration, drug formulation, stomach content, and gastric pH (Conlon 1988). Although buffered aspirin is more soluble than plain aspirin, a larger proportion is ionized and less rapidly absorbed. The amount absorbed of both products is the same (Chastain 1987). Aspirin undergoes rapid metabolism to the hydrolyzed active product, salicylic acid. This metabolite is not as potent an analgesic or anti-inflammatory drug because of the loss of the acetyl group, which is able to acetylate key proteins (Chastain 1987). Salicylic acid is between 50 and 70% bound to serum albumin among species (Davis and Westfall 1972). Hypoalbuminemia may result in transient increases in plasma drug concentrations, with associated adverse effects. Distribution of salicylic acid into extracellular fluid is rapid and includes synovial and peritoneal fluid, saliva, and milk. Salicylic acid is eliminated by hepatic conjugation with glucuronide and glycine and by renal excretion by glomerular filtration and tubular secretion (Davis and Westfall 1972; Short et al. 1990). Species differences in the biotransformation and elimination of salicylate are dramatic. Plasma half-lives among species studied range from 1.0 (ponies) to 37.6 (cats) hours (Davis and Westfall 1972). Excretion is more rapid in alkaline urine; therefore, elevation of urine pH can be used therapeutically to treat acute aspirin intoxication.

Aspirin is characterized by a wide safety margin in most species. The recommended therapeutic range in humans is 100-250 μg/mL (Beasley and Buck 1980). Toxicity occurs if serum salicylate concentrations exceed 300 μg/mL; however, analgesia and antipyresis require concentrations of only 20-50 μg/mL (Chastain 1987). Control of inflammation may require concentrations that exceed 50 μg/mL; rheumatoid arthritis in human beings requires concentrations of about 200 μg/mL. Although drug concentrations necessary to achieve an antithrombotic effect have not been established for aspirin in animals, small doses are recommended. Toxic (acute) overdose is usually manifested in depression, vomition, hyperthermia, electrolyte imbalances, convulsions, coma, and death. Acute toxicity includes serious acid-base disturbances due to uncoupling of oxidative phosphorylation. Hyperventilation due to direct stimulation of the respiratory center may be followed by depression at high doses. Bleeding disorders may also be evident (Larson 1963; Chastain 1987). Dose-dependent hepatotoxicity may also occur.

Oral salicylates such as sulfasalazine have been used to treat chronic inflammatory conditions of the bowel.

Although their mechanism of action is unclear, they cause splitting of the diazo bond by colonic bacteria to yield sulfapyridine and 5-aminosalicylic acid (5-ASA). The 5-ASA is considered to be the active moiety (M. G. Robinson 1989). Both the sulfapyridine and the sulfasalazine (up to 25%) are absorbed from the small intestine, but the majority of the 5-ASA remains in the colon. That absorbed (approximately 20% in humans) is rapidly acetylated and inactivated by either the colonic mucosa or liver. Newer products composed principally of 5-ASA are being investigated for the treatment of chronic inflammatory bowel diseases (M. G. Robinson 1989).

RUMINANTS. Although orally bioavailable (70%), salicylate absorption following administration of aspirin is slow in ruminants (absorption half-life of 3 hours) (Gingerich et al. 1975) while elimination is very rapid (elimination half-life of 32 minutes) (Gingerich et al. 1975). The drug is distributed to a volume of 0.24 L/kg. Thus, compared to other species, much larger oral doses (100 mg/kg) of aspirin must be given to achieve and maintain therapeutic concentrations (30 µg/mL) in the cow. Salicylate elimination in goats appears to be similar to that in cows. In both species, salicyluric acid is the sole metabolite detected in urine following oral or IV administration. In cows, a significantly larger portion of administered drug is eliminated as the glycine conjugate rather than as the parent drug. Glucuronide and sulfate conjugates are not detectable in goats or cows (Short et al. 1990). Aspirin has been used to treat acute mastitis in cows (Moore 1986).

HORSES. Aspirin is characterized by a very short half-life (less than 1 hour) in horses, in part because urinary pH is basic (Tobin 1979; Davis and Westfall 1972). Effective doses must be very large and given frequently (Pasargiklian and Bianco 1986). Prolonged bleeding time and decreased platelet stickiness have been reported in horses receiving a single oral dose (20 mg/kg) of aspirin. While it may prove clinically useful as an antithrombotic, aspirin may potentiate epistaxis in some training or exercising horses (Lee and Higgins 1985). Salicylate is a normal constituent of horse urine, thus making it difficult to detect therapeutic use (Tobin 1979).

DOGS. In dogs, aspirin is distributed to a volume ranging from 0.4 to 0.6 L/kg. Bioavailability probably varies with the manufacturer as well as preparation and ranges from 68 to 76% (Morton and Knottenbelt 1989). Bioavailability of plain, buffered, and enteric coated aspirin (25 mg/kg) does not appear to vary markedly, although plasma salicylate concentrations were most variable for the enteric coated preparation (Lipowitz et al. 1986). Following several doses of 25 mg/kg at 12-hour intervals, the biological half-life of aspirin is 7.5 hours in dogs. However, this time increased to a mean of 12.2 hours when the dosing interval was decreased to 8 hours (Konturek 1986). In another study, the elimination half-life of aspirin varied following IV injection of 36-60 mg/kg, ranging from 2.2 to 8.7 hours. The dose necessary to maintain clinical control of various lamenesses in dogs in one study ranged from 23 to 86 mg/kg twice daily, resulting in plasma drug concentrations ranging from 71 to 281 µg/mL (Jezyk 1983). Marked individual variability in drug elimination among animals suggests that therapeutic drug monitoring may be useful to ensure that therapeutic drug concentrations have been achieved and toxic concentrations (>300 µg/mL) are avoided (Morton and Knottenbelt 1989). One study in clinical patients found that plasma salicylate concentrations correlated with response (Morton and Knottenbelt 1989). When 25 mg/kg is administered at 8-hour intervals, therapeutic concentrations can be expected to be maintained throughout the dosing interval. GI side effects of aspirin in dogs appear to be dose and preparation related. Doses of 25 mg/kg of plain aspirin caused mucosal erosions in 50% of dogs which received plain aspirin, while there was minimal damage in animals receiving buffered and enteric coated preparations (Lipowitz et al. 1986).

CATS. As a phenol, aspirin is a compound that cats glucuronidate poorly (Larson 1963; Yeary and Swanson 1973). Plasma elimination half-life of aspirin in cats is 37.6 hours (Davis et al. 1973). The elimination of aspirin may be dose dependent: the half-life is 22-27 hours following doses of 5-12 mg/kg but 45 hours following administration of 25 mg/kg (Hochberg 1989). No clinical signs of toxicosis occurred in one study in which cats were treated with 25 mg/kg every 48 hours (Yeary and Swanson 1973).

Phenylbutazone. Phenylbutazone is a weakly acidic, lipophilic NSAID approved by the FDA for use in horses and dogs. Inhibition of the AA cascade occurs after conversion to reactive intermediate at prostaglandin H synthase and prostacyclin synthase. Prostanoid-dependent swelling, edema, erythema, and associated pain are reduced (Tobin et al. 1986). Phenylbutazone has been associated with some attenuation of some of the clinical signs associated with endotoxic shock in experimental models (Moore et al. 1986; Jarlov et al. 1992).

Bioavailability following intramuscular (IM) administration of phenylbutazone is less than that following oral administration in most species studied because of precipitation in the neutral pH of muscle (Williams 1988; De Backer et al. 1980; Tobin et al. 1986). Phenylbutazone is metabolized by the liver, with less than 2% of the drug being excreted as parent compound in the urine in some species. Its major metabolites are oxyphenylbutazone, which is less active than phenylbutazone, and inactive γ-hydroxyphenylbutazone (Tobin et al. 1986). Reported adverse reactions caused by phenylbutazone include bleeding dyscrasias, hepatopathy, and nephropathy (Tobin et al. 1986; Carlisle et al. 1968; Murray 1985; Tandy and Thorpe 1967).

RUMINANTS. Phenylbutazone is absorbed slowly following oral administration in ruminants (mean absorption half-life hours) and is only approximately 66% bioavailable, although this varies among animals (range, 41.9-95.5%). Peak plasma drug concentration following oral administration is 36 ± 1.9 µg/mL (De Backer et al. 1980). Bioavailability of phenylbutazone following IM administration in cows is 89% (Williams 1988; Eberhardson et al. 1979). Phenylbutazone is cleared more slowly in ruminants (1.24 ± 0.14 mL/kg/hr) than in horses and carnivores. Following a single IV administration of 5 mg/kg, phenylbutazone elimination half-life ranges from 30 to 82 hours (mean 55 ± 6) (De Backer et al. 1980). The apparent volume of distribution (total drug measured) is 0.09 L/kg. Phenylbutazone is 93% bound to plasma proteins in the cow, with unbound drug distributing to extracellular fluid (Williams 1988; Eberhardson et al. 1979). Following repeated administration, drug concentrations in milk are less than 1% of plasma drug concentrations, although total drug concentration increases with increased plasma drug concentration (Martin et al. 1984). Tissue binding of phenylbutazone is minimal.

Dosing once daily or every other day has been recommended in cows in order to achieve and maintain plasma drug concentrations within the therapeutic range recommended in human beings (60-90 µg/mL). Administration of a single loading dose can be used to achieve steady-state drug concentrations rapidly (De Backer et al. 1980). If an appropriate dosing regimen is used, peak plasma drug concentrations of 70 µg/mL can be expected (Williams 1988). In contrast to horses and dogs, elimination of phenylbutazone is not dose dependent in cows. In fact, steady-state plasma drug concentrations following repetitive doses (9 days) may be lower than predicted (Martin et al. 1984). Increased elimination probably reflects an increase in the fraction of unbound drug, with subsequent distribution into tissues (increased volume of distribution). The induction of hepatic drug-metabolizing enzymes is also likely to be responsible for the decrease (Martin et al. 1984). Phenylbutazone has been associated with decreased peripheral leukocyte count and serum bilirubin in cows (Martin et al. 1984). Phenylbutazone is recommended in cows for long-term analgesia and to control inflammation associated with arthritis, spondylitis, and laminitis (Williams 1988).

HORSES. Phenylbutazone is approved for use in horses as an oral tablet, paste, or gel or as an IV preparation. As in other species, bioavailability of phenylbutazone in horses is less following IM, compared to oral, administration. Bioavailability varies with drug preparation and product and feeding schedule (Tobin et al. 1986; Maitho et al. 1986). Among oral preparations, paste preparations are more bioavailable than powder (Tobin et al. 1986). Food reduces both peak plasma drug concentration and time to reach peak concentration (Tobin et al. 1986; Munsiff et al. 1988). Adsorption of the drug on hay in the GI tract contributes to decreased bioavailability and delayed absorption. In Welsh ponies, mean time to peak plasma drug concentration was 13 hours in animals fed before and after dosing compared to 1.3-5.8 hours in fasted animals (Maitho et al. 1986). Drug adsorbed to hay is subsequently released by fermentative processes in the colon and cecum and can cause a second peak in plasma drug concentration (Maitho et al. 1986). Ulceration of the cecum and colon may occur.

In horses, 96-99% of phenylbutazone in plasma is bound to plasma proteins (Tobin et al. 1986). Unbound drug is distributed to a volume of 0.25 L/kg. After IV administration, elimination half-life ranges from 3 to 10 hours and appears to be dose dependent, although apparently not within therapeutic concentrations (Tobin et al. 1986). Mean residence time is 1.7 hours (Mealey et al. 1997). Phenylbutazone is eliminated by hepatic metabolism, with less than 2% of the drug being excreted in the urine as the parent compound (Tobin et al. 1986). Clearance of phenylbutazone may be influenced by age, being twice as fast in 3-year-old ponies as in 8- to 10-year-old ponies (Tobin et al. 1986; Traub et al. 1983).

Although increasing urinary pH up to 8.5 increases the concentration of parent compound and selected metabolites (most notably oxyphenylbutazone) in the urine, plasma drug concentration and elimination half-life are not affected (Tobin et al. 1986). Approximately 77 elimination half-lives, or up to 26 days, must elapse in horses before 99% of a dose of phenylbutazone is eliminated. Although plasma concentrations apparently are not affected by urinary pH (little of the parent drug is eliminated in urine), the detection of the drug in urine can be enhanced by increasing urinary pH. As urinary pH increases, the amount of phenylbutazone and its metabolites in urine also increases. Depending on the sensitivity of the assay used for detection, the drug can still be detected in urine 24-96 hours following a dose. Detection time can be prolonged as much as threefold by altering urine pH (Tobin et al. 1986).

Phenylbutazone is characterized by a narrow therapeutic index in horses. The recommended therapeutic concentration of phenylbutazone in horses is 5-20 µg/mL, which is much lower than the concentration recommended in humans (50-150 µg/mL). This may reflect lower plasma protein binding and thus a greater proportion of active drug in horses (Lee and Higgins 1985). Alternatively, the drug may persist longer in exudative tissue than in plasma, which may explain prolonged efficacy despite subtherapeutic plasma drug concentrations (Tobin et al. 1986).

Drug accumulation predisposes animals with longer drug half-life to drug-induced toxicity. In general, toxicity seems most likely when manufacturer's recommended doses are exceeded. Although oral administration may increase the likelihood of GI toxicity, lesions also occur following IV administration (Tobin et al. 1986). In one study, horses receiving 8-14 mg/kg for 7-14 days showed evidence of toxicity, with 3 of 8 horses dying (Tobin et al. 1986). In a more recent study, phenylbutazone was compared with two other NSAIDs (flunixin meglumine and ketoprofen) and was cited as the most potentially toxic, causing GI ulceration in horses treated with 4.4 mg/kg phenylbutazone IV every 8 hours for 12 days (MacAllister et al. 1993). Ponies may be more susceptible to toxicity than horses (Tobin et al. 1986). Lesions predominate in the GI tract and range from shallow erosions to massive ulcerations of the cecum and colon. Renal papillary necrosis has also been reported. Initial signs of GI toxicity include inappetence, depression, and weight loss. With progression, classic signs of hypovolemic shock occur. Toxicity can occur weeks after drug administration has discontinued. Decreased serum total protein secondary to protein-losing enteropathy appears to be the most sensitive indicator of toxicity (Tobin et al. 1986). Some clinical evidence of renal disease may also occur (Tobin et al. 1986). One study also documented neutropenia, bone marrow suppression, and a toxic left shift in horses receiving large doses of phenylbutazone (Murray 1985). Necrotizing phlebitis occurs in portal veins following oral administration and in jugular veins following IV administration. Finally, one study provided evidence that phenylbutazone can produce a dose-dependent hepatotoxicity in horses (Tobin et al. 1986). Despite its relatively low safety margin, phenylbutazone remains the most widely used drug for the treatment of osteoarthritic and osteoporotic conditions. Large IV doses are necessary for treatment of equine colic (Lee and Higgins 1985).

DONKEYS. Phenylbutazone has been studied in donkeys (Mealey et al. 1997). Clearance in donkeys was greater (up to fivefold) than in horses, and the appearance of the metabolite oxyphenbutazone in serum was more rapid in donkeys than in horses, indicating that hepatic metabolism of phenylbutazone is more rapid in donkeys than in horses. Dosing intervals subsequently may need to be shorter in donkeys than in horses.

CATS. Although phenylbutazone has been used in cats, a high incidence of toxicity suggests extreme caution. In one study, 100% of cats treated with 44 mg/kg daily became anorectic at 2-3 days, with 80% mortality at 2-3 weeks. Toxicity occurs primarily in the bone marrow and is characterized by decreased erythroblastic activity and possible interference with myeloid maturation. GI toxicity, nephrotoxicity, and hepatotoxicity also occur (Carlisle et al. 1968).

DOGS. Despite FDA approval of the oral preparation for use in dogs, there is little information regarding the use of phenylbutazone. Dogs apparently are more tolerant of phenylbutazone than humans are. Toxicity manifested as hemorrhage, biliary stasis, and renal failure has been reported in one dog receiving close to recommended doses (Tandy and Thorpe 1967). For reasons not explained, the package insert notes a total maximum dose and requires the drug to be discontinued slowly.

Flunixin Meglumine. Flunixin meglumine is a nicotinic acid derivative approved for use in the horse. Described as a potent analgesic agent, it has been used to control pain that might otherwise respond only to opioids. It is particularly useful for visceral pain. In addition to its analgesic effects, flunixin meglumine has been studied and cited for its antiendotoxic effects in experimental models of septic shock in several species (Hardie et al. 1983; Moore et al. 1986; Templeton et al. 1987; Jarlov et al. 1992; Davidson et al. 1992).

RUMINANTS. Flunixin meglumine elimination half-life in cows is 8.12 hours, which is significantly longer than that reported in either horses (1.6-2.5 hours) (Semrad et al. 1985; Lee and Higgins 1985) or dogs (3.67 hours). Flunixin has been used to treat acute mastitis. However, a study comparing phenylbutazone and flunixin meglumine for treatment of acute mastitis found no differences among treatment groups (Dascanio et al. 1995). Flunixin megulmine acts as an antipyretic in cows given intramammary endotoxin (Anderson et al. 1986a,b; Jarlov et al. 1992). Although it is not approved for use in cows, flunixin has been recommended for treatment of acute bovine pulmonary emphysema in lieu of corticosteroids, which often cause abortion.

HORSES. Flunixin meglumine is FDA approved for use in horses following IV or oral paste or granule administration. Oral and IM absorption of flunixin meglumine is rapid in horses, with peak plasma drug concentrations occurring within 30 minutes. Onset of action occurs within 2 hours, with peak effect between 2 and 16 hours. Oral bioavailability is approximately 80% (Semrad et al. 1985; Lee and Higgins 1985). Elimination does not appear to be dose dependent in horses. Following IV administration of 0.25-1.1 mg/kg, the drug is distributed to a volume of 0.2-0.3 L/kg and is cleared at a rate of 0.76-0.98 mL/min/kg. Drug concentrations at the recommended dose peak at 1.6 μg/mL. Reported elimination half-life is short, ranging from 1.6 to 2.5 hours (Semrad et al. 1985; Lee and Higgins 1985). Renal excretion appears to contribute significantly to elimination of flunixin in horses (Lee and Higgins 1985).

Toxicity to flunixin meglumine appears to be rare in horses. Oral administration at 3 times the recommended dose for 10 days failed to induce signs of toxicity in one study (Lee and Higgins 1985). However, hypoproteinemia was reported in one Shetland pony. In a more recent study, GI ulceration/erosion occurred in 80% of horses receiving 1.1 mg/kg IV every 8 hours for 12 days (MacAllister et al. 1993). While more potent than phenylbutazone in an experimental model of equine pain, improved efficacy was not demonstrated. However, in another study, flunixin improved lameness in horses by 55% and swelling by 34% compared to 52% and 23%, respectively, for phenylbutazone (Tobin 1979). The wider margin of safety for flunixin compared to phenylbutazone may justify the former as the preferred musculoskeletal anti-inflammatory (Lee and Higgins 1985). The duration of response that characterizes flunixin may be an additional advantage. Onset of efficacy is rapid. Although peak response may take as long as 12 hours after the dose, duration of effect is up to 30 hours (Tobin 1979). Although the mode of action has not been documented, flunixin is specifically recommended as an analgesic in the treatment of colic. It also appears useful for the treatment (and especially pretreatment) of endotoxic shock (Lee and Higgins 1985). It prevents many of the adverse effects caused by administration of endotoxin, thromboxane A_2, and prostaglandin I_2 (Hardie et al. 1985).

DOGS. Following an IV dose of 1.1 mg/kg in healthy dogs, the elimination half-life of flunixin meglumine is 3.67 ± 1.2 hours and its clearance is 0.064 ± 0.01 L/hr/kg. Its volume of distribution is 0.18 ± 0.08 L/kg (Hardie et al. 1985). Flunixin meglumine appears to modulate response to septic shock in dogs (Hardie et al. 1983; Davidson et al. 1992; McKellar et al. 1989). In dogs, a dose of 1.1 mg/kg flunixin meglumine blocks prostaglandin I_2 production, and 2.2 mg/kg improves survival times of septic dogs (Hardie et al. 1985). The pharmacokinetics of flunixin in septic dogs does not appear to differ from that of control dogs (Hardie et al. 1985). Toxicity, most commonly manifested as GI upset, limits use of this drug in dogs to 2-3 days. Doses at 3-5 times that recommended caused GI disturbances in one study. Thomas et al. (1997) have documented that phenylbutazone can be detected in the urine of greyhounds following topical administration in a commercially available cream.

Carprofen. Carprofen is approved for use in dogs in the US and both dogs and cats in selected countries outside the US. The mechanism of action of this NSAID appears to involve specific inhibition of COX 2. The physiologic or protective actions of prostaglandins appear to be minimally inhibited with no loss of anti-inflammatory efficacy. Other proposed mechanisms of carprofen include inhibition of phospholipase and impaired release of AA. Like other NSAIDs, carprofen is highly protein bound. Carprofen is metabolized by the liver and in dogs is characterized by a half-life of 10 hours. Carprofen is equally or more effective than most other NSAIDs studied in the control of inflammation and presumably the pain associated with inflammation of osteoarthritis. Its safety is supported by the lack of GI side effects in dogs dosed with more than 10 times the dose necessary to achieve therapeutic concentrations. A clinical trial of 70 dogs found that 6 of 36 carprofen-treated dogs developed clinical signs indicative of GI upset; 3 placebo dogs also developed GI signs (Vasseur et al. 1995).

Carprofen is approved for use in the treatment of osteoarthritis in dogs (Vasseur et al. 1995). Effects of carpofen on cartilage synthesis appear to be concentration dependent. At lower concentrations (<10 μg/mL), in vitro studies reveal no inhibitory effects of carprofen on cartilage synthesis and an increase in polysulfated glycosaminoglycan (GAG) synthesis. However, at 10 μg/mL, carprofen inhibited GAG and protein synthesis (Benton et al. 1997). Concentrations that occur in dog synovial fluid following administration of a therapeutic dose of carprofen have not been determined. Thus, the most likely effect of carprofen on cartilage is not apparent.

Since carprofen's release in 1999, GI upset typical of NSAIDs has been reported in a number of dogs. Although the drug still is among the safest of the NSAIDs used in dogs, precautions must still be discussed with owners when contemplating the use of this drug in dogs. Hepatotoxicity reflecting acute hepatic necrosis has been reported as an unexpected adverse effect of carprofen in dogs (MacPhail et al. 1998). Although death has occurred in some animals, discontinuation of the drug can lead to complete resolution of biochemical abnormalities. Animals with liver disease in one study also had evidence of renal tubular disease (MacPhail et al. 1998). In addition, acute hepatopathy (perhaps idiosyncratic) has been described in a number of dogs receiving the drug. Older dogs appear to be predisposed, as might animals receiving drugs that induce drug-metabolizing enzymes (e.g., phenobarbital).

Carprofen has been studied in cats and is characterized by a small volume of distribution but long half-life. Cats, like humans, do not appear to benefit from the same level of safety of carprofen as do dogs, and carprofen should be used only short term in cats.

Carprofen is such an effective analgesic that it shows potential for control of postoperative pain (Lascelles et al. 1995). Carprofen appears to be an effective postoperative analgesic in cats (4 mg/kg SC) (Balmer et al. 1998) and dogs (Welsh et al. 1997) when administered short term preoperatively.

A number of studies with carprofen have been performed in large animals. A tissue cage model of inflammation in calves demonstrated that carprofen was effective for control of inflammation (Lees et al. 1996).

Naproxen

HORSES. Naproxen is FDA approved for use in horses as an oral granular preparation. As a granule, naproxen is approximately 50% bioavailable in horses (Pasargiklian and Bianco 1986). Peak plasma drug concentrations of 25 μg/mL occur 2-3 hours following administration of 10 mg/kg. Elimination half-life from plasma is 46 hours (Tobin 1979). Easily detected in urine, the approximate half-life of naproxen and its major metabolite is 6 hours in urine (Tobin 1979). The drug appears to have a relatively wide margin of safety in horses. Toxicity does not occur following oral administration of 3 times the recommended dose for 6 weeks (Lee and Higgins 1985). Naproxen was proved more efficacious than either phenylbutazone or placebo for the treatment of experimentally induced myositis (Lee and Higgins 1985; Tobin 1979). The drug appears to be particularly efficacious for the treatment of soft tissue inflammation.

DOGS. In dogs, naproxen is rapidly absorbed following oral administration, with maximal plasma drug concentrations occurring at 0.5-3 hours. Bioavailability ranges from 68 to 100%. Naproxen is 99% bound to serum proteins in dogs, resulting in a volume of distribution of 0.13 L/kg. Total body clearance is 0.021 mg/kg/min. Notably, compared to 12-15 hours in humans and 5 hours in horses, the elimination half-life of naproxen following IV administration in dogs ranges from 45 to 92 hours (Frey and Rieh 1981). Extensive enterohepatic circulation has been credited as the cause for prolonged elimination in dogs. Because of its long half-life, naproxen need only be given once daily in dogs, and a loading dose is indicated. The dog has been described as the animal most sensitive to naproxen (Frey and Rieh 1981). GI toxicity occurs at doses of 5 mg/kg daily. Bleeding and GI toxicities have been reported. Toxicity appears most likely when plasma drug concentrations exceed 50 µg/mL. Bleeding dyscrasias have also been reported in dogs receiving large doses of naproxen (Frey and Rieh 1981; Roudebush and Morse 1981; Gfeller and Sandors 1991).

Ibuprofen. Ibuprofen is a propionic acid derivative which has been used in dogs. Ibuprofen is less effective as an analgesic compared to aspirin, perhaps due to differences in binding of cyclooxygenase (reversible for ibuprofen and irreversible for aspirin). Ibuprofen is a popular drug in human medicine because its use is associated with a low incidence of GI side effects. However, GI erosions consistently occur in dogs receiving therapeutic doses for 2-6 weeks.

Ibuprofen is rapidly absorbed following oral administration in dogs, with peak plasma drug concentrations occurring between 0.5 and 3 hours and bioavailability ranging from 60 to 80% (mean, 77%). Volume of distribution is 0.164 L/kg. Plasma elimination half-life following oral or IV administration is 4.6 ± 0.8 hours, and clearance is 0.49 mL/min/kg. Pharmacokinetics are similar at doses of 5 and 10 mg/kg (Scherkl and Frey 1987). However, a dose of 12-15 mg/kg is necessary to achieve therapeutic concentrations as reported in humans (Scherkl and Frey 1987). Following repetitive administration of this dose, plasma drug concentrations decrease despite no change in drug half-life (Scherkl and Frey 1987).

Vomition commonly occurs following 2-6 days following ibuprofen therapy in dogs with either the gelatin or enteric coated capsules (Scherkl and Frey 1987). GI inflammation and gastric erosions have been documented following administration of 8 mg/kg daily despite the lack of clinical signs of toxicity (Scherkl and Frey 1987). Because gastric lesions occur at doses less than those necessary to achieve therapeutic concentrations, ibuprofen is not recommended for use in dogs.

Meclofenamic Acid

RUMINANTS. Meclofenamate is an anthranilic NSAID available as a palatable granular preparation intended to be mixed with food. Among the NSAIDs, it is noted for its slow onset of action. Sodium meclofenamate, which is more water soluble than meclofenamic acid, has been studied in calves. Following oral administration of 2 mg/kg, peak plasma concentrations of 0.54-1.43 µg/mL occurred at 0.5 hours. Decline in plasma drug concentrations is followed by a second (and, in some animals, higher) peak at 4-6 hours. The second peak likely reflects enterohepatic circulation. Plasma half-life after the second peak is 4 hours. A similar pattern occurs following IV injection, although peak concentrations are approximately 10 times higher. Slower absorption in calves following intraruminal administration suggests that oral administration is characterized by passage directly into the abomasum (Aitken and Sanford 1975).

HORSES. Little information regarding the safety and clinical efficacy is available for the use of meclofenamic acid in horses. There appears to be a narrow therapeutic window, and strict adherence to the manufacturer's recommended dosing regimen is indicated (Lee and Higgins 1985). Decreased plasma protein concentration has been documented following 10 days of 2.2 mg/kg in ponies, although no adverse effects were documented following over 2 months of administration in stallions and mares (Lee and Higgins 1985). Symptoms of toxicosis, when they occur, are similar to those induced by phenylbutazone. Despite a plasma elimination half-life of 2.5 hours, once-a-day dosing is sufficient for the treatment of acute and chronic inflammatory conditions in horses. Although peak plasma drug concentrations of 1 µg/mL are attained within 0.5-4 hours following oral administration of meclofenamic acid, onset of action is slow, requiring 36-96 hours. Thus, clinical efficacy requires 2-4 days of dosing (Lee and Higgins 1985). Less than 15% of the drug is eliminated in the urine, suggesting that elimination in the bile may be important (Tobin 1979). However, the drug is detectable in urine for up to 96 hours (Tobin 1979). Clinical experience suggests that this drug is particularly effective for the treatment of acute and chronic laminitis and skeletal conditions (Lee and Higgins 1985). One clinical trial reported a 78% response rate in cases with navicular disease, 76% in cases with laminitis, and 61% in cases with osteoarthritis (Tobin 1979).

Ketoprofen. Ketoprofen is a propionic acid NSAID approved for use in humans and horses. Because ketoprofen is a strong inhibitor of cyclooxygenase, it has powerful anti-inflammatory, analgesic, and antipyretic properties. In human patients suffering from rheumatoid arthritis, ketoprofen has been shown to be as efficacious as aspirin, naproxen, indomethacin, ibuprofen, diclofenac, and piroxicam (Avouac and Teule 1988).

Similar results occurred in cancer patients receiving either aspirin-codeine combinations or ketoprofen (Stambough and Drew 1988). In control of postoperative pain, ketoprofen has proven as effective as pentazocine and meperidine (Avouac and Teule 1988) and as effective as but longer lasting than acetaminophen-codeine combinations (Turek and Baird 1988). Although not firmly established, the efficacy of ketoprofen has also been attributed to its ability to inhibit some lipoxygenases and thus formation of leukotrienes (Williams and Upton 1988). Ketoprofen is also a powerful inhibitor of bradykinin (Williams and Upton 1988).

Ketoprofen is rapidly absorbed from the GI tract. Although peak plasma drug concentrations are lower in dogs following oral, compared to IV, administration, mean residence times (4.59 vs. 3.81 hours, respectively) were very similar (Schmitt and Guentert 1990). Although peak drug concentrations may be decreased, bioavailability does not seem to be impaired by food. As with other NSAIDs, ketoprofen is approximately 99% protein bound, principally to albumin. Elimination is via metabolism to inactive metabolites by the liver and excretion as the glucuronide conjugate in the urine (Williams and Upton 1988). Drug interactions involving ketoprofen have not yet been documented (Cailleteau 1988).

About 30% of the human patients studied reported adverse reactions to ketoprofen (Beaver 1988; Stambough and Drew 1988). The most frequent complaint was upper GI upset. Other commonly encountered side effects were CNS reactions, such as headaches and dizziness, and nephritis. Side effects were severe enough in one report that therapy was discontinued in approximately 13% of patients (Cailleteau 1988). In a comparison of phenylbutazone, flunixin meglumine, and ketoprofen in horses, ketoprofen was determined to be the least potentially toxic of the drugs, although all three drugs were administered at doses that exceeded those recommended on the drug labels (MacAllister et al. 1993). Anorexia, evident with the other two drugs, did not occur in horses receiving ketoprofen. Erosions or ulcers of the tongue and of both glandular and nonglandular portions of the stomach occurred in all horses receiving ketoprofen. Alternative preparations, such as rectal suppositories, have been formulated for ketoprofen to reduce the incidence of GI toxicity (Schmitt and Guentert 1990). Ketoprofen is approved for IV use in horses and is currently being considered for approval for use in dogs.

Piroxicam. Piroxicam is an oxicam NSAID approved for use in humans that has been used to treat osteoarthritis in dogs. More recently, it has received attention for its ability to reduce the size of tumors (transitional cell tumors and others) in dogs (Knapp et al. 1992). This latter effect may result from immunomodulation, but more likely it results from decreased inflammation at the tumor site. Piroxicam is a potent anti-inflammatory in musculoskeletal conditions. Oral absorption is rapid, with 100% bioavailability (Galbraith and McKellar 1991). Distributed to a volume of 0.34 L/kg, its half-life of 40-45 hours in dogs is similar to that in humans. Although the LD_{50} of piroxicam is greater than 700 mg/kg in dogs, gastric lesions and renal papillary necrosis have occurred in dogs receiving 1 mg/kg daily (Galbraith and McKellar 1991; Knapp et al. 1992). However, little evidence of toxicity (GI or bleeding) was noted after administration of 0.3 mg/kg every other day (Galbraith and McKellar 1991; Knapp et al. 1992). Extrapolation from use in humans to dogs should be done cautiously because of possible differences in volume of distribution, therapeutic concentrations, or safety margin.

Indomethacin. Indomethacin is a NSAID that was developed specifically to abate the inflammatory response to the indolic hormones serotonin and tryptophan (Boynton et al. 1988). As a powerful anti-inflammatory, it became a standard for comparison. In humans, toxicities are not serious but CNS side effects are undesirable (Boynton et al. 1988). The incidence of GI hemorrhage following administration of indomethacin at doses of 2-5 mg/kg precludes its clinical utility in dogs. In one study, all dogs developed melena within 1 week of receiving 2 mg/kg daily; 60% of these animals had gastric ulcers (Ewing 1972).

Acetaminophen. Acetaminophen (paracetamol) is a coal tar analgesic used in human medicine as an effective alternative to aspirin for control of fever and pain. It has been assumed to have poor anti-inflammatory activity, although this view has recently become more controversial (Mburu et al. 1988). Although often classified as a NSAID, its mechanism does not involve inhibition of cyclooxygenase. Rather, acetaminophen interferes with the endoperoxide intermediates of AA conversion. Its relatively weak anti-inflammatory activity has been attributed to the high concentration of peroxides occurring in peripheral inflammatory lesions. Acetaminophen may be more effective against inflammatory conditions in the CNS.

The major disadvantage to the use of acetaminophen in veterinary patients is the narrow safety margin that characterizes its use in cats. The drug is normally conjugated with glucuronide and to a lesser degree with sulfate. Drug that is not conjugated is metabolized by phase I microsomal enzymes to cytotoxic oxidative metabolites. Intracellular glutathione normally scavenges the metabolites, but in the case of overdose or glucuronide deficiency (as with the cat), the formation of toxic metabolites overwhelms the glutathione scavenging system. In cats, methemoglobinemia is the most common indication of toxicity, although centrolobular hepatic necrosis may also occur.

Treatment of acetaminophen toxicity includes administration of antioxidants, including *N*-acetylcysteine, a precursor of glutathione, and ascorbic acid (vitamin C) (St. Omer and McKnight 1980; Cullison 1984; Savides et al. 1985). The administration of cimetidine, a microsomal enzyme inhibitor, will reduce the formation of toxic metabolites and will result in clinical improvement if given within 48 hours of acetaminophen administration (Jackson 1982; Ruffalo and Thompson 1982).

Acetaminophen may be as effective as aspirin for the control of postoperative pain and inflammation in dogs. At daily doses of 0.5 g every 8 hours (average weight 18 kg) acetaminophen causes no clinical signs of adverse drug effects (Mburu et al. 1988). However, other studies have shown that adverse reactions (depression, methemoglobinemia, and vomiting) can occur at higher (0.1 g/kg) doses (Hjelle and Grauer 1986; Savides and Oehme 1983). In another study, 0.9 g/kg IV caused fulminant hepatic failure in dogs (Francavilla et al. 1989).

TREATMENT OF OSTEOARTHRITIS. Recent advances in the pathophysiology of degenerative joint disease (DJD; osteoarthritis) have provided new therapeutic foci. The progressive degeneration of articular cartilage which characterizes this disease reflects an imbalance between cartilage matrix synthesis and breakdown. The role of inflammation in the pathophysiology of DJD is controversial. Mechanisms of therapeutic drugs designed to retard DJD deterioration include inhibition of synovial cell-derived cytokines and chondrocyte-derived degradative enzymes, inactivation of superoxide radicals, stimulation of matrix synthesis, and enhancement of synovial fluid lubrication (Pinals 1992; Altman et al. 1989). The impact of NSAID therapy is apparently either harmful or beneficial, depending on the drug. The primary effect of NSAIDs on the disease is probably analgesic rather than anti-inflammatory (Pinals 1992). A number of other anti-inflammatory drugs have been studied for their efficacy in the treatment of DJD.

Orgotein. Orgotein, or superoxide dismutase, is a copper- and zinc-containing metalloprotein that can be an effective anti-inflammatory. As an endogenous intracellular enzyme, it occurs at very low concentrations in many tissues, but particularly the liver, where it scavenges tissue-damaging oxygen radicals. Phagocytic cells (neutrophils and macrophages) generate large amounts of cytotoxic superoxides during the inflammatory process. The half-life of phagocytic cells is prolonged in the presence of superoxide dismutase (Salin and McCord 1975; Tobin 1979). Approximately 2-6 weeks of therapy may be required before therapeutic benefits are realized. Orgotein is characterized by a wide margin of safety, with the lethal dose being over 40,000 times the therapeutic dose. As a large molecule, efficacy via any route other than intra-articular is questionable due to poor absorption. However, the drug has also been administered clinically both IM and orally (Breshears et al. 1974). Molecular size limits renal elimination of the drug. Following intra-articular administration, orgotein was 94% effective in horses lame for less than 2 months, compared to only 49% in horses lame for greater than 2 months prior to treatment (Ahlengard et al. 1978).

Polysulfated Glycosaminoglycan. Recent efforts in the treatment of osteoarthritis have focused on drugs that favorably shift the balance between degradation and synthesis of cartilage matrix.

CHEMISTRY. Polysulfated glycosaminoglycan (PSGAG; Adequan; Arteparon) is a polymeric chain of repeating units of hexosamine and hexuronic acid. Considered a hypersulfated compound, approximately 14% of the drug is sulfated. It is extracted and purified from bovine tracheal tissues (White 1988). Normal cartilage matrix is composed of proteoglycan complexes, collagen, and water. Side chains of glycosaminoglycans (keratin and chondroitin) are attached to the core protein of the proteoglycan molecule by a strand of hyaluronate. Water trapped in between these complexes accounts for the resiliency of cartilage. PSGAG closely mimics the proteoglycan complexes found in normal articular cartilage.

PHARMACOLOGIC EFFECT. PSGAG appears to be chondroprotective in both in vitro and in vivo models. In vivo models have included chemically and traumatically induced cartilage damage (Francis et al. 1989; Hannan et al. 1987). Cartilage degradation is retarded in the presence of PSGAG. Although the mechanisms of these protective actions are not known, chondrocyte proliferation and matrix biosynthesis appear to be important (Hannan et al. 1987). Collagen, proteoglycan, and hyaluronic acid synthesis increases (Nethery et al. 1992). In addition, proteolytic enzymes such as collagenase (Halverson et al. 1987; Nethery et al. 1992), leukocyte elastase (Rao et al. 1990), proteases (White 1988; Montefiori et al. 1990), and lysosomes are inhibited (Montefiori et al. 1990), although these actions are likely to be complex (Nethery et al. 1992). Complement activity is also inhibited; the degree of inhibition appears to be related to the sulfate load of the chondroitin sulfate matrix (Biffoni and Paroli 1991). PSGAG appears to have no effect on the ability of interleukin-1 to stimulate metalloproteinase activity in cartilage (Arsenis and McDonnell 1989).

DISPOSITION AND SAFETY. Deposition of PSGAG in normal and damaged cartilage has been demonstrated after parenteral administration. Drug that is not retained in cartilage is excreted primarily by the kidneys with minimal degradation of the parent compound. Toxicity is limited in all species studied. In dogs, the LD_{50} is 1000 mg/kg. In horses, the reported rate of adverse reaction (0.02%) has been much lower than the expected reaction rate of 1.8% (White 1988). Heparin and PSGAG are chemically similar. Adverse effects related to the anticoagulant activity of PSGAG have been suggested but not reported. However, heparin-associated thrombocytopenia, a decrease in circulating platelets presumably immunologically mediated, has been reported in human patients receiving PSGAG (Greinacher et al. 1992).

CLINICAL USE. PSGAG (Adequan) is approved for use in the horse with intra-articular administration, but it has been widely used as an antiarthritic in both horses (White 1988) and dogs with IM administration. However, the disposition of PSGAG following IM administration has not been reported, and the current label is for intra-articular use only. The drug is currently being considered for approval for use in dogs.

Hyaluronic Acid. Hyaluronic acid is an essential component of synovial fluid, where it is chemically linked to proteoglycans in articular cartilage. Its mode of action is not certain, but it is assumed to function as a lubricant (Pinals 1992). Following intra-articular injection, the drug persists in joints for several days. High molecular weight hyaluronic acid inhibits phagocytosis and lymphocyte migration and synovial permeability. Prior treatment with glucocorticosteroids or bony changes limits response (Tobin 1979). Intra-articular injection of the drug has met with variable success in horses (Asheim and Lindblad 1976) and dogs.

Dimethylsulfoxide. Dimethylsulfoxide (DMSO) is a hygroscopic solvent derived from wood pulp. It is used as a drug vehicle because of its ability to dissolve drugs not soluble in water. Because of its chemical characteristics, DMSO is variably categorized (Brayton 1986; Alsup 1984).

PHARMACOLOGIC EFFECT. As an anti-inflammatory, DMSO is a scavenger of free oxygen radicals. Anti-inflammatory effects have been reported in acute musculoskeletal injuries, CNS inflammatory processes, and CNS trauma (Wong and Reinertson 1984; Spitzer 1991). Chronic diseases are less responsive to the anti-inflammatory effects of DMSO. Immunomodulation may be responsible for some of its anti-inflammatory effects. The drug inhibits white blood cell migration, antibody production, and fibroblast proliferation. The analgesic effects of DMSO have been compared to those of narcotic analgesics. Analgesia has been reported in a variety of situations, including acute and chronic musculoskeletal disorders and postoperative pain. Although nerve blockade has been reported in vitro, it is unlikely that sufficient concentrations occur in vivo to effect this response. Opiate receptors also do not seem to be involved. Other pharmacologic effects include inhibition or stimulation of enzymes, vasodilation (due to histamine release), inhibition of platelet aggregation, radioprotection, cryopreservation, and antimicrobial (antifungal, bacterial, and viral) activity (Wong and Reinertson 1984; Brayton 1986). Diuresis occurs after topical, oral, or parenteral administration, probably due to its hygroscopic nature and ability to pull water into the tubules. DMSO (3.0 mg/kg in 20% solution) has been reported to protect the kidneys against ischemic insults to the kidneys. A sedative effect has also been reported in several species (Brayton 1986).

DISPOSITION. Following oral administration of 1 g/kg, peak plasma drug concentrations occur within 4-6 hours, and detectable levels persist in the plasma for 400 hours (Wong and Reinertson 1984). Within 20 minutes of topical application, DMSO penetrates the skin and can be detected in all organs of the body (Brayton 1986). Peak plasma drug concentrations occur 2 hours after topical administration (Wong and Reinertson 1984). Its ability to penetrate the skin is believed to reflect exchange and interchange with water in biological membranes. Mucous membranes, lipid membranes of cells and organelles, and the blood-brain barrier are similarly penetrated without irreversible membrane damage (Brayton 1986). Tooth enamel and keratin appear to be the only tissues that DMSO does not penetrate (Wong and Reinertson 1984). DMSO facilitates penetration of other substances across membranes; cutaneous penetration of steroids, sulfadiazine, phenylbutazone, and other drugs has been documented (Brayton 1986; Alsup 1984). Enhanced absorption of therapeutic drugs can lead to toxicity, particularly for anesthetic, cardioactive, and anticholinesterase drugs.

DMSO is partially metabolized by hepatic microsomal enzymes (Brayton 1986), but the primary route of elimination appears to be in the urine as the parent compound (Wong and Reinertson 1984). Although a significant amount of DMSO may be eliminated in the bile, most undergoes enterohepatic circulation (Wong and Reinertson 1984). Hepatic metabolism of a small amount of DMSO (3-6%) to dimethylsulfide and subsequent pulmonary excretion of this metabolite account for the halitosis which occurs regardless of the route of administration (Wong and Reinertson 1984).

ADVERSE EFFECTS. DMSO has a large safety margin. Signs associated with near lethal IV doses include sedation, diuresis, intravascular hemolysis, and hematuria. Death is preceded by hypotension, prostration, convulsions, and respiratory distress characterized by dyspnea, tachypnea, and pulmonary edema. Phlebitis and venous obstruction may occur with IV dosing. Intravascular hemolysis is concentration and rate dependent, and concentrations less than 10% are recommended for IV administration. Susceptibility to hemolysis will vary with species due to differences in erythrocyte fragility. Nephrotoxicity has been reported in some species. Necropsy lesions include hematuria, hemoglobinuria, and mild tubular nephrosis. Chronic toxicity studies in laboratory animals have documented hepatotoxicity, which may be due to its metabolism by the liver to toxic metabolites. DMSO may also enhance hepatotoxicity of other drugs as well as hepatic binding and metabolism of selected carcinogens. Teratogenicity has also been reported in some animals. Ocular toxicity occurs with daily, long-term administration and develops more rapidly in young animals. Lesions occur in the lens and appear as altered relucency, making animals myopic. Histologic abnormalities are not apparent. Such a response was reported in one horse which received 0.6 g/kg daily, cutaneously, for 2 months. Skin reactions are common, particularly at higher concentrations, and are manifested as erythema, warmth, and local vasodilation. A wheal-and-flare response and pruritus may also occur. Repeated application may result in drying and desquamation of the epithelium (Brayton 1986).

CLINICAL USE. DMSO is FDA approved for topical application in horses suffering from acute swelling due to trauma and in the treatment of acute or chronic otitis. In humans, DMSO is approved for interstitial cystitis. Although not approved, DMSO has been recommended for therapy in male cats suffering from urinary tract obstruction (Brayton 1986). Other reported applications of DMSO include facilitation of healing of skin wounds (including habronemiasis of horses), acral lick dermatitis in dogs, postoperative fibrous adhesions, acute CNS trauma, inflammation, edema or ischemia, intervertebral disk disease, fibrocartilaginous embolization, ischemic insults, postoperative myositis, rheumatic diseases, myasthenia gravis, and chronic musculoskeletal conditions. DMSO also inhibits alcohol dehydrogenase and thus has been recommended for the treatment of ethylene glycol toxicity (Brayton 1986).

An understanding of the clinical pharmacodynamics of cardiac drugs is essential to veterinary medicine for two important reasons. First, the indispensable pumping function of the heart in maintaining circulation rules that life-threatening events are often present when pharmacologic agents are needed to control the heart. Second, cardiac dysfunctional states that are amenable to drug therapy are common in some species. This chapter considers the more important drugs used in therapeutic management of cardiac disorders, with focus on basic aspects of cardiac function, digitalis and related cardiac glycosides, bipyridine inotropic drugs, and vasodilator agents. Antiarrhythmic drugs are covered in Chap. 24. Other classes of drugs that elicit prominent cardiac responses (e.g., adrenergic and cholinergic agents) are addressed specifically in appropriate chapters.

BASIC ASPECTS OF CARDIAC FUNCTION.

The heart, blood, lungs, and blood vessels compose an integrated physiologic system that supplies oxygen and other nutrients to tissues and removes carbon dioxide and other waste products. Efficiency of the heart muscle and of tissue functions throughout the body is critically dependent on adequate supplies of oxygenated blood. This necessitates a series of sensitive and dynamic control mechanisms to ensure that cardiac output is sufficient to supply cellular demands.

The three primary pathways by which the heart can increase its cardiac output in response to body needs for increased blood flow are: an intrinsic response of the muscle to changes in muscle length, changes in heart rate, and adjustments in contractility. These physiologic control systems are of considerable importance to pharmacology because the net response of the heart to drugs is controlled by these mechanisms.

Intrinsic Regulation. Contractile response of cardiac muscle to a change in its own length is the primary mechanism whereby the heart adjusts its pumping activity under normal physiologic conditions (Fozzard 1976). In the whole heart, the volume of blood returning to cardiac chambers from the veins controls resting muscle length. Individual myofibers are stretched as the intraventricular diastolic volume expands to accommodate increased venous return. The stretched muscle responds in turn with enhanced contractile strength, thereby pumping the increased volume of blood into the arterial circuits.

The fundamental capability of the heart to autoregulate its pumping capacity in response to end-diastolic filling, and thus muscle length, is referred to as the Frank-Starling law of the heart (Frank 1895; Starling 1918). This length-force relationship is the result of stretching the sarcomere to a more optimal interdigitating arrangement of the actin and myosin elements. The relationship between end-diastolic filling and cardiac output under basal conditions and under dominance by the sympathetic and parasympathetic nervous systems is shown in Fig. 23.1.

Regulation by the Nervous System. The autonomic nervous system regulates the heart mainly by adjusting cardiac rate and myocardial contractility. Details concerning cardiac effects and mechanisms of action of the sympathetic neurotransmitter norepinephrine and the parasympathetic neurotransmitter acetylcholine (ACh) are presented in Chaps. 5-7.

Sympathetic stimulation of cardiac muscle markedly increases the force of contraction irrespective of end-diastolic muscle length. A change in contractile strength that is independent of muscle length is referred to as a change in contractility (inotropy). In the presence of inotropic stimulation by the sympathetic system, cardiac output at each level of ventricular filling is enhanced considerably over the basal state (Fig. 23.1). Conversely, parasympathetic nerves exert their primary influences on cardiac output, not by changing the inotropic state, but by adjusting heart rate. Vagal discharge produces bradycardia; with fewer heartbeats per unit of time, less blood can be pumped and cardiac output is decreased at all levels of venous return (Fig. 23.1). In contrast, sympathetic stimulation produces marked tachycardia and, within physiologic limits, cardiac output is increased proportionately. Coronary blood flow increases in response to sympathetic stimulation, but much of this change is secondary to increased metabolic-oxygen demands of the heart muscle.

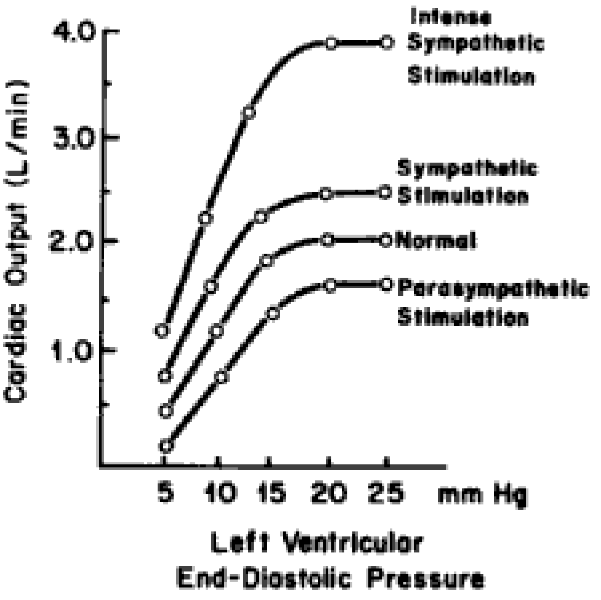

FIG. 23.1—Frank-Starling law of the heart. As end-diastolic ventricular volume increases, the myofiber is stretched, enhancing the contractile state of the muscle; cardiac output is thus increased. The cardiac output curve can be influenced by different degrees of sympathetic and parasympathetic stimulation.

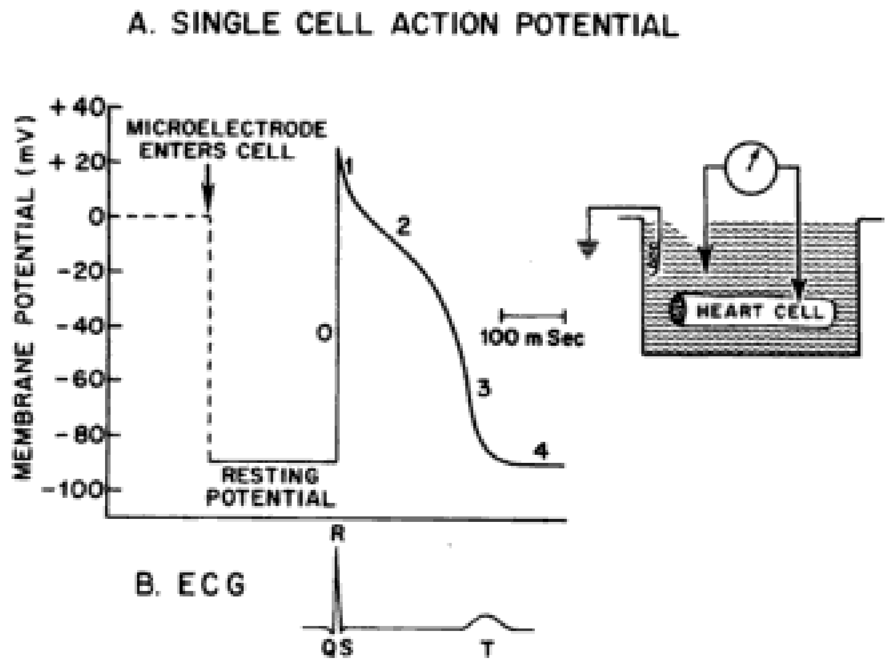
Myocardial oxygen demand varies directly with three main factors: heart rate, myocardial wall tension, and inotropic state. Myocardial wall tension is directly proportional to ventricular radius (cardiac size) and intraventricular pressure, i.e., the law of Laplace. Primary determinants of ventricular wall tension are preload (i.e., end-diastolic volume and stretch) and afterload (aortic blood pressure). By reducing preload or afterload, certain drugs can elicit marked reduction in cardiac work without direct inotropic action on a heart muscle cell.

Cellular Concepts. The basic contractile unit of a heart muscle cell is the sarcomere, composed of the interdigitating protein filaments actin (thin filament) and myosin (thick filament). Activation of the filaments is regulated by a protein assembly unit composed of tropomyosin and troponin and associated with actin molecules. Availability of ionized calcium (Ca^{++}) in the vicinity of troponin is the obligate modulator of the relaxation-contraction cycle.



A. SINGLE CELL ACTION POTENTIAL

B. ECG

FIG. 23.2—(A) Cardiac action potential recorded from a single myocardial cell. The following phases are listed: 0 = rapid depolarization upstroke, 1 = rapid repolarization, 2 = plateau, 3 = delayed repolarization, and 4 = diastolic potential. The plateau phase is due partly to a slow current representing entry of Ca^{++} into the cell during excitation-contraction coupling. (B) Electrocardiogram (ECG) of the ventricle correlating with the respective phases above (Parker and Adams 1977).

Binding of Ca^{++} to a high-affinity subunit of the troponin molecule evokes the movement of tropomyosin from its diastolic blocking position on actin. Cross-linkages or "cross-bridges" are formed between projections of the myosin molecules and exposed sites on actin. As cross-bridges are formed, the thick and thin filaments move laterally in relation to one another, and contraction occurs. Calcium delivery to the myofibrils is initiated by bioelectric events at the cell membrane, represented by the cardiac action potential.

CARDIAC ACTION POTENTIAL. The diastolic (resting) membrane potential in heart cells is maintained at about –90 mV (negative inside in relation to outside the cell), primarily as a result of uneven distribution of potassium ions (K^+) inside, $(K^+)_i$, and outside, $(K^+)_o$, the cell. The cell membrane (sarcolemma) is selectively permeable to K^+ during diastole compared to other electrolytes like sodium ions (Na^+), and yet an active ion transport system maintains high $(K^+)_i$ relative to $(K^+)_o$, and low $(Na^+)_i$ relative to $(Na^+)_o$. The high permeability of the cell membrane to K^+ allows a net outward leakage of this positively charged ion. This outward current, in combination with impermeate organic anions within the cell, yields a negatively charged intracellular space. When the cell is stimulated, selective permeability characteristics of the sarcolemma to K^+ are lost. The resulting change in ion distribution can be recorded as an action potential by using a microelectrode capable of penetrating a single myocardial cell (Fozzard and Gibbons 1973).

The action potential of a ventricular muscle cell contains two basic components, depolarization and repolarization, which can be differentiated into five phases (Fig. 23.2). The rapid upstroke, phase 0, is similar to the depolarization spike seen in skeletal muscle and neurons; it represents a rapid flux of Na^+ into the cell. As the permeability characteristics of the cell membrane are reestablished, rapid (phase 1) and delayed (phase 3) repolarization occur, restoring the membrane potential to its diastolic level (phase 4).

The plateau (phase 2) is due partly to a slow inward current that is carried by Ca^{++} through membrane passageways (channels or pores) that are distinct from those participating in the rapid Na^+ upstroke phase of the action potential. The plateau phase is critically important because the slow inward Ca^{++} current is believed to be the link in heart muscle that couples membrane excitation with activation of the contractile apparatus (Reuter 1979, 1985; see Chap. 24).

EXCITATION-CONTRACTION COUPLING. Although Ca^{++} enters the cell during the plateau phase of the action potential, the amount of Ca^{++} that enters by this slow-current pathway is insufficient by itself for optimal activation of the contractile apparatus (Solaro et al. 1974). Instead, the small amount of Ca^{++} entering the cell during the plateau of the action potential fills sarcoplasmic reticulum stores of Ca^{++} and also acts as a trigger to cause a regenerative release of additional amounts of this cation that have been previously sequestered at the sarcoplasmic reticulum (Fabiato and Fabiato 1979).

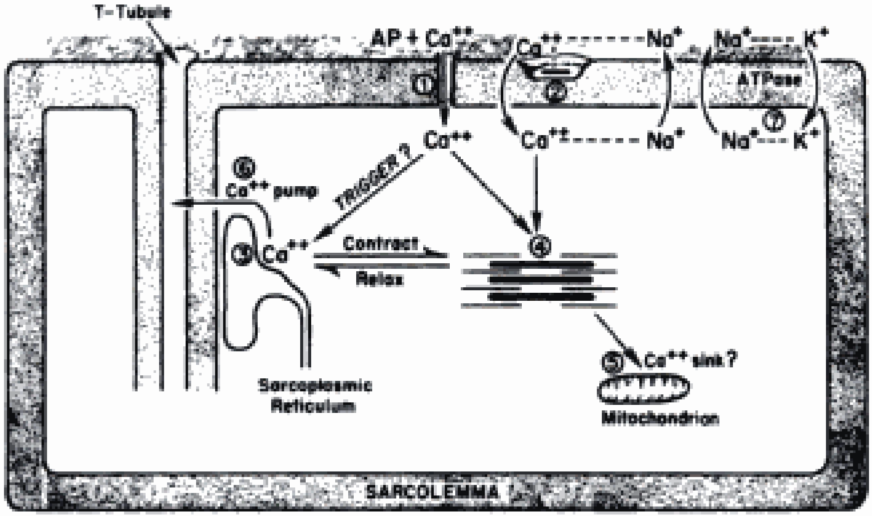


FIG. 23.3—Schematic representation of cellular ion movements controlling excitation-contraction coupling in heart muscle. An action potential (AP) instigates the inward movement of Ca^{++} through slow Ca^{++} channels of the sarcolemma (1). Inward-moving calcium fills sarcoplasmic reticulum stores of the cation and also serves as a trigger to release additional Ca^{++} from storage sites of the sarcoplasmic reticulum (3). These Ca^{++} sources and that resulting from Na^{+}–Ca^{++} exchanges across the sarcolemma (2) activate the contractile proteins (4). Relaxation occurs as calcium is sequestered at storage sites of sarcoplasmic reticulum (3). Mitochondrion (5). Ca^{++} is pumped out of the cell (6). Altered sodium pump activity (7) may also affect sodium concentrations available from Na^{+}–Ca^{++} exchange (Parker and Adams 1977).

At least a portion of the contractile-dependent Ca^{++} in heart muscle is in rapid equilibrium with extracellular Ca^{++} and is derived from superficial binding sites on the cell membrane. Two separate pathways of movement of superficial Ca^{++} are believed to be involved (Langer 1976, 1980; Parker and Adams 1977). The primary electrogenic route is associated with the previously discussed plateau phase of the action potential. An additional influx of Ca^{++} is linked with a Ca^{++}-Na^{+} exchange across the sarcolemma. In this system, an increase in the amount of Na^{+} at the interior surface of the cell membrane would activate a membrane carrier molecule that would translocate three Na^{+} across the sarcolemma in an outward direction and in return carry one Ca^{++} into the cell. The Na^{+}-Ca^{++} exchange system is a bidirectional transporter, and during diastole it seems to move Ca^{++} into the interstitium, thus facilitating relaxation (Reuter 1985). A schematic representation of excitation-contraction coupling in mammalian heart muscle is shown in Fig. 23.3.

RELAXATION. During repolarization, Ca^{++} is actively sequestered by the sarcoplasmic reticulum, which avidly binds and stores myoplasmic Ca^{++} with affinity greater than troponin. Relaxation occurs as Ca^{++} moves to the sarcoplasmic reticulum from troponin binding sites on the myofibrils, and the cytoplasmic Ca^{++} concentration decreases below the threshold required to trigger actin-myosin cross-bridge formation (Fig. 23.3).

MAINTENANCE OF ELECTROLYTE GRADIENTS. There is a net influx of Na^{+} and Ca^{++} and efflux of K^{+} with each action potential. Membrane-bound enzymes that act as pumps to relocate ions and prevent their improper accumulation have been identified (Gadsby 1984). Sodium-potassium-activated adenosine triphosphatase (Na^{+},K^{+}-ATPase) localized in the cell membrane propels Na^{+} out of and K^{+} into the cell, against their respective concentration gradients. Excess intracellular Ca^{++} is pumped out of the cell by systems believed to be localized in regions of the sarcoplasmic reticulum that are in close approximation to the sarcolemma (Fig. 23.3). A sarcolemmal Ca^{++}-ATPase also contributes to extrusion of Ca^{++}.

Although many aspects of the actual processes involved in excitation-contraction coupling are unresolved, the necessity of an adequate supply of superficial membrane-bound Ca^{++} in heart muscle is unequivocal. Superficial Ca^{++} sources are now known to be causally involved in the mechanism of action of many clinically useful drugs, including the digitalis glycosides.

DIGITALIS AND RELATED CARDIAC GLYCOSIDES. Digitalis and several closely allied chemicals are derived from the purple foxglove plant (*Digitalis purpurea*), other related species of the figwort family, and some plant species unrelated to digitalis. Medicinal use of plant extracts containing cardioactive principles has a long and colorful history, dating to ancient times of the Greeks and Romans.

Application of digitalis to modern medicine can be traced to 1785, when William Withering, a physician of Birmingham, England, reported his account of the therapeutic use of foxglove. This remarkable story starts with an old woman from Shropshire who for many years had concocted an herbal folk remedy purported to be efficacious in treating dropsy (edema). Although the remedy was a family secret and included at least 20 different herbs, Withering correctly ascribed beneficial therapeutic results to the foxglove ingredient. After 10 years of study, Withering was convinced of the therapeutic value of the plant and published his now classic monograph, "An Account of the Foxglove and Some of Its Medical Uses: With Practical Remarks on Dropsy and Other Diseases."

Withering recognized that only some types of dropsy were improved with digitalis, but he apparently failed to distinguish congestive heart failure from other edema-producing conditions. Because of the often pronounced diuretic response, the kidney was thought to be the primary target organ of foxglove; however, Withering stated, "It has the power over the motion of the heart, to a degree yet unobserved in any other medicine, and this power may be converted to salutary ends."

Subsequent studies by numerous investigators clearly identified the heart as the focus of digitalis action in congestive failure patients and designated a positive inotropic effect on the myocardium as the relevant mechanism of action. These agents also exert important antiarrhythmic action that has therapeutic application whether or not congestive failure is present. Thus the principal indications for therapeutic use in veterinary medicine are congestive failure and certain forms of cardiac dysrhythmias.

Chemistry and Sources. Chemical and structure-activity relationships of the digitalis glycosides are quite complex, but several basic similarities are retained in the different compounds. The nomenclature is interesting, since it is not derived from specific chemical structures but is based instead on botanical origins.

Official digitalis is the dried leaf of the purple foxglove plant; 100 mg of this material is equivalent to 1 USP Digitalis Unit. Three cardiac glycosides are derived from the leaves: digitoxin, which is used in clinical medicine, and the less well known gitoxin and gitalin. Digitoxin, digoxin (another glycoside used therapeutically), and gitoxin also can be extracted from the leaf of a related plant, *D. lanta*, the woolly foxglove. Strophanthidin and ouabain are important glycosides contained in the seeds of *Strophanthus* sp.; *S. gratus*, the source of ouabain, is an African tree. Acetylstrophanthidin is a semisynthetic derivative of strophanthidin used experimentally. Of toxicologic interest, several cardioactive glycosides are found in the skin of some toads (*Bufo vulgaris*, *B. maritimus*), in certain oleander plants, and in a large number of other unrelated botanical species.

Although 300 or more cardioactive principals of vegetable origin have been identified, the three compounds most important to veterinary therapeutics are digoxin, digitoxin, and ouabain. Because of considerable pharmacologic similarities between the different glycosides, the collective term digitalis is used to designate the entire group rather than referring only to the dried leaf.

	X	Y
Digitoxigenin	H	H
Digitoxin	Digitoxose (3)	H
Digoxin	Digitoxose (3)	OH
Digoxigenin	H	OH

FIG. 23.4—Structural arrangements of digoxin and digitoxin and the aglycones digoxigenin and digitoxigenin.

The term "glycoside" in general refers to a compound linked by an oxygen atom to a sugar molecule(s). Plant-derivative digitalis glycosides with the most intense pharmacologic activity consist of an aglycone (genin) moiety combined with one to four sugar molecules. Aglycones are structurally related to sterols, bile acids, and sex and adrenocorticosteroid hormones. The basic steroid-type nucleus is a cyclopentanoperhydrophenanthrene to which is attached an unsaturated lactone ring at carbon atom 17 (C-17). The sugar molecules usually are attached at C-3; they influence water solubility, cell penetrability, duration of action, and other pharmacokinetic characteristics.

Cardioactivity of the molecule resides principally in the aglycone moiety, but the positive myocardial actions of these entities are somewhat less potent and of briefer duration than the parent glycoside. In modern medicine, the pure glycosides are increasingly being used instead of the older powdered leaf or other impure admixtures that required biologic assay. Bioassay techniques depended on lethal potency of an unknown preparation in cats, frogs, and pigeons or emetic effects in pigeons. Pure glycosides can now be measured spectrophotometrically.

The structures of digitoxin, digoxin, and the aglycones digitoxigenin and digoxigenin are shown for comparative purposes in Fig. 23.4; some chemical aspects of several important compounds are summarized in Table 23.1.

Cardiovascular Effects. The therapeutic response to digitalis in congestive heart failure patients entails a

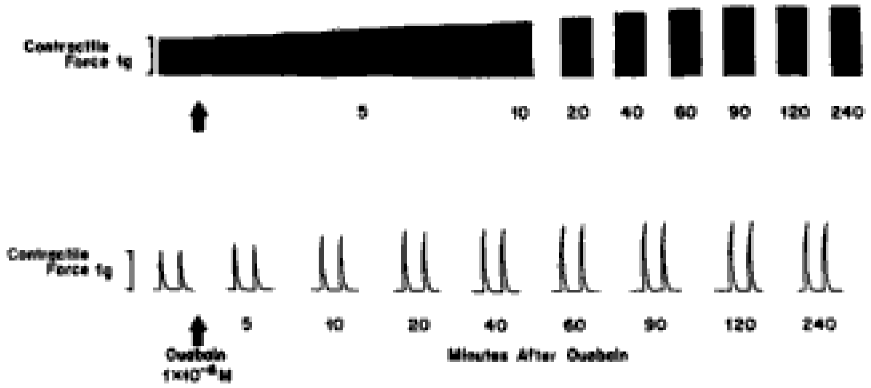

FIG. 23.5—Myographic recordings from a heart muscle before and after exposure to the cardiac glycoside ouabain. Top tracings were taken at a slow recording speed; bottom tracings show individual muscle contractions at designated intervals after addition of ouabain. Notice that contractile force increased by almost 100% and that this effect lasted for the 4-hour measurement period.

broad scope of hemodynamic adjustments: augmented myocardial contractility; increased cardiac output; diuresis and diminution of edema; control of cardiac arrhythmias; and reductions in blood volume, venous pressures, heart size, and heart rate. Improved myocardial contractility undoubtedly is the most important; it is the primary action on which other effects depend.

MYOCARDIAL CONTRACTILITY. The ability of cardiac glycosides to increase contractile vigor of the heart has been demonstrated in a multitude of experimental preparations. Heart muscle suspended at constant external length responds to digitalis with an increase in isometric systolic force; studied under isotonic conditions, muscle shortening is enhanced. Intravenous (IV) infusion of the drug augments intraventricular pressure development in intact subjects even when heart rate, venous return, and blood pressure are maintained constant by experimental means. These results validate a direct effect on contractile strength independent of changes in resting fiber length, heart rate, or afterload. A typical response of heart muscle to the cardiac glycoside ouabain is shown in Fig. 23.5.

The positive inotropic action of cardiac glycosides is particularly pronounced in the hypodynamic or failing heart. However, this should not be construed as evidence that digitalis selectively corrects the specific biochemical defect in the chronically failing heart. This defect has yet to be identified in a satisfactory manner. Digitalis, by increasing Ca^{++} availability in the myocardial fiber (see section on cellular mechanisms of inotropic action), increases contractility of the normal as well as the failing heart. Thus cardiac glycosides may increase contractile strength by way of a cellular pathway that bypasses or only partially involves the spontaneous defect (Aranow 1992).

CELLULAR MECHANISMS OF INOTROPIC ACTION. The mechanism of digitalis action that is helpful in congestive failure is a positive inotropic effect on the heart muscle. However, what is the cellular mechanism of action whereby cardiac glycosides enhance inotropy of the individual muscle fibers in heart failure patients (Feldman 1993)? Only portions of this question can be answered without controversy.

LACK OF DEPENDENCE ON ADRENERGIC MECHANISMS. The inotropic response to digitalis is not prevented by reserpine (which depletes endogenous catecholamines) or propranolol (which blocks β-adrenergic receptors). Digitalis drugs do not increase intracellular concentration of cyclic 3′,5′-adenosine monophosphate (cAMP), an effect closely associated with positive inotropic action of catecholamines (Ezrailson et al. 1977) (see Chap. 5). Thus a preponderance of data clearly has established that the positive inotropic action of digitalis does not depend on release of norepinephrine from adrenergic nerve terminals and that these two agents exert contractile effects through dissimilar receptors and cellular pathways.

CONTRACTILE PROTEINS. Cardiac glycosides do not appear to act by directly modifying energy production or storage, nor is there convincing evidence for improved energy utilization at the level of the contractile proteins and associated enzymes. Similarly, most studies indicate unremarkable effects of cardiac glycosides on isolated actomyosin and the troponin-tropomyosin complex. Thus an intact cell is a prerequisite to the inotropic action of digitalis, and considerable evidence linking this activity with ionic changes is now available.

INHIBITION OF NA$^+$,K$^+$-ATPASE. Total cellular Ca^{++} is increased by the glycosides; this net gain reflects an augmented Ca^{++} influx. However, phase 2 of the cardiac action potential, which depends partly on electrogenic influx of Ca^{++}, does not seem to be affected remarkably by therapeutic amounts of digitalis. These data have led investigators to propose an increased influx of Ca^{++} across the cell membrane in exchange for Na$^+$ as a mechanism of inotropic action of digitalis. This change in Ca^{++} movement as well as modifications of Na$^+$ and K$^+$ locations are explained by the well-known inhibitory effect of digitalis glycosides on the Na$^+$-K$^+$ pump of the sarcolemma (Fozzard and Sheets 1985; Katz 1985).

The Mg^{++}-dependent Na$^+$,K$^+$-ATPase of the cell membrane supplies energy for the active pumping of Na$^+$ outward and K$^+$ inward against their large concentration gradients (Fig. 23.3). Beginning with experiments on erythrocytes by Schatzmann (1953), the ability of cardiac glycosides to inhibit membrane transport of Na$^+$ and K$^+$ has been confirmed in several tissues, including the heart. The Na$^+$,K$^+$-ATPase is believed to be the cellular receptor for digitalis glycosides (Schwartz 1977; Akera and Ng 1991).

Inhibition of Na$^+$,K$^+$-ATPase results in progressive reduction of (K$^+$)$_i$ as the ability of the pump to transport K$^+$ inward and Na$^+$ outward progressively fails. A decrease in (K$^+$)$_i$ and/or an increase in (K$^+$)$_o$ reduces resting membrane potential to a less negative value, which can lead to increased automaticity and eventually impaired conduction and excitability. Inhibition of ATPase and resulting depletion of (K$^+$)$_i$ are responsible for many toxic arrhythmogenic activities of digitalis.

The inotropic effect involves activation of a Na$^+$-Ca^{++} exchange mechanism through accumulation of (Na$^+$)$_i$. Baker et al. (1969) demonstrated with the giant squid axon that an increase in (Na$^+$)$_i$ enhanced the uptake of Ca^{++} by a Na$^+$-Ca^{++} exchange process. This mechanism seems to be operative in other excitable tissues and has been evoked as the link between inhibition of Na$^+$,Ka$^+$-ATPase and digitalis inotropy in the heart (Langer 1977). The sequence of events can be visualized to include the following progression: digitalis interacts with and inhibits cell membrane Na$^+$,K$^+$-ATPase, outward pumping of Na$^+$ is slowed, (Na$^+$)$_i$ accumulates, increased (Na$^+$)$_i$ augments transmembrane exchange of intracellular Na$^+$ for extracellular Ca^{++}, (Ca^{++})$_i$ is increased, and Ca^{++} delivery to the contractile proteins is increased; thus the positive inotropic effect is gained. A schematic that illustrates the dominance of Na$^+$-K$^+$ exchange in the normal state and the putative augmentation of Na$^+$-Ca^{++} exchange after inhibition of ATPase by digitalis is shown in Fig. 23.6.

CARDIAC OUTPUT. Digitalis glycosides exert a fundamentally similar action on the normal and failing myocardium, an increase in contractility. However, changes in cardiac output are influenced by the functional status of the cardiovascular system at the time of digitalis administration.

NORMAL HEART. Output of the normal heart increases minimally and may even decrease slightly after treatment with digitalis (Braunwald 1985). Total peripheral resistance is increased by digitalis in the normal subject as a result of a centrally mediated increase in sympathetic vasomotor tone and direct vasoconstrictor effect. Impedance of the arterial circuit to ventricular ejection is thereby increased, which opposes the trend toward increased output produced by positive inotropic response to the drug. Increased outflow impedance and increased cardiac contractility tend to counteract each other, yielding little net change in cardiac output in normal populations.

FAILING HEART. The work capacity of the failing ventricle at any given end-diastolic volume or pressure is inadequate to generate a normal stroke volume (Fig. 23.7). The ejection fraction is diminished accordingly, which increases residual blood in the ventricle after systole (Moalic et al. 1993). If diastolic filling continues at a near normal rate, the ventricle will dilate to accommodate increased end-diastolic volume. After digitalization, the above processes are reversed. Digitalis-increased contractile vigor of the heart muscle augments work capacity of the ventricle at any given end-diastolic filling pressure, as illustrated in Fig. 23.7, where ventricular function curves derived in the pre-failure state (normal) are compared with curves derived from congestive failure patients prior to and after digitalis therapy. Digitalis shifts the complete ventricular function curve upward in the direction of improved contractility (Mason 1973; Braunwald 1985). Systolic emptying is now more complete, and residual ventricular volume is diminished. Cardiac output increases and

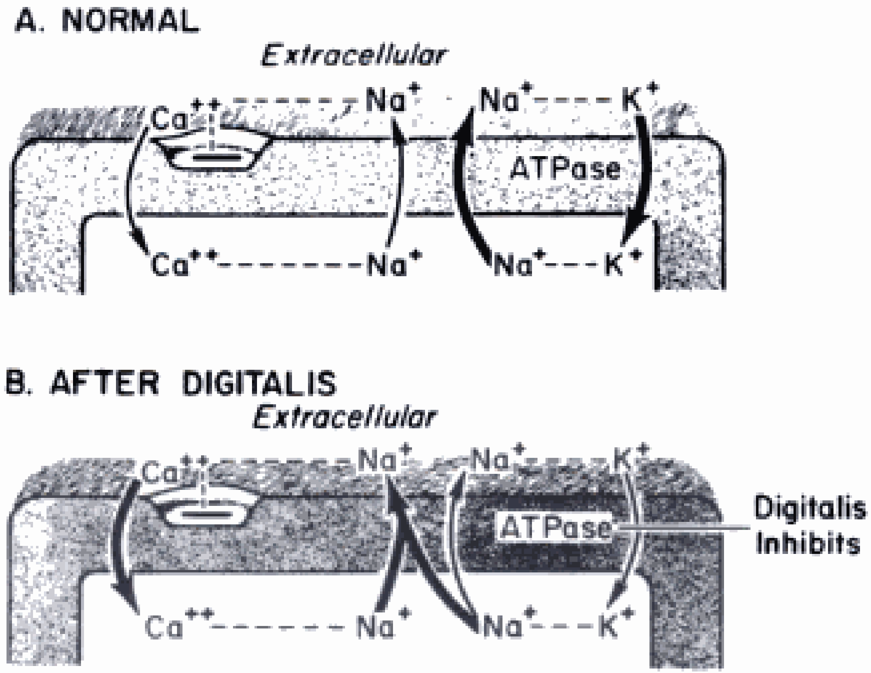

FIG. 23.6—Schematic representation of a proposed mechanism for the positive inotropic action of cardiac glycosides. Inhibition of Na^+,K^+–ATPase (sodium pump) by digitalis results in increased intracellular concentrations of sodium available for exchange with calcium. Heavy arrows designate the dominant pathway of ion exchange during normal conditions (A) and after inhibition by digitalis of Na^+,K^+–ATPase (B). (After Langer 1976; from Parker and Adams 1977.)

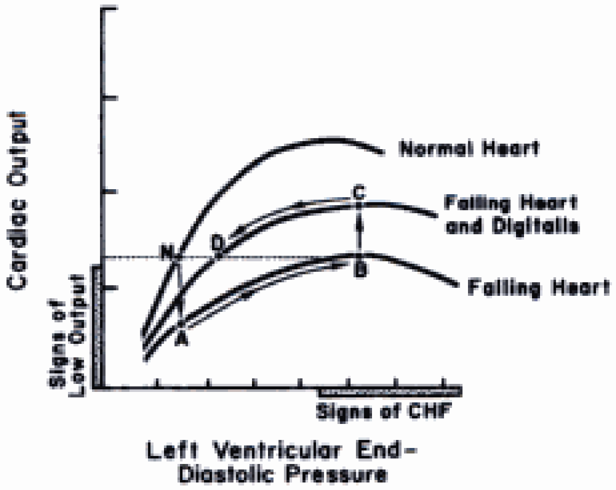

FIG. 23.7—Diagrammatic representation of how changes in left ventricular filling influence cardiac output by the Frank-Starling mechanism in a normal heart and in a failing heart before and after digitalis. The points N to D represent in sequence: N–A, normal cardiac output falls to A because of initial contractile depression from congestive heart failure (CHF); A–B, shift to higher end-diastolic filling and thus higher cardiac output in accord with the Frank-Starling law; B–C, increase in contractility after digitalization; C–D, reduction in use of Frank-Starling compensation, which digitalis allows. N, B, and D: identical cardiac output on the vertical axis but achieved at different end-diastolic filling pressure on the horizontal axis. Levels of cardiac output and end-diastolic filling associated with signs of low output (e.g., fatigue) or CHF (e.g., dyspnea, edema) are represented by the dotted areas. (Modeled after Mason 1973.)

size of the heart is reduced as ventricular filling volume is lowered.

Subsequent hemodynamic adjustments evoke other responses that contribute to maintenance of improved cardiac output in the congestive failure patient; e.g., sympathetically mediated vasoconstriction and its attending increase in peripheral vascular resistance are already in progress in these individuals as part of the compensatory response to their pathophysiologic condition; increased impedance to ventricular ejection is in force. After digitalis, however, the pronounced augmentation of myocardial contractility and stroke volume set into motion a reflex withdrawal of vasomotor tone. This in turn evokes peripheral vasodilation, reduced peripheral resistance, and diminished outflow impedance. This sequence of events continues to dominate as peripheral perfusion and tissue oxygenation improve, and it more than compensates for the direct vasoconstrictor effect of digitalis. The increase in cardiac output persists as long as the state of myocardial compensation prevails.

CARDIAC ENERGY METABOLISM. Early studies provided evidence that the positive inotropic response to cardiac glycosides was unique, when contrasted to catecholamine activity, because digitalis increased contractile strength without a commensurate increase in oxygen consumption. Later studies with nonfailing muscle, however, showed that cardiac glycosides increased oxygen consumption proportionately with increased contractile force (Lee and Klaus 1971).

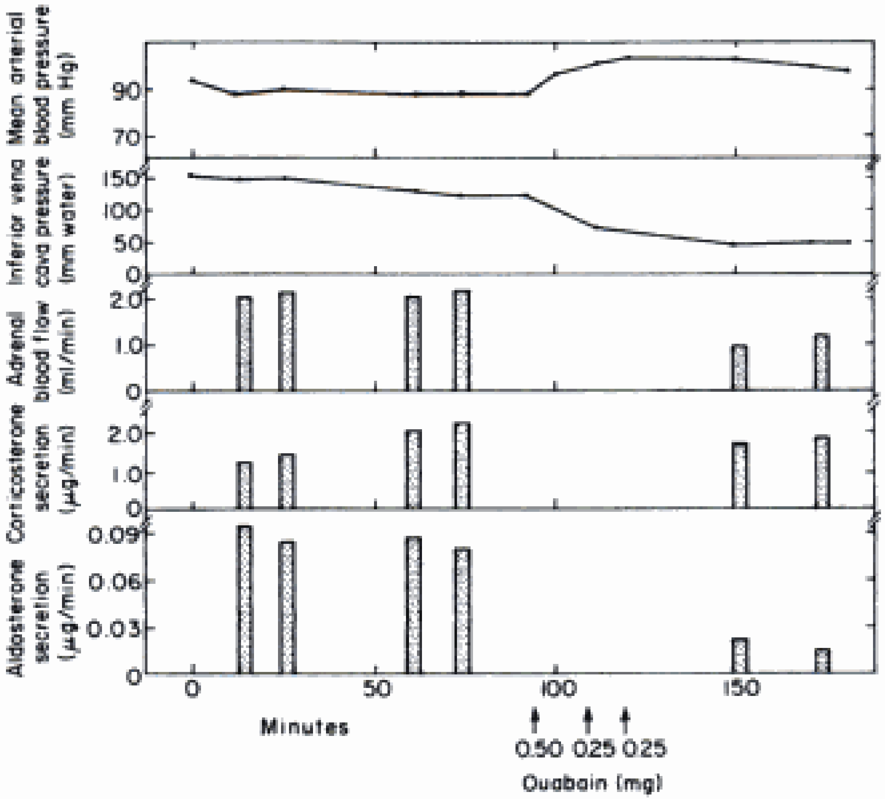

FIG. 23.8—The effects of IV ouabain injection (total dose 0.05 mg/kg) in an 8-year-old, 20 kg male Pointer with naturally occurring congestive heart failure. Following injection, mean arterial blood pressure increased from 88 mm Hg to a maximum of 110 mm Hg, and inferior vena cava pressure fell from a control value of 150-140 mm water to a minimum of 38 mm water; these changes started within 5 minutes after beginning the ouabain injection and reached a maximum 40-50 minutes postinjection. Following drug administration, there was also a marked fall in adrenal corticosterone and aldosterone secretion (Carpenter et al. 1962).

These seemingly contradictory data can be reconciled by comparing the cardiodynamics of digitalis in normal and failing hearts. The heart with a normal ventricular volume responds to digitalis with increase in oxygen consumption commensurate with increase in contractility. Increased oxygen consumption is the direct result of increased contractility, in accordance with the concept that myocardial oxygen demand (MVO_2) is influenced directly by the inotropic state, heart rate, and wall tension. Ventricular wall tension is directly proportional to ventricular pressure and radius (tension ≈ pressure × radius; Laplace relation); tension will decrease if either pressure or radius is reduced. In the failing and dilated heart, reduction in cardiac size secondary to the inotropic action of digitalis therapy leads to a significant reduction in wall tension, which in turn leads to decreased MVO_2.

That is, increased contractility at constant fiber length increases oxygen consumption (response of normal heart); however, decreased fiber length reduces wall tension and thus oxygen consumption (response of dilated heart). If the latter processes dominate enough in the failing heart to yield a net reduction in oxygen consumption in the presence of positive inotropic action of digitalis, this agent can indeed increase mechanical efficiency of the failing heart.

BLOOD PRESSURE. Adjustments in blood pressure after cardiac glycoside therapy are secondary to cardiodynamic improvement in the congestive failure patient, and systemic pressure tends to normalize (Fig. 23.8).

CARDIAC RATE AND RHYTHM. The principal effects of digitalis therapy on heart rate and rhythmicity in congestive failure patients are a decrease in sinus rate and a slowing of atrioventricular (AV) impulse conduction. These responses are gained by complex mechanisms involving direct action on cardiac fibers and, especially, readjustments in autonomic nervous system traffic to the heart (Gillis and Quest 1980; Watanabe 1985).

SYMPATHETIC TONE. Reflex sinus tachycardia is not an uncommon finding as part of the compensatory effort in congestive failure. Circulatory improvement after digitalization tends to remove the stimuli responsible for reflex increments in heart rate, allowing sinus rate to return toward normal. Thus slowing of heart rate by digitalis is mainly secondary to hemodynamic improvement and the resulting reflex decrease in sympathetic tone and increase in vagal tone to the heart.

VAGAL DEPENDENT ACTION. The portion of the digitalis-induced decrease in heart rate and slowing of AV conduction that is blocked by atropine is referred to as the vagal-dependent or atropine-sensitive action of the cardiac glycosides. By releasing ACh, vagal discharge evokes characteristic effects in the atria: slowing of sinus rate, decreased action potential duration and refractory period, and slowed impulse conduction. Cholinergic stimulation also slows impulse conduction in the AV node but lengthens the refractory period in this tissue. Thus vagal discharge can slow sinus rate and exacerbate atrial tachyarrhythmias but can effectively slow AV impulse conduction at the same time. Digitalis, by evoking vagal-dependent actions, can accomplish similar effects.

The vagal component of cardiac glycoside action has been attributed to at least three mechanisms: direct stimulation of vagal centers in the brain, sensitization of carotid sinus baroreceptors to blood pressure, and enhancement at the myocardial level of the pacemaker response to ACh (Gillis and Quest 1980).

EXTRAVAGAL ACTIONS. Extravagal actions are unmasked by pretreatment with atropine or large doses of digitalis that overwhelm indirect (nervous system) effects. In the atropinized or denervated heart, the ability of digitalis to slow AV conduction is somewhat reduced compared to intact hearts. Duration of the atrial refractory period, although abbreviated by vagal action, is actually prolonged by digitalis after atropine. Direct effects are mediated in part by disruption of cellular electrolyte gradients associated with ATPase inhibition. A portion of the nonvagal effect is reflected by an antagonism of the cardiac response to adrenergic stimulation; e.g., the facilitatory effect of sympathetic stimulation on pacemaker discharge and AV conduction is reduced in dogs by acetyldigoxin (Mendez et al. 1961a,b). This activity has been designated as a sympatholytic or antiadrenergic action of digitalis. Paradoxically, toxic doses of digitalis may also increase sympathetic nerve traffic to the heart (Gillis and Quest 1980; Watanabe 1985).

BIOELECTRIC CHANGES IN THE HEART. As stated, the principal rhythm adjustments beneficial to the patient treated with digitalis are slowing of sinus rate and AV conduction, which are mediated by direct and, especially, indirect mechanisms. Direct and indirect electrophysiologic effects of digitalis can be demonstrated throughout the heart (Gillis and Quest 1980). In the following discussion and in Table 23.2, only the more important aspects of digitalis-evoked actions on electrophysiologic activities of the heart are summarized. Remember that the positive inotropic response to digitalis can occur before transmembrane potential changes are produced.

EXCITABILITY. The reduced intracellular K^+ and increased intracellular Na^+ resulting from inhibition of Na^+,K^+-ATPase yield a partial depolarization of the cell; i.e., negativity of the cell interior is diminished. The resulting decrease in diastolic potential brings this value closer to threshold, thus tending to enhance excitability. Increased excitability can be observed in atria and ventricles with a small dose of digitalis; however, excitability becomes depressed with progressively larger amounts of the drug as diastolic depolarization progresses beyond a critical limit.

AUTOMATICITY. Pacemaker cells are characterized by phase 4 spontaneous depolarization, which lowers diastolic potential to the threshold potential required for activation of phase 0, thereby firing automatically (see Chap. 24). Therapeutic doses of cardiac glycosides produce a decrease in the slope of spontaneous depolarization of the sinoatrial pacemaker, which yields a reduced firing rate. This effect, however, is secondary to increased vagal tone and decreased sympathetic tone. After pretreatment with atropine, or with relatively high doses of digitalis, the nonvagal effects dominate, and an increase in automaticity is observed; this response is prevalent in the specialized conducting systems of atria and, especially, ventricles. A typical transmembrane potential recording of a subsidiary pacemaker cell prior to and after digitalis is shown in Fig. 23.9.

Increased automaticity evoked by cardiac glycosides is due to an accelerated rate of spontaneous diastolic depolarization (Fig. 23.9). The normally latent pacemaker activities of cells within the ventricular conducting system are thereby magnified, leading to ectopic ventricular beats as an important early sign of digitalis toxicity. In contrast, muscle fibers in atria and ventricles can be depolarized to the extent of inexcitability without demonstrating spontaneous impulse generation. If excitability of ventricular muscle falls below normal concomitantly with increased frequency of ectopic impulses from specialized conduction fibers, the tendency for ventricular fibrillation is promoted.

The clinical significance of the unusual "delayed afterdepolarizations" that can be seen with digitalis toxicity is not completely resolved. These secondary depolarizations of the transmembrane potential initially are subthreshold and appear spontaneously during diastole after a usual action potential. The afterdepolarizations can reach threshold as toxicity worsens; the resulting extrasystoles contribute to ectopic arrhythmias associated with digitalis intoxication.

IMPULSE CONDUCTION AND REFRACTORY PERIODS. Conduction in atrial and ventricular muscle fibers may be enhanced slightly by low doses of digitalis if excitability is increased. However, the dominant effect of digitalis on impulse conduction is to slow conduction velocity by both vagal and nonvagal mechanisms. This response is particularly prevalent in the AV transmission system and contributes importantly to the beneficial effects of digitalis in controlling ventricular rate during atrial fibrillation and flutter.

TABLE 23.2—Characteristic effects of digitalis on electrophysiologic properties of the heart

Electrophysiologic property	Cardiac region	Effects	Response
Automaticity	SA node	Decreases as a result of vagal-dependent actions and sympathetic withdrawal (may increase after atrophine)	Decreases sinus rate
	Atrial specialized conducting fibers	Little change; increases with toxicity	Increases ectopic pacemakers
	AV junction tissues	Variable; increases with larger doses	Increases AV junctional rhythms
	Purkinje fibers	Variable; increases with larger doses	Increases ectopic pacemakers
	Atrial and ventricular muscle	Usually little change; rarely increases with toxic doses	
Excitability	Atrial and ventricular muscle	Variable; progressively decreases with larger doses; severe decrease with toxicity	
	Purkinje fibers	Variable; progressively decreases with larger doses	
Conduction	Atrial and ventricular muscle	Increases slightly; decreases with larger doses	Promotes atrial fibrillation
	AV junctional tissues	Decreases as a result of vagal-dependent actions; progressively decreases with toxicity	Decreases ventricular rate in atrial fibrillation; AV block
	Purkinje fibers	Decreases; further decrease with toxicity	Promotes ventricular reentry forms of arrhythmias
Refractoriness	Atrium	Decreases as a result of vagal-dependent actions; (increase after atropine)	Promotes atrial fibrillation
	Ventricle	Decreases	Favors reentry forms of arrhythmias
	AV junctional tissues	Increases as a result of vagal-dependent actions	Contributes to ventricular rate decreases in atrial fibrillation; AV block with toxicity
	Purkinje fibers	Increases; progressively decreases with larger doses	Favors reentry forms of arrhythmias

Note: SA = sinoatrial; AV = atrioventricular.

Refractory periods also are influenced by cardiac glycosides through direct and indirect mechanisms. Vagal-dependent actions in the intact animal shorten the refractory period of atrial fibers, which tends to exacerbate atrial fibrillatory rhythms. In contrast, the refractory period of the AV conduction system is prolonged markedly by the vagal mechanisms. Digitalis shortens the refractory period in the ventricle, which contributes to reentrant arrhythmias (Table 23.2).

COMBINED EFFECTS DURING ATRIAL FIBRILLATION AND FLUTTER. During atrial fibrillation, the ventricular rate is rapid and dysrhythmic as a result of rapid but irregular transmission of impulses through the AV node. This contributes further to heart failure syndrome by promoting incomplete ventricular filling and ejection. Because digitalis prolongs the refractory period and delays impulse conduction through the AV junction, the ventricle will be bombarded by fewer impulses effectively traversing the junction. Thus the ventricular rate is adjusted to a slower, more physiologic level (Meijler 1985).

Similar benefits are gained during atrial flutter. Digitalis can convert this rhythm to atrial fibrillation (or increase the frequency of the latter) by vagal-dependent mechanisms, evoking a reduction in the atrial refractory period. Ventricular rate is still decreased, however, through prolonged AV refractoriness and slowed impulse conduction. Conversion of atrial flutter to fibrillation by digitalis is viewed optimistically because ventricular rate is controlled more easily during fibrillation than during flutter.

EFFECTS ON THE ELECTROCARDIOGRAM. The multiplicity of electrophysiologic effects of cardiac glycosides in myocardial tissues can be expressed as equally complex changes in the electrocardiogram (ECG). Most types of conduction disturbances and dysrhythmias detected in diseased animals can be reproduced in normal individuals by the cardiac glycosides. Most of these changes are more important to diagnosis of digitalis toxicosis than to therapy.

Congestive failure patients with sinus tachycardia or other supraventricular tachyarrhythmias usually demonstrate return toward more normal ECG patterns after digitalization. Rapid ventricular rates associated with atrial fibrillation or flutter should be reduced as the AV depressing action of digitalis is manifested.

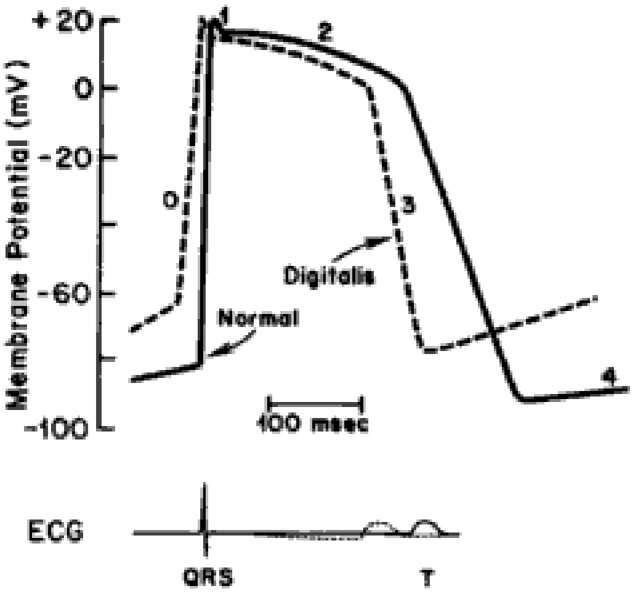

FIG. 23.9—Electrophysiologic effects of digitalis on transmembrane potential of a subsidiary pacemaker cell. Digitalis (*a*) decreases (less negative) the maximal diastolic potential, (*b*) decreases the maximal rate of depolarization of phase 0, V_{max}, and (*c*) enhances automaticity by increasing the slope of phase 4 spontaneous depolarization.(*a*) and (*b*) lead to decreased conduction velocity and, in conjunction with (*c*), can lead to arrhythmias of both impulse formation and impulse conduction. (Modeled after Mason et al. 1971.)

Prolonged PR intervals, reflecting delayed AV conduction, are relatively common ECG features of digitalized dogs. Conversely, a lengthened PR interval is not necessarily a prerequisite for the therapeutic response. Some cardiologists believe that prolongation of the PR interval can be a borderline sign of digitalis toxicity (Tilley 1979).

Different types of ECG abnormalities can appear if therapeutic response to digitalis degenerates into intoxication. The following progression of ECG signs has been recognized as evidence of digoxin action (Detweiler 1977): (1) signs occasionally observed in normal dogs but also characteristic of digoxin effects (first degree AV block or AV block with dropped beats), (2) signs unlikely to occur spontaneously in normal resting dogs (sinus bradycardia less than 50 beats/min or sinus tachycardia exceeding 200 beats/min), and (3) signs not occurring in normal dogs (AV dissociation, paroxysmal atrial tachycardia with or without block, ectopic atrial beats, fusion beats, intraventricular block, or ventricular ectopic beats).

KIDNEYS AND DIURESIS. Compensatory mechanisms that participate in an attempt to restore blood flow in congestive failure include reflex increases in sympathetic vasoconstrictor tone. Arteriolar constriction in the kidney is particularly crucial because diminished renal blood flow reduces glomerular filtration rate, resulting in sodium and water retention. Renal underperfusion also activates a kidney-dependent humoral mechanism that further promotes salt and water reabsorption. This sequence involves the following progressive pathway: diminished cardiac output, hypotension, baroreceptor reflexes, increased sympathetic activity, renal arteriolar constriction, reduced renal flow, release of renin, increased formation of angiotensin, increased release of aldosterone, sodium retention, water retention, and blood volume expansion.

Increased blood volume tends to increase cardiac output; however, a detrimental consequence is increased interstitial fluid volume, which promotes edema formation. As blood volume expands and intravascular pressures increase, likelihood for edema increases proportionately. Edema forms in the lungs and more peripheral tissue respectively if left and right ventricular failure progressively worsens.

After digitalization, the above processes are reversed. Reflex vasoconstriction withdraws as cardiac output and hemodynamics are improved; renal blood flow and glomerular filtration rate increase and stimuli for increased release of aldosterone are diminished. A remarkable fall in aldosterone secretion can be measured after digitalization in the dog with naturally occurring congestive failure (Fig. 23.8). Profuse diuresis results as salt and water retention by the kidneys is decreased. Diuresis and a lowering of capillary hydrostatic pressure move tissue water from the interstitial compartment into the vascular space, providing relief from edema. Diuresis is not a prominent feature of digitalis therapy if edema does not accompany the congestive failure syndrome. Similarly, digitalis does not evoke diuresis if edema is not cardiogenic. Thus the diuretic response to digitalis is secondary to circulatory improvement and is not from a direct effect on the kidney.

Extracirculatory Effects. Cardiac glycosides can affect cellular functions throughout the body, apparently by inhibiting the ubiquitous Na^+,K^+-ATPase; e.g., these agents can affect skeletal muscle function, thyroid gland activity, hematologic parameters, and numerous other functions. Such activities are believed to have little therapeutic importance except for overt toxicosis and generally require quantities of the drug in excess of those that should be administered.

Vomiting reactions after digitalis are due mainly to a central action and occur even after parenteral administration in the eviscerated animal. Both the chemoreceptor trigger zone and the medullary emetic center seem to be involved; local irritation of the gastric mucosa also may participate in the emetic response after oral administration.

Administration of a subtherapeutic dose of digitalis through a catheter in one renal artery results in sodium and water diuresis only in that kidney. This and other related findings were interpreted as evidence that Na^+,K^+-ATPase is involved in urine concentration mechanisms and that by inhibiting this enzyme, digitalis could evoke a direct diuretic effect on the kidney

(Robinson 1972). However, this experimental observation is believed to be unimportant in relation to diuresis achieved by circulatory improvement in congestive failure patients after effective digitalization.

Pharmacokinetics. In general, absorption across biologic membranes and the extent of protein binding and biotransformation of the individual glycosides are related directly to their lipid solubility and thus inversely to their polarity. The number of hydroxyl groups on the steroid nucleus basically determines polarity. Digitoxin has only one steroidal hydroxyl group and is therefore relatively nonpolar; it is well absorbed after oral administration, is highly bound to plasma proteins, and undergoes metabolic degradation. Digoxin, with two hydroxyl groups, is absorbed somewhat less effectively than digitoxin; the former also undergoes less protein binding and biotransformation. Ouabain, with five hydroxyl groups, is absorbed inefficiently across the gastrointestinal (GI) mucosa; it is not bound extensively to plasma proteins and is excreted unchanged by the kidneys (Moe and Farah 1975).

The small intestine is the principal site of digitalis absorption after oral administration, but the rate and extent of this process vary with different compounds and their formulations. Ouabain is absorbed inefficiently after the oral route, only 5-10% in dogs and cats. Absorption of digoxin and digitoxin after oral administration of an elixir usually is uniform, up to 75-90%, with peak serum concentrations attained in 45-60 minutes (Krasula et al. 1976). The peak serum value is smaller and occurs somewhat later (90 minutes) when the tablet form is used. Depending on the pharmaceutical methods used in formulating tablets, absorption of digitalis glycosides can be erratic and inefficient to the extent that therapeutically useful serum concentrations are not gained.

After IV administration, the maximal positive inotropic responses to digitoxin and digoxin were obtained within 60 minutes after injection (Hamlin et al. 1971). There is an initial fall in serum concentration as the drug mixes in the vascular compartment and distributes through the tissues; a slower exponential decline follows. Biologic half-life values for digitalis glycosides in dogs remain somewhat uncertain because of variable results obtained from laboratory to laboratory and even within the same one. Breznock (1973) reported that the plasma half-life value for digoxin and digitoxin was 38.9 hours and 48.6 hours respectively. In a later study, Breznock (1975) reported almost the opposite, 55.9 hours for digoxin and 37.9 hours for digitoxin. Other approximate values include digoxin, 27 hours (Barr et al. 1972), 30 hours (Hahn 1977), 24 hours (Doherty 1973), and 31 hours (De Rick et al. 1978); digitoxin, 14 hours (De Rick et al. 1978), and 21 hours (Beck 1969). Differences can be attributed to analytical problems, perhaps, but remarkable interpatient variability is also observed; e.g., the half-life for digoxin in dogs after therapy for 13 days varied from 14.4 to 46.5 hours (De Rick et al. 1978). These variables strengthen the need for adoption of individual dosage regimens depending on the patient's response.

Approximately 70-90% of digitoxin can be bound to plasma proteins, whereas digoxin is bound perhaps 25% (Breznock 1973). There is some biotransformation of digitoxin by the liver, whereas urinary excretion seems to be the more important route of elimination for digoxin. Digitalis glycosides and their biotransformation products can follow an enterohepatic cycle in which compounds are excreted by the liver into bile and some parent glycoside and metabolites are subsequently reabsorbed. The importance of this cyclic pathway varies from one species to another. In humans, digitoxin undergoes relatively slow hepatic biotransformation and is extensively recycled and slowly eliminated by both renal and biliary routes; the plasma half-life may be as long as 5-7.5 days. Digoxin undergoes insignificant metabolism in humans and is minimally recycled and eliminated mainly by renal excretion; the half-life is generally 1.5-3 days. In dogs, both digoxin and digitoxin undergo some hepatic biotransformation, but their recycling is less important and their biologic half-life values are shorter than in humans.

Cardiac glycosides are not concentrated selectively in the heart but are distributed in numerous organs. Highest concentrations, as with many drugs, are found in excretory tissues such as liver, bile, intestinal tract, and kidneys. Moderate concentrations are localized in lungs, spleen, and heart, while lower concentrations are found in blood, skeletal muscle, and nervous system.

Digitalis Toxicity

PLASMA CONCENTRATIONS. Development of an accurate radioimmunoassay for measuring quantities of digoxin and digitoxin in biologic fluids is an important advancement in the field of pharmacology. The clinical application of this method permits correlation of serum concentrations of the drugs with therapeutic or toxic effects (Haber 1985).

Digitoxin plasma concentrations of 14-26 ng/mL are considered to be within the therapeutic range in humans, whereas values higher than 34 ng/mL are considered toxic. Therapeutic concentrations of digitoxin in dogs with spontaneous cardiac failure are not available, but values of 26-77 ng/mL are associated with signs of toxicity; plasma concentrations less than 15 ng/mL are nontoxic in normal dogs. In humans, therapeutic and toxic plasma concentrations of digoxin usually are set at 0.8-1.6 ng/mL and greater than 2.4 ng/mL respectively (Moe and Farah 1975). Similar numbers have been derived from studies with animals; e.g., digoxin plasma concentrations of 0.5-2 ng/mL were nontoxic in horses (Button et al. 1980c); 2.3 ng/mL were not toxic in cats (Ericksen et al. 1980). Plasma digoxin concentrations up to 2.5 ng/mL were reported to be essentially nontoxic in healthy dogs and in dogs with spontaneous cardiac failure; importantly, values from 0.8 to 1.9 ng/mL may have been therapeutically effective in the latter group. Concentrations of digoxin greater than 2.5-3 ng/mL were associated with increased probability of toxicosis in these animals (De Rick et al. 1978).

The acute toxic IV dose of digoxin in dogs was determined in one study as approximately 0.177 mg/kg (Beck 1969). Subacute digoxin toxicosis could be induced and maintained in healthy Beagle dogs by an IV loading dose of 0.125-0.150 mg/kg given in increments at 0, 1, 4, and 24 hours, followed by a daily IV maintenance dose of 0.015-0.025 mg/kg (Fillmore and Detweiler 1973; Teske et al. 1976). Signs of toxicity were generally mild or absent when serum digoxin concentrations were less than 2.5 ng/mL. Moderate signs of intoxication were associated with concentrations of 2.5-6 ng/mL, whereas severe toxicosis and some deaths occurred when levels exceeded 6 ng/mL. The highest digoxin concentrations were associated with mild hypothermia (0.6-1.7° C reduction), increased blood urea nitrogen (BUN), and increased serum creatinine. The unexpected increase in serum creatinine and BUN concentrations was interpreted as evidence that digoxin toxicity compromised renal function.

CLINICAL SIGNS. Digitalis intoxication is characterized by several clinical signs varying from mild GI upset to chronic weight loss and life-threatening arrhythmias (Detweiler 1977; Tilley 1979). Initial anorexia and loose stools are common side effects; if they do not progressively worsen, a reduction in dose may not be necessary. Vomiting after IV administration of cardiac glycosides is a relatively common reaction and usually not cause for alarm. Vomiting in dogs receiving oral digitalis preparations is viewed more seriously, especially if protracted diarrhea is an accompaniment; these individuals should be examined for additional evidence of toxicity. GI disturbances are certainly troublesome and may debilitate the patient; however, the lethal outcome of digitalis intoxication is due to cardiac arrhythmias.

A variety of abnormalities can appear in the ECG as digitalis toxicity develops. The reduced sinus rate and slowed AV conduction attained with digitalis therapy can progress to incomplete or complete heart block with dropped beats and ST segment changes as intoxication supervenes. AV block in turn may progress to junctional escape rhythms and ventricular premature systoles. If an extra QRS complex recurs after each regular systole, then digitalis has evoked ventricular bigeminy (coupled ventricular systoles). Ventricular bigeminal rhythm can appear prior to, with, or after development of other arrhythmias that may be associated with digitalis intoxication. Paroxysmal ventricular or atrial tachycardia with block and multifocal premature ventricular systoles are further evidence of serious cardiac disturbances. Occurrence of these or any other important ECG abnormalities necessitates complete withdrawal of digitalis therapy; treatment with smaller doses should not be instituted until the ECG is free of such arrhythmias.

Large therapeutic and toxic doses of digitalis drugs have been associated with various neurologic disturbances in humans, including central nervous system depression, ataxia, psychotic episodes, mental confusion, restlessness, hallucinations, delirium, and coma. These problems are not commonly detected in dogs receiving digitalis, but their presence could be masked by the generalized weakness and malaise that may accompany cardiac toxicity.

Species differences in sensitivity to acute toxic effects of digitalis glycosides were reviewed by Detweiler (1967). The relative median lethal dose in several species, taking the cat as unity, are: cat, 1; rabbit, 2; various frogs, 28; various toads, >400; and rat, 671. Resistance to digitalis toxicity seems to reside in the heart and may be a reflection of the relative sensitivity of the Na^+,K^+-ATPase to glycoside inhibition.

ELECTROLYTE INVOLVEMENT. Cardiac toxicity of digitalis is affected by availability of electrolytes, especially K^+ and Ca^{++}. Potassium has considerable influence on arrhythmias and conduction disturbances evoked by digitalis but less effect on inotropic activity of the drug. In essence, reduced K^+ potentiates digitalis arrhythmogenicity, whereas excess K^+ antagonizes arrhythmogenic activity. The antiarrhythmic activity of K^+ in digitalis intoxication is probably related to direct effects of K^+ and an inhibition by the cation of glycoside binding to the Na^+,K^+-ATPase. The intracellular-extracellular ratio of K^+ seems to be a primary determinant of the interaction between this ion and digitalis rather than interstitial concentrations of K^+ alone. Digitalis-induced dysrhythmia can occur in the presence of normal K^+ plasma concentration because of the intracellular depletion of this cation that accompanies Na^+,K^+-ATPase inhibition (Rosen 1985).

Intoxication with digitalis can be precipitated by intervals of hypoxemia, hypomagnesemia, disturbances in acid-based balance, and hypercalcemia. Digitalis cardiac toxicosis provoked by hypoxia and acidosis may be due in part to further depletion of myocardial K^+. Hypokalemia can be secondary to malnutrition, corticosteroid therapy, hemodialysis, and too vigorous use of diuretics that do not spare K^+. All these factors should be considered when a differential diagnosis is made between an absolute digitalis overdosage and a relative overdosage caused by K^+ disturbances.

Cardiac actions of Ca^{++} are similar in certain ways to those evoked by digitalis in this tissue, and there is considerable concern by clinicians that excess Ca^{++} augments digitalis intoxication. In canine experiments a synergistic or additive interaction between Ca^{++} and digitalis could be demonstrated with concentrations of each agent that were toxic or near toxic even when given alone (Lown et al. 1960). In an effort to exploit Ca^{++}-digitalis interaction, Ca^{++} chelating agents such as ethylenediaminetetraacetic acid (EDTA) and sodium citrate have been used to lower serum Ca^{++} and thereby control digitalis-induced arrhythmias. Whether the antiarrhythmic action of chelating agents under these circumstances are specific or nonspecific remains unclear.

The divalent cation magnesium (Mg^{++}) depresses cardiac contractility and excitability when present in excessively high concentrations. This substance has only a transient and inconstant protective effect against digitalis arrhythmias, but there is some evidence that Mg^{++} depletion may sensitize the heart to cardiac glycosides (Lown et al. 1960).

TREATMENT. Although radioimmunoassay techniques can distinguish obviously subtherapeutic and toxic plasma concentrations of digitalis, considerable overlap occurs; a therapeutic concentration in one patient may be toxic to another. Clinical experience and judgment must still be exercised when digitalis intoxication is differentiated from exacerbation of cardiac failure with its attending dysrhythmias.

When digitalis intoxication is diagnosed, the first procedure is to withdraw glycoside therapy; the patient's progress should then be followed closely with frequent ECG monitoring. These conservative measures in conjunction with cage rest often are effective in controlling cardiac arrhythmias and other signs of intoxication; however, appropriate therapy should be instituted if arrhythmias worsen or fail to revert spontaneously.

Potassium chloride (KCl) has been administered in an attempt to increase plasma K^+ concentrations to upper limits of the normal range and thereby suppress glycoside arrhythmias. Conversely, if plasma K^+ is already high in the digitalis-intoxicated dog, administration of exogenous K^+ can actually cause further deterioration of ECG patterns. Obviously, considerable care should be exerted when K^+ therapy is employed in managing digitalis toxicity. In dogs, the dosage schedule for KCl has included 0.6-1 g orally as the initial dose, followed by 0.3-0.5 g every 1-2 hours for 2 doses, and continued at 4-hour intervals as necessary to control arrhythmias (Detweiler 1977). Slow IV infusion of KCl with frequent monitoring of the ECG and serum K^+ concentrations may be attempted (Ettinger and Suter 1970). However, too rapid an infusion of potassium salts may precipitate other arrhythmias, including ventricular fibrillation.

Cholestyramine Resin, USP, is an exchange resin that binds glycoside within the digestive tract; it has been used experimentally in attempts to interrupt the enterohepatic cycle and thereby hasten elimination of the digitalis compound. The use of specific antiglycoside antibodies is another therapy (Haber 1985; Kurowski et al. 1992). Agents such as Mg^{++}, procainamide, quinidine, EDTA, sodium citrate, saturated lactones, and salts of canrenoate have received little clinical use in animals. Of the antiarrhythmic agents, lidocaine, propranolol, and, especially, phenytoin are the most useful in controlling digitalis-induced arrhythmias (see Chap. 24). Atropine may be helpful in cases with severe sinus bradycardia. In the presence of AV block, antiarrhythmic agents and K^+ therapy should be avoided. Use of antiarrhythmic interventions so that the dose of digitalis can be increased in the hope of attaining a larger inotropic response is dangerous and unwarranted. Quinidine may actually cause an increase in plasma concentrations of digoxin (see Chap. 24).

Therapeutic Indications for Digitalis

CONGESTIVE HEART FAILURE. The most important indication for digitalis therapy in veterinary medicine, as in human medicine, is congestive heart failure. However, while there are considerable data available from experimental studies in animals and clinical studies in humans, there is remarkably less information about clinical use of digitalis in animals with spontaneous heart disease. Accordingly, controversy exists relative to the actual survival benefits of digitalis glycosides in the long-term therapeutic management of cardiac disease in animal patients (Hamlin et al. 1973; Patterson et al. 1973). Nevertheless, many, if not most, clinicians and cardiologists believe firmly that digitalis remains a mainstay of therapy for congestive heart failure (Braunwald 1985).

In a study of 10 large-breed dogs with idiopathic congestive cardiomyopathy, Kittleson et al. (1985a) reported that only 4 dogs showed echocardiographic evidence of a positive inotropic response to digoxin (0.22 mg/m^2 body surface area, twice a day). The average survival time for the 4 digoxin-responsive patients was almost 10 months, and 3 of these lived for 2-7 years. Survival time of the 6 nonresponders ranged only from 1 to 12 weeks. These studies suggest that only a portion of large dogs with congestive cardiomyopathy respond to digoxin but that survival may be prolonged in this subset of patients. Alternatively, as the authors point out, perhaps the 4 responsive dogs simply had reversible heart disease and with the aid of digoxin therapy reverted to normal function. These types of clinical pharmacologic studies are needed in veterinary medicine, and they should be expanded to include larger numbers of patients and drug withdrawal study periods.

Cardiac glycosides are indicated in congestive failure irrespective of whether it is predominantly of the left ventricle, right ventricle, or both. Heart failure resulting from an absolute or relative chronic overload in which the supply of energy to the heart is uncompromised is especially responsive to digitalis therapy. These types of problems include valvular lesions, hypertension, passive outflow impedance (e.g., dirofilariasis), and idiopathic dilated cardiomyopathy. Cardiac dysrhythmias can affect the response to digitalis glycosides, but they do not alter the indication for the drug if congestive failure is present.

ATRIAL ARRHYTHMIAS. Digitalis often is considered the most useful drug in treatment of atrial fibrillation or flutter, whether or not congestive heart disease is present. However, the drug should not be employed for abolition of the arrhythmic pattern. The goal of digitalis therapy in either of these states is to reduce ventricular rate by slowing AV conduction, eliminate the pulse deficit if present, and improve cardiac efficiency (Meijler 1985). Subsequently, quinidine can be used to abort atrial dysrhythmia. (However, see Chap. 24.) The potential involvement of latent or hidden congestive heart failure in pathogenesis of atrial fibrillation in some animals should not be discounted; the beneficial results from digitalis in treating what seems to be uncomplicated atrial fibrillation may well involve such complexities.

PROPHYLACTIC DIGITALIZATION. Digitalis pretreatment may be of some value in patients scheduled for unusual cardiac strain, as in open-heart surgery, if there is evidence of reduced cardiac reserve. Experimentally, the positive inotropic effect of the drug provides some protection to the heart against depressant effects of anesthetics. Early studies indicated that prophylactic digitalization protected dogs from myocardial weakening in experimental hemorrhagic shock and thus prolonged survival time (Braunwald and Kahler 1964). However, routine clinical use of digitalis in such situations is not recommended and actually may be contraindicated. As stated earlier, digitalis therapy can cause peripheral vasoconstriction in the normal patient without congestive failure syndrome. Splanchnic arteriolar constriction can intensify tissue hypoxia in shock. An obvious major hazard of prophylactic therapy with digitalis is inadvertent attainment of intoxication rather than digitalization. In most situations, therefore, digitalis should be reserved for therapy of congestive heart failure and should not be used in attempts to prevent cardiac failure in seemingly normal patients.

PRECAUTIONS. Digitalis is not indicated in cases of circulatory shock, renal failure, hepatic failure, ventricular premature contractions, ventricular tachycardia, or heart block unless the abnormality is associated with congestive heart failure. Digitalis therapy in congestive failure patients with heart block or ventricular tachycardia should be supervised in a particularly intensive manner, and digitalization should be monitored closely with an ECG. Digitalis can accentuate AV block and a serious decrease in ventricular rate may result. Digitalis treatment can also transform ventricular tachyarrhythmias to fibrillation.

Although digitalis slows sinus rate in congestive heart disease, this activity is complex and has no application in attempts to reduce heart rate when sinus tachycardia is present without evidence of congestive failure. Tachycardia associated with other conditions such as fever, thyrotoxicosis, constrictive pericarditis, or cardiac tamponade is not amenable to digitalis therapy. Hypertrophic cardiomyopathies and ruptured chorda tendinae constitute other nonindications for digitalis therapy.

Digitalis toxicosis can simulate certain aspects of cardiac disease, especially serious arrhythmias. Clinicians should always ascertain that any patient scheduled for cardiac glycoside treatment has not recently received any digitalis preparation; otherwise, an attempt to produce therapeutic digitalization in a patient actually suffering from unrecognized digitalis intoxication can have negative results.

Clinical Procedures

SELECTION OF DIGITALIS GLYCOSIDE. Ouabain is the most potent of the three glycosides, it acts most rapidly, and its effect dissipates most quickly. Ouabain is absorbed too poorly to be effective if given orally, and its use has been reserved for IV administration during emergencies. Currently, however, ouabain is rarely used in clinical veterinary medicine because digoxin is also effective when parenterally administered and is believed to be relatively less toxic than ouabain. Both digoxin and digitoxin are suitable for oral and parenteral digitalization and maintenance therapy. Digoxin often is preferred over digitoxin when a more rapid effect with oral administration is desired (Detweiler 1977). It should be emphasized, however, that well-controlled clinical comparisons between digitoxin and digoxin are lacking. Some clinicians believe that digoxin is more effective, more reliable, and less toxic than digitoxin. Conversely, some clinicians advocate that digitoxin is just as dependable and less toxic than digoxin. Additional documentation of clinical results is needed to resolve these differences.

DIGITALIZATION. A basic procedure followed in the past by many clinicians involves initial administration of a large amount of digitalis in several divided doses over a relatively short period (24-48 hours) to quickly achieve the desired therapeutic effect. Treatment is then continued daily with smaller doses to maintain therapeutic efficacy. The quantity of drug necessary to achieve the initial response is commonly designated as the digitalization or loading dose, whereas the daily dose needed to maintain this level of therapeutic action is called the maintenance dose. The digitalization and even the maintenance dose cannot be precalculated with absolute precision because of marked interpatient variation in response to therapeutic and toxic actions of the glycosides. Thus digitalization of each patient should be considered an individual and separate project subject somewhat to trial and error as the search is made for an efficacious dose without inducing toxic side effects.

To achieve this objective, an estimate of the digitalization dose is based on the standard range of loading doses for the selected glycoside and severity of the physiologic status of the patient (e.g., age, phase of cardiac disease, renal function). An estimate of the maintenance dose is based in turn on the standard maintenance dose range of the drug and, most importantly, the patient's response to the loading dose regimen. In essence, the goal is to determine the smallest amount of glycoside that will effectively maintain the patient in a state of cardiac compensation without inducing signs of intoxication.

ORAL SCHEDULES AND MAINTENANCE DOSES. Techniques used for achieving oral digitalization can be placed into three general time courses: slow, rapid, and intensive. The slow method is generally used when mild failure is presented; the total estimated loading dose is administered in 5 equal parts over 48 hours until salutary effects are gained or toxicity supervenes. With the rapid technique, the loading dose is divided into 3 equal amounts given at intervals of 6 hours. The intensive schedule is usually not selected unless an emergency or near emergency exists; one-half the loading dose is given initially, one-fourth is given 6 hours later, and one-eighth is given at 4- to 6-hour intervals. After digitalization is achieved with the above schedules, the maintenance dosage regimen is then instituted (Detweiler 1977).

In actual practice, the precise schedule selected can be less important than the care taken in monitoring patient response during implementation. In all cases, a predetermined dose should not be administered indiscriminately until toxic effects are seen. Careful supervision of the patient should allow detection of therapeutic benefits before toxicity is evoked. Nevertheless, if signs of intoxication supervene early in the digitalization schedule before salutary effects are attained, treatment must be halted and resumed at a lower dose after signs of toxicosis are absent. Similarly, if toxicity develops during maintenance therapy, the dose must be readjusted to a lower level. Conversely, the dose may have to be increased or administered at shorter intervals if therapeutic effects are not achieved with the predetermined schedule. Thus semantics about rigid time schedules should be interpreted in the clinic in accordance with needs of the individual patient. Unquestionably, as pointed out below, many clinicians now believe that loading dose digitalization techniques are unnecessary and may lead to intoxication.

A listing of average dose levels of digitalis glycosides is provided in Table 23.3. An approximate total loading dose for digoxin in dogs is 0.11-0.22 mg/kg; this amount can be divided into 5 equal doses of 0.022-0.044 mg/kg and each dose administered at 12-hour intervals for 48 hours. The daily maintenance dose of digoxin is 0.022 mg/kg; this can be divided into 2 equal doses of 0.011 mg/kg and each dose administered at 12-hour intervals after initial digitalization has been achieved (Table 23.3).

Modifications of the above procedure have been proposed. Data published by De Rick et al. (1978) indicated that administration of 0.025 mg/kg digoxin every 12 hours for 36 hours (i.e., a total digitalization dose of 0.1 mg/kg), followed by a maintenance dose of 0.01 mg/kg every 12 hours, was associated with less toxicity than larger loading dose techniques. The digoxin data presented in Fig. 23.10 show that this schedule leads to therapeutic blood levels, whereas a larger loading dose results in initial plasma concentrations associated with toxicosis.

Harris (1974) and Hahn (1977) advocated that a loading dose of digoxin is not necessary in dogs and that daily maintenance doses of 0.022 mg/kg given in 2 equal amounts at 12-hour intervals should be implemented as the original procedure. This would reduce the likelihood of intoxication associated with the larger loading dose techniques. Using complex pharmacokinetic calculations based on individual animals, Button et al. (1980a,b) found that the standard 0.022 mg/kg was a likely daily maintenance dose of digoxin in dogs.

Kittleson (1983) pointed out that because of its high toxic/therapeutic dose ratio, digitalis should be administered according to body surface area rather than body weight. Thus, since the body surface area/body weight ratio generally decreases as the size of the dog

TABLE 23.3—Guidelines for approximating doses and dosage schedules for digitalis glycosides in dogs

	Loading dose technique		
Drug	Total dose	Administration schedule	Daily maintenance dose and schedule
Oral			
Digitoxin*	0.11–0.22 mg/kg	0.022–0.044 mg/kg q12h for 48 hr	0.011 mg/kg q12h
Digoxin†	0.066 mg/kg	Three divided doses on day 1 of therapy	0.022 mg/kg daily
Digoxin§	0.1 mg/kg	0.025 mg/kg q12h for 36 hr	0.011 mg/kg q12h
Digoxin‖	...	...	0.011 mg/kg q12h
Digitoxin*	0.022–0.044 mg/kg	0.0044–0.0088 mg/kg q12h	0.0022–0.0044 mg/kg q12h
Digitoxin#	0.44 mg/kg	Divided doses over 48 hr	0.11 mg/kg daily
Parental			
Ouabain	0.022–0.033 mg/kg	Three divided doses over 24 hr	Oral digoxin 0.011 mg/kg q12h
Digoxin	0.022–0.044 mg/kg	Three divided doses over 24 hr	Oral digoxin 0.011 mg/kg q12h

Note: q12h = every 12 hours.

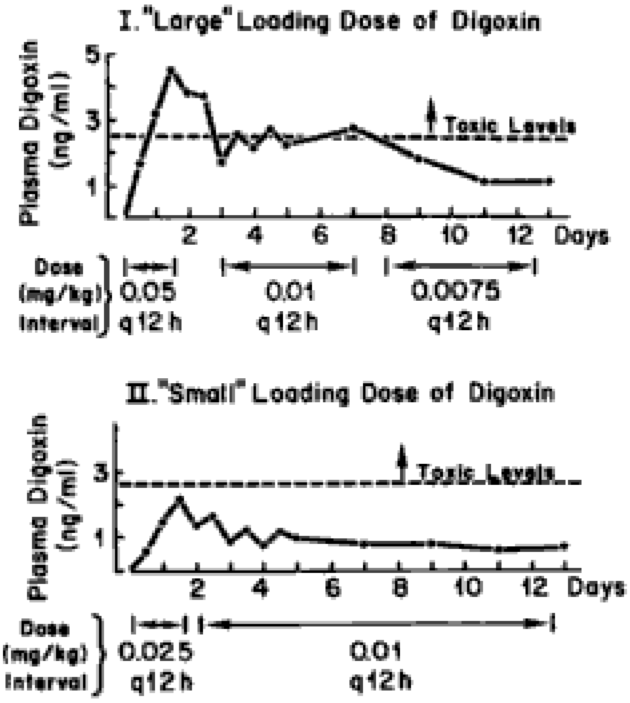

FIG. 23.10—Dosage schedules and plasma concentrations of digoxin after oral digitalization with a "large" (I) or "small" (II) loading dose. Notice in the top graph that with a large loading dose technique (0.05 mg/kg every 12 hr), plasma concentrations initially were in the toxic range (>2.5 ng/mL), whereas in the bottom graph with the smaller loading dose technique (0.025 mg/kg/12 hr), plasma concentrations did not exceed toxic levels and remained within presumed therapeutically effective concentrations. (Modeled after De Rick et al. 1978.)

increases, larger canine breeds would require less digitalis per kilogram of body weight than the small breeds. According to a recommended twice-a-day digoxin dose of 0.22 mg/m^2 body surface area (Kittleson 1983), dogs weighing 10, 20, 30, 40, and 50 kg would receive 0.011, 0.009, 0.008, 0.007, and 0.006 mg digoxin/kg respectively twice daily. Clinical trials support the merit of this approach (Kittleson et al. 1985a).

One pharmaceutical company that produces digitoxin suggested a loading dose of 0.022-0.044 mg/kg, followed by a maintenance dose of 0.0044-0.0154 mg/kg every 24 hours in dogs. Another company proposed a loading dose of 0.044 mg/kg divided into 10 equal doses, each dose given every 8 hours, followed by a daily maintenance dose of one-fifth of the digitalization dose (i.e., 0.0088 mg/kg) (Table 23.3). Much larger amounts of digitoxin have been used and advocated by clinicians (Ettinger 1966; Detweiler 1977). Differences may well relate to product formulations, routes of administration, bioavailability, and technical methods. These problems validate the need for the clinician to become thoroughly familiar with use of a few preparations rather than attempting to use a wide variety of the different products now available.

Cats are generally much more sensitive to digitalis than are dogs, and digitalis is not commonly used in cats. Tilley and Weitz (1977) indicated that an average maintenance dose of digoxin in cats is 0.008-0.01 mg/kg/day, divided into 2 equal doses.

Body weight resulting from edema fluid should be discounted in estimating the digitalis dose. Because of the importance of renal and hepatic function in eliminating digitalis glycosides, dose levels also should be reduced in animals with kidney or liver disease. Otherwise, toxicosis may develop unexpectedly following usual loading doses. As outlined earlier, dogs weighing more than 12-15 kg generally require less digitalis per kilogram of body weight than smaller dogs.

PARENTERAL SCHEDULES. IV administration of cardiac glycosides is indicated when the patient does not retain oral medications or has acute cardiac decompensation or respiratory distress.

Dose schedules for routine parenteral digitalization with digoxin and ouabain are included in Table 23.3. IV administration increases the likelihood for toxic arrhythmias, and this limitation should be considered. Intramuscular injection reduces the danger, but pain and swelling at the injection site limits patient acceptance of this method. Oral maintenance doses should be substituted if feasible.

The positive inotropic response to digoxin and digitoxin can be detected within 15-30 minutes after IV administration in dogs (Hamlin et al. 1971), somewhat sooner with ouabain. The rapid hemodynamic effects of ouabain in a dog with congestive failure are illustrated in Fig. 23.8. When an emergency is presented, the total IV loading dose for both ouabain and digoxin is approximately 0.044 mg/kg (Ettinger and Suter 1970). These two drugs are administered somewhat differently based on their dissimilar durations of action. With both ouabain and digoxin, 25-50% of the total dose is administered initially by slow IV injection; an additional 25% is given every 30-60 minutes (ouabain) or 60-120 minutes (digoxin). Patients treated with these techniques should be closely examined for signs of intoxication and monitored continuously for ECG abnormalities. Other emergency procedures are covered later.

LARGE ANIMALS. Loading or digitalization dose ranges for several digitalis preparations used in horses and cattle are given in Table 23.4. The daily maintenance dose is generally set at one-eighth to one-fifth of the loading dose. Actually, however, relatively little clinical work has been done with digitalis in these species, and dosage recommendations should be considered provisional (Detweiler and Patterson 1963). Parenteral administration is used in cattle and other ruminants because ruminal microorganisms can inactivate a large portion of digitalis.

Based on experimental pharmacokinetic data derived from normal horses, Button et al. (1980c) proposed the following schedule for digoxin: an IV loading dose of

TABLE 23.4—Approximate digitalization doses for horses and cattle

Preparation	Route	Total dose
Horses		
Digitalis powder	Oral	33-66 mg/kg
Digitalis tincture	Oral	0.33-0.66 ml/kg
Digitoxin	Oral	0.033-0.066 mg/kg
Digoxin	Oral	0.066 mg/kg
Digoxin	Parenteral	0.022-0.033 mg/kg
Ouabain	Parenteral	0.0132-0.022 mg/kg
Cattle		
Digitoxin	Intramuscular	0.031 mg/kg
Digoxin	Intravenous	0.0088 mg/kg
Ouabain	Intravenous	0.0132-0.022 mg/kg

Source: Detweiler 1977.

0.014 mg/kg, an IV maintenance dose of 0.007 mg/kg/24 hr, an oral loading dose of 0.07 mg/kg, and an oral maintenance dose of 0.035 mg/kg/24 hr. When these doses were given to horses, plasma digoxin concentrations measured 12 and 24 hours after administration were mostly in the assumed therapeutic range of 0.5-2 ng/mL.

Preparations. *Digitalis,* USP—*Digitalis purpurea;* potency of digitalis (100 mg) should be equivalent to but not less than 1 USP Digitalis Unit.

Powdered Digitalis, USP.

Digitalis Tablets, USP—tablets, 60 and 100 mg.

Digitoxin, USP—cardiotonic glycoside from *D. purpurea, D. lanata,* and other suitable species of the genus *Digitalis.*

Digitoxin Injection, USP—digitoxin in 5-50% alcohol; injections, 0.2 mg digitoxin/1 mL.

Digitoxin Tablets, USP—tablets, 0.1 and 0.5 mg.

Digoxin, USP—cardiotonic glycoside from *D. lanata.*

Digoxin Injection, USP—digoxin in 10% alcohol; injections, 0.5 mg/2 mL.

Digoxin Tablets, USP—tablets, 0.25 and 0.5 mg.

Digoxin Elixir—digoxin, 0.05 or 0.15 mg/mL in 30% alcohol.

Ouabain, USP—G-strophanthin.

Ouabain Injection, USP—injections, 0.25 mg/mL and 0.5 mg/2 mL.

AMRINONE AND MILRINONE. Amrinone and milrinone are bipyridine derivatives commonly referred to as nonglycoside, noncatecholamine inotropic drugs. These compounds were discovered during an investigative search for cardiac stimulant agents that could be used to replace digitalis in the therapy of heart failure (Alousi et al. 1979). Numerous studies have now confirmed that amrinone and milrinone evoke both a positive inotropic action in the heart and a peripheral vasodilator effect. The mechanism of action of the bipyridines is dissimilar from that of digitalis and does not involve adrenergic or other cell surface receptors. Rather, the cardiac inotropic and peripheral vasodilator actions of amrinone and milrinone involve inhibition of the type III cyclic nucleotide phosphodiesterase enzyme. This enzyme is responsible for the selective metabolism of cAMP; hence, inhibition of type III phosphodiesterase by amrinone or milrinone results in the accumulation of intracellular cAMP in cardiac and vascular tissues. Cyclic AMP subserves a positive inotropic response in myocardium and a vasodilatory response in blood vessels. Because of concurrent inotropic and vasodilator actions, considerable attention has been focused first on amrinone and more recently on milrinone as alternatives for digitalis in managing congestive heart failure patients (Mancini et al. 1985; Colucci et al. 1986a,b).

Amrinone. IV administration of amrinone (1-10 mg/kg) to anesthetized and unanesthetized dogs increased cardiac contractile force and left ventricular pressure with relatively small changes in heart rate and blood pressure. Administered orally to dogs, amrinone (2-10 mg/kg) produced a positive inotropic effect with rapid onset (within 15 minutes) and long duration of action (approximately 5 hours). Acute hemodynamic response to amrinone also has been studied extensively in human patients with refractory heart failure. Amrinone by oral or IV administration consistently enhanced cardiac contractile indexes while decreasing ventricular filling pressure/volume (preload) and systemic vascular resistance (afterload). Heart rate and blood pressure were affected slightly by therapeutic doses. Importantly, amrinone also decreased myocardial oxygen consumption of the failing heart. Thus reductions in cardiac preload and afterload represent important aspects of amrinone's hemodynamic profile because they apparently offset the metabolic cost of the drug's positive inotropic action. Because of this beneficial spectrum of cardiovascular effects, parenterally administered amrinone was approved for use in the short-term therapy of heart failure in humans.

Despite obvious beneficial actions of amrinone in managing acute exacerbation of heart failure, studies in humans have questioned whether long-term oral administration of amrinone is clinically effective in therapy of chronic congestive heart failure (Massie et al. 1985). These results illustrate the potential pitfalls of trying to extrapolate results from acute studies to the exceedingly more complex situation of chronic therapy of heart failure. Moreover, adverse side effects occurred in 83% of these amrinone-treated patients after long-term therapy, necessitating drug withdrawal in 34%. Thrombocytopenia is a serious side effect of amrinone in about 15% of human patients chronically treated. This untoward reaction does not seem to be a problem in dogs.

Milrinone. Milrinone is a structural congener of amrinone, and the former is 20-30 times more potent than the latter. Initial studies suggested that milrinone might be relatively free of adverse side effects in reasonable doses and could be helpful in the management of heart failure patients in human medicine (Colucci et al. 1986a, b). However, studies with human patients with moderately severe heart failure indicated that milrinone was less effective than digoxin, and the combination of milrinone and digoxin was no more effective than digoxin alone. Moreover, milrinone administration was associated with an increased incidence of both ventricular and supraventricular tachyarrhythmias as adverse side effects (DiBianco et al. 1989).

Tachyarrhythmias could have been predicted as an adverse side effect of milrinone and other phosphodiesterase inhibitors inasmuch as their mechanism of action depends upon accumulation of cAMP. The latter not only subserves positive inotropic actions in the heart but also increases cardiac automaticity in sinoatrial pacemaker cells and other cardiac tissues that carry spontaneous automaticity. Emergence of latent pacemakers and associated ectopic beats and tachyarrhythmias can be expected as limiting side effects of drugs that affect the heart through the cAMP system. Hence, the initial enthusiasm for cardiac uses of milrinone and other type III phosphodiesterase inhibitors has decreased (Massie et al. 1985; DiBianco et al. 1989).

A collaborative investigation involving three teaching veterinary hospitals provided evidence that milrinone may be effective in dogs with spontaneous heart failure (Kittleson et al. 1985b). This study included a randomized blinded evaluation of milrinone (0.5-1.0 mg/kg) versus placebo for a 4-week period in a total of 14 dogs, 11 with left ventricular failure and 3 with right ventricular failure. All dogs in this study with echocardiographic evidence of mild-to-severe myocardial failure and clinical evidence of poor-to-good compensation for their heart failure responded favorably to treatment with milrinone as the sole therapeutic agent, as determined by echocardiography. This salutary effect was sustained for the 4 weeks of the study; it was not due to spontaneous remission of the disease because heart failure worsened when milrinone was withdrawn and improved when the drug was reinstituted. The only apparent adverse reactions were asymptomatic ventricular dysrhythmias in 2 dogs. The improved ventricular performance observed in this study was attributed to a direct increase in myocardial contractility owing to milrinone's positive inotropic action, to a decrease in cardiac work load owing to milrinone's vasodilator effects or, more likely, to a combination of both. These investigators concluded that milrinone may be an effective drug for treating myocardial failure in the dog when administered orally twice daily in 0.5-1 mg/kg doses.

The biologic half-life of milrinone is about 2 hours in dogs; the onset of action occurs within 30 minutes of oral administration and the duration of effect has been reported to be about 6 hours. However, the maximal response to milrinone in dogs with spontaneous heart failure develops about 1.5-2 hours after administration and dissipates rather quickly thereafter. Kittleson et al. (1985b) suggested, therefore, that dogs with severe decompensation of their heart failure may benefit from 3-4 daily doses of milrinone to take advantage of the maximal effects of the drug.

Milrinone was advanced as either a primary drug of choice in congestive heart failure or as an alternative in congestive failure patients who become refractory to digitalis. Additional controlled clinical trials with milrinone are needed to determine whether the beneficial results observed by Kittleson et al. (1985b) during their 4-week study are sustained over longer intervals without limiting side effects. It is unclear if arrhythmogenic side effects will be a limiting factor for milrinone in dogs, as it is in humans (DiBianco et al. 1989).

VASODILATOR DRUGS. Careful use of peripheral vasodilator drugs has been developed extensively as treatment in congestive failure to "unload" the failing heart (Hamlin 1977; Zelis et al. 1979; Remme 1993). The rationale for this treatment is the idea that decreasing the work load of the heart is better for the patient than administering a positive inotropic agent with considerable toxic potential (i.e., digitalis). If systemic arterial pressure (i.e., left ventricular afterload) is reduced by a vasodilator drug, the left ventricle will be ejecting blood into a circuit with lowered resistance. Further, peripheral venodilation will divert blood volume from the pulmonary to the systemic vasculature. This response is antagonistic to the formation of pulmonary edema and also tends to restrict venous return to the heart (i.e., ventricular preload). Left ventricular size and wall tension decrease in response to reduction in ventricular preload and afterload. Myocardial oxygen demands decrease accordingly as the workload of the heart is reduced; cardiac output and hemodynamics should improve (Packer 1984; Abrams 1985).

Before resorting to vasodilator therapy in treating congestive failure in animals, the clinician should be aware of potential problems; e.g., it has been assumed that drug-induced vasodilation would automatically increase peripheral perfusion and thereby increase oxygen availability to all tissues. However, vasodilator agents of the nitroglycerin type exert a predominant reduction in peripheral venous resistance as compared to arteriolar resistance. Pooling of blood in the venous capacitance beds in no way ensures increased perfusion of all tissues. Vasodilators are beneficial to the failing heart because they decrease cardiac workload, not by directly improving peripheral perfusion because of vascular dilation. Furthermore, if arterial pressure is critically decreased, blood flow through the coronary and renal vascular beds may be compromised further. Reflex tachycardia accompanied by increased myocardial oxygen demand is another potential problem associated with fall in systemic blood pressure.

Prazosin. Atwell (1979) indicated that peripheral vasodilation induced by prazosin hydrochloride (Minipress), an α_1-adrenergic selective blocking agent (Chap. 6), was effective in 4 dogs with congestive failure that were refractory to digoxin. However, digoxin was actually continued in 3 of the 4 dogs at reduced dosage levels. Thus the beneficial response may well have resulted from a combination of mechanisms involving both a positive inotropic action on the heart (digoxin) and peripheral vasodilation (prazosin).

Hydralazine Hydrochloride. *Hydralazine Hydrochloride,* USP (Apresoline), is an arteriolar dilator that has undergone limited clinical trial in dogs with volume-overload heart failure (Kittleson et al. 1983). Because of its vasodilator action in systemic arterial beds, hydralazine reduces peripheral vascular resistance and lowers impedance to left ventricular ejection. Stroke volume and cardiac output increase proportionately, thereby initiating hemodynamic improvement.

Beneficial effects of hydralazine are manifested mainly in congestive heart failure that is secondary to mitral valve insufficiency. In this pathophysiologic state, forward left ventricular stroke volume is reduced owing to a regurgitant fraction being pumped backward through the incompetent AV valve into the left atrium. By lowering systemic impedance to left ventricular ejection, hydralazine increases forward stroke volume and thereby reduces the regurgitant fraction. End-systolic volume and cardiac size are reduced because more blood is pumped out of the cardiac chambers per beat. Reduction in cardiac size leads to commensurate decreases in wall tension and myocardial oxygen consumption and, also importantly, to reduction of the orifice of the incompetent mitral valve. The latter contributes in turn to further diminution of the regurgitant fraction. This cycle leads to hemodynamic improvement and, it is hoped, pharmacologically supported compensation of the heart failure patient. Indeed, clinical studies indicate that hydralazine therapy is effective in dogs with volume-overload congestive failure caused by mitral valve insufficiency (Kittleson et al. 1983). Hydralazine may be similarly effective in aortic valvular insufficiency.

Hydralazine is absorbed rapidly after oral administration in dogs; its onset of action develops within 1 hour, and peak response occurs at 3-5 hours. The drug undergoes extensive hepatic metabolism during its initial passage through the liver in the portal blood. There is evidence that uremia in some way affects biotransformation of hydralazine, so that blood concentrations may increase in uremic patients. A recommended dose schedule for hydralazine in dogs involves the initial oral administration of 1 mg/kg; this dose can be adjusted upward, depending upon evidence of clinical improvement, but should not exceed 3 mg/kg. Average-size adult cats may require an initial oral dose of 2.5 mg, which may be adjusted upward to 10 mg. The therapeutic response generally lasts 11-13 hours; thus twice daily administration is suggested as the standard (Kittleson 1983).

Important side effects of hydralazine therapy in humans are tachycardia and hypotension. It was reported that hypotension was not a problem in dogs when hydralazine dosage was titrated carefully against signs of clinical improvement; however, tachycardia does seem to be a common untoward development in congestive-failure dogs treated with hydralazine (Kittleson et al. 1983). Since tachycardia increases myocardial oxygen consumption and may therefore lead to cardiac decompensation, heart rate should be monitored during therapeutic implementation with hydralazine or any other vasodilating drug.

Concomitant administration of a β-blocking drug might reduce the reflex tachycardia produced by hypotensive reactions to hydralazine. On the other hand, the potential negative inotropic response to β-receptor blockade in the heart may exacerbate heart failure (see Chap. 6).

Captopril and Enalapril Maleate. Recognition of the contribution of the renin-angiotensin-aldosterone axis to the pathophysiology of congestive heart failure led to development of a new group of vasodilator agents. These compounds are the angiotensin-converting enzyme (ACE) inhibitors such as captopril and enalapril maleate (Holtz 1993; Dietz et al. 1993).

Reduced perfusion of the kidneys during heart failure evokes release into the circulation of the renal enzyme renin. As detailed in Chap. 20, renin synthesizes the formation of angiotensin I. The latter is relatively inactive; however, it is metabolized by ACE into the potent vasoconstrictor angiotensin II. Thus, by inhibiting ACE, captopril and enalapril decrease the formation of angiotensin II and through this mechanism evoke peripheral vasodilation in the heart failure patient. Angiotensin II-mediated release of aldosterone also is decreased by ACE inhibitors, thus facilitating sodium excretion and diuresis. Captopril improves hemodynamics in dogs with experimental heart failure (Kittleson et al. 1993), and reduces blood concentrations of aldosterone and improves clinical status in dogs with naturally occurring heart failure (Knowlen et al. 1983); 1-2 mg/kg orally 3 times daily has been suggested as a successful dose for captopril in congestive failure in dogs (Kittleson 1983).

Recent studies with ACE inhibitors in human medicine have indicated that these agents exert substantial beneficial effects in heart failure patients (Dietz et al. 1993; Swedberg 1993). Enalapril and other ACE inhibitors improve exercise tolerance, decrease signs and symptoms of heart failure, and prolong life. Because of the rapidly expanding role of ACE inhibitors in cardiovascular therapeutics in human medicine, these drugs also are being tested in animals with spontaneous cardiac disease.

The therapeutic efficacy of the ACE inhibitor enalapril was examined in a carefully controlled study involving over 400 dogs with naturally occurring dilated cardiomyopathy or chronic valvular heart disease (Ettinger et al. 1994). Some of the dogs were subjected to invasive monitoring of cardiodynamic functions, while other dogs were observed for signs of clinical improvement or mortality. Nearly all of the dogs continued to receive conventional therapy for heart failure involving diuretics (usually furosemide) without or with digoxin. Thus, this multicenter trial actually examined the ability of ACE inhibition to augment digitalis and diuretic therapy of heart failure, rather than therapeutic benefits from enalapril alone. Nevertheless, this study yielded convincing evidence that inhibition of ACE with enalapril can improve quality of life and delay mortality in dogs with heart failure.

Enalapril reduced the following variables in dogs with heart failure: pulmonary capillary wedge pressure, heart rate, mean blood pressure, and pulmonary arterial pressure (Sisson 1992). Similar results were also seen in experimental studies with captopril (Kittleson et al. 1993). Improvements in cardiovascular functions were evident over the first 24 hours of treatment with enalapril. After 3-4 weeks of enalapril plus conventional therapy, improvement was detected in several clinical markers of hemodynamic function. These included increased exercise capacity and resulting reduction in class of heart failure, reduced signs of pulmonary edema, and overall improvement in well being. Mortality was lower in the dogs treated with enalapril, and fewer of these patients exhibited progressive worsening of heart failure (Ettinger et al. 1994).

In a subset of 148 dogs, the long-term efficacy of enalapril was evaluated by measuring when the patients died or when they had to be removed from the study because of clinical deterioration. Dogs treated with enalapril (plus standard heart failure therapy) remained in the trial for 169 ± 14 days, compared to 90 ± 17 days for dogs receiving placebo (plus standard heart failure therapy). A group of 17 Doberman Pinschers treated with enalapril and standard therapy remained in the study for 80 ± 11 days, compared to only 38 ± 8 days in the placebo cohort group of 19 Dobermans. All other breeds of dogs treated with enalapril remained in the trial 189 ± 15 days, compared to 110 ± 14 days for the placebo group. When the dogs that died from congestive heart failure or died suddenly were analyzed separately, dogs treated with enalapril lived approximately 50% longer than placebo-treated dogs. Although these studies did not evaluate enalapril alone, they clearly indicate that enalapril is markedly beneficial in the management of heart failure when added to conventional therapy with diuretics and digoxin (Ettinger et al. 1994).

Because of the importance of angiotensin in maintaining renal perfusion in heart failure and other low cardiac output conditions, renal function should be monitored during therapy with ACE inhibitors. However, results from the multicenter trial with enalapril in dogs indicated that sporadic episodes of azotemia (elevated BUN and/or serum creatinine) were seen with approximately the same frequency in the enalapril and placebo groups. Furthermore, regression analysis indicated that BUN was correlated with the dose of furosemide but not with the dose of either digoxin or enalapril. Based on these data, Ettinger et al. (1994) supported the position that the dose of furosemide should be decreased first should azotemia occur in a dog with heart failure receiving furosemide and enalapril with or without digoxin. Nevertheless, the potential for renal failure should be closely followed whenever ACE inhibitors are used.

Based on results from the multicenter study with enalapril, Ettinger et al. (1994) proposed the following guidelines for pharmacologic treatment of dogs with chronic valvular heart disease or dilated cardiomyopathy. Treatment programs should be customized to the severity of the patient's disease.

1. Dogs with Class I heart disease do not have clinical evidence of heart disease except in response to exceptionally powerful exercise or other severe cardiovascular challenges. In general, these patients do not require drugs. High-salt diets should be avoided to prevent water retention and hypervolemia. Both chronic valvular disease and idiopathic dilated cardiomyopathy are progressive and usually irreversible conditions. Their rate of progression may be abated by therapeutic intervention; however, currently there are no reliable measures that will cease progressive deterioration of the heart in these pathologic entities.
2. Dogs with Class II heart disease exhibit signs of insufficient cardiac function upon mild or moderate exercise. Enalapril at a dosage of 0.5 mg/kg once daily should be considered along with a restricted-salt diet. Renal function should be monitored regularly as signs of clinical improvement are followed.
3. Dogs with Class III heart disease have overt signs of heart failure during mild exercise; signs include dyspnea, orthopnea, cardiac cough, and episodes of pulmonary edema. Exercise tolerance is markedly diminished. Ascites and other evidence of right side heart failure commonly appear. Aggressive drug therapy should be implemented along with restriction of physical activity and dietary salt. A diuretic such as furosemide is usually started first for 2-4 days, followed by institution of enalapril at 0.5 mg/kg once daily. The dose of enalapril may be increased to a total of 1 mg/kg per day in two divided doses, depending upon clinical response. Digoxin may also be prescribed at a standard dosage and concomitantly with the diuretic, depending on signs of heart failure and cardiac tachyarrhythmias.
4. Dogs with Class IV heart failure are in acute decompensation and usually require aggressive emergency therapy with oxygen, morphine, cardiac inotropes, IV diuretics, and preload reducers. ACE inhibitors should be reserved until the patient is out of danger from acute pulmonary edema and cardiac decompensation.

ACE inhibitors such as enalapril truly represent a major new addition to drug therapy of heart failure. However, renal function should be monitored to ensure adequate perfusion of the kidneys. Furthermore, despite the impressive results of the multicenter trial with enalapril (Ettinger et al. 1994), it should be remembered that enalapril was studied only as an adjunct to conventional therapy with digoxin and diuretics. The results with these combined therapies will most likely be improved upon as additional studies examine the full therapeutic spectrum for ACE inhibitors such as enalapril.

Calcium Channel Blocking Drugs. These agents suppress calcium ion (Ca^{++}) influx through plasma membrane channels in cardiac tissues, vascular smooth muscle, and other excitable cell types (Katz 1985; Allert and Adams 1987; Opie 1984). The resulting decrease in intracellular Ca^{++} concentration leads to characteristic changes in physiologic activity of affected tissues, including reduction in myocardial contractility, vasodilation in coronary and peripheral arterial beds, lowered impedance to left ventricular ejection, reduced myocardial oxygen demand, and slowed AV impulse conduction. Because of this diverse pharmacologic profile, Ca^{++} channel blockers have been studied extensively for therapeutic application in a wide spectrum of cardiovascular disorders. Drugs of this group have been approved for the management of ischemic heart disease, hypertension, and some forms of cardiac dysrhythmias in human medicine. Other indications in people include obstructive cardiomyopathies, asthma, and cerebral ischemia (Stone and Antmann 1983; Conti et al. 1985).

Although Ca^{++} channel blockade has become a therapeutic mainstay in human medicine (Katz 1985), less is known about the clinical application of this concept in veterinary medicine (Adams 1986a; Novotny and Adams 1986; Johnson 1985; Bright 1992). The present discussion is an overview of this topic and addresses the pharmacodynamic rationale for Ca^{++} channel blocking drugs in cardiovascular therapeutics in animals, as summarized by Allert and Adams (1987). The use of verapamil and diltiazem as Class IV antiarrhythmics in treating supraventricular tachyarrhythmias is addressed in Chap. 24.

HISTORY AND TERMINOLOGY. Discovery of Ca^{++} channel blocking drugs can be traced to 1964, when the German cardiologist Fleckenstein reported that the newly synthesized drug verapamil mimicked the cardiac effects of Ca^{++} withdrawal (Fleckenstein 1983). Verapamil was being developed as a coronary vasodilator, but it also inhibited myocardial contractile strength while leaving the cardiac action potential essentially intact. Importantly, the cardiodepressant effects of verapamil could be antagonized promptly and completely by excess Ca^{++}. Fleckenstein coined the term "Ca^{++} antagonists" to describe verapamil and other drugs that exerted this basic Ca^{++}-dependent inhibitory effect as their predominant pharmacologic property (Fleckenstein 1983). Dozens of drugs that share this action subsequently have been identified, and several have been approved for clinical use in human medicine, including nifedipine, verapamil, and diltiazem. Only the last two have found useful application in veterinary medicine.

The term "Ca^{++} antagonist" is used commonly in the scientific literature. Others have questioned its pharmacologic appropriateness, however, because these drugs are not Ca^{++} analogs and they do not act by inhibiting Ca^{++} binding to cellular Ca^{++}-binding receptors such as calmodulin or troponin (Katz 1985). Rather, these agents interfere with the function of plasma membrane channels that mediate Ca^{++} entry into excitable cells. For these reasons, the terms "Ca^{++} antagonists," "Ca^{++} entry blockers," "Ca^{++} channel antagonists," and other nomenclatures are sometimes used interchangeably. Regardless of terminology, the pharmacologic rationale for therapeutic use of these drugs resides in the fundamental importance of Ca^{++} influx as an intracellular messenger system in cardiovascular tissues (Schramm and Towart 1985; Janis and Triggle 1984).

FUNDAMENTALS OF Ca^{++} CHANNEL BLOCKADE

PHARMACOLOGIC CONCEPTS. The essential roles of Ca^{++} in coupling cell membrane excitation to intracellular functions in cardiac and vascular muscle have been reviewed in detail (Janis and Triggle 1984; Reuter 1985). In essence, Ca^{++} influxing through specific plasma membrane channels gains access to intracellular organelles and through this pathway leads to activation of Ca^{++}-dependent cellular functions.

The molecular architecture and biophysical operation of the cell membrane Ca^{++} channels are incompletely understood. The channel structures are protein moieties embedded within and spanning the permeability barrier of the phospholipid plasma membrane biolayer, as illustrated in Fig. 23.11. Some of the Ca^{++} channel blocking drugs interact with specific ligand binding sites of channel elements, others seem to "plug" the outer orifice of the channel pore, whereas others may have to gain access to the cytosolic face of the cell membrane to interfere with channel operation (Schramm and Towart 1985; Janis and Triggle 1984). Despite dissimilar molecular mechanisms, the Ca^{++} channel blockers share a common pharmacodynamic property: they all inhibit Ca^{++} influx and the associated Ca^{++}-dependent physiologic responses of affected cells.

PHYSIOLOGIC CONCEPTS. A schematic representation of excitation-contraction coupling in heart muscle cells and the importance of Ca^{++} channels in this physiologic process are presented in Fig. 23.11. Cardiac excitation initially involves a rapid influx of sodium ions (Na^+) through plasma membrane passageways referred to as "fast Na^+ channels." Rapid Na^+ influx depolarizes the cell membrane. Depolarization then leads to a voltage-dependent opening of another type of plasma membrane channel referred, to as "slow Ca^{++} channels" or simply as "Ca^{++} channels" (Reuter 1985). Calcium moves inward through these open channels and serves two critical interconnected functions on a beat-to-beat basis. It replenishes sarcoplasmic reticulum stores of Ca^{++} and triggers the release of additional amounts of Ca^{++} from sarcoplasmic reticulum storage sites into the

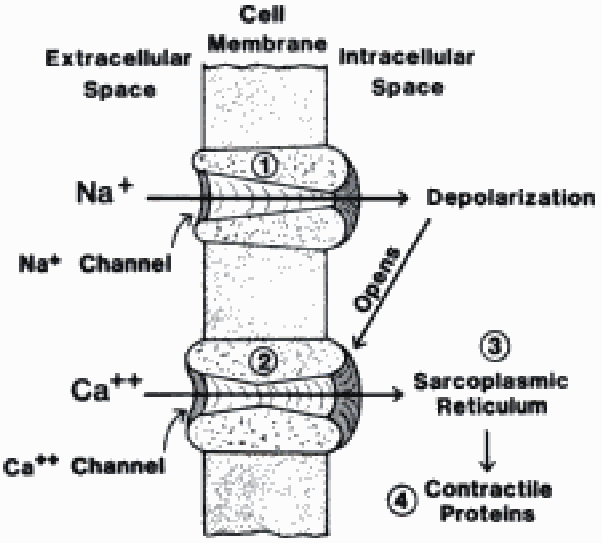

FIG. 23.11—Schematic representation of cell membrane Ca^{++} channel involvement in excitation-contraction coupling in mammalian heart. Na^{+} channels (1) open during cell excitation, and the inward Na^{+} current depolarizes the cell membrane. Depolarization opens Ca^{++} channels (2), and Ca^{++} influx triggers shift of additional Ca^{++} from sarcoplasmic reticulum (3) to contractile proteins (4). Calcium channel blocking drugs reduce Ca^{++} influx through the Ca^{++} channels (2) (Allert and Adams 1987).

cytosol. The resulting increase in intracellular Ca^{++} concentration ($[Ca^{++}]_i$) proportionately activates the contractile proteins of the cardiac myocyte (Fig. 23.11), and the heart contracts. Diastolic relaxation develops as the sarcoplasmic reticulum avidly resequesters Ca^{++} away from the contractile apparatus. Thus, Ca^{++} channel blocking drugs induce negative inotropic effects in the heart by reducing trans-sarcolemmal influx of activator Ca^{++} (Fig. 23.11).

Contraction of vascular smooth muscle is mediated by Ca^{++} and depends on the influx of Ca^{++} through cell membrane channels (Somlyo 1985). Therefore, Ca^{++} channel blockade in vascular smooth muscle evokes vascular smooth muscle relaxation and vasodilatory responses in different vascular beds. The resultant peripheral vasodilation and accompanying decrease in peripheral vascular resistance lower impedance to left ventricular ejection, thereby reducing ventricular wall tension during stroke volume ejection. Diminution of ventricular wall tension during systole (i.e., reduced cardiac afterload), coupled to direct negative inotropic actions of Ca^{++} channel blockade in the heart muscle, proportionately lowers myocardial oxygen demand. Hence, and this is an important aspect, Ca^{++} channel blocking drugs can preserve cardiac integrity by hemodynamically lowering myocardial oxygen demand. Certain Ca^{++} channel blocking drugs also have pronounced coronary vasodilator effects, which further improve tissue perfusion-metabolic demand relationships in the heart. This complex pharmacologic spectrum probably explains the salutary effects of Ca^{++} channel blockade in managing coronary artery-ischemic heart disease and the resulting anginal pain in people (Katz 1985; Nayler 1980; Opie 1984; Stone and Antmann 1983; Conti et al. 1985).

ELECTROPHYSIOLOGIC CONCEPTS. The importance of slow inward Ca^{++} currents to normal and abnormal rhythmicity mechanisms in the heart is reviewed in Chap. 24 (Adams 1986b; Novotny and Adams 1986). Briefly, usual electrophysiologic mechanisms of the sinoatrial (SA) and AV nodes involve Ca^{++} influx through the plasma membrane Ca^{++} channels in these tissues. Calcium channel blockade can suppress these normal mechanisms, reduce sinus rate, and slow AV conduction velocity. There also is evidence that aberrant Ca^{++} currents can arise from injured cardiac tissue and lead to reentry and automaticity forms of arrhythmias that are responsive to Ca^{++} channel blockade. Because of their unique Ca^{++}-dependent antiarrhythmic mechanism, the Ca^{++} channel blockers are considered Class IV antiarrhythmic agents (Adams 1986b; Novotny and Adams 1986; Vaughn Williams 1984) (see Chap. 24).

PATHOPHYSIOLOGIC CONCEPTS. Cellular Ca^{++} influx-efflux control mechanisms are set awry during ischemia and perhaps in many other fundamental forms of cellular injury (Trump et al. 1982; White et al. 1984). During ischemic and hypoxemic conditions, the failure of oxidative metabolism results in progressive depletion of cellular energy stores. The ability of the cell to maintain energy-dependent ionic gradients is impaired, leading to intracellular potassium ion (K^{+}) depletion and concomitant intracellular Na^{+} and Ca^{++} overloads. One consequence of increased $[Ca^{++}]_i$ is activation of Ca^{++}-regulated catabolic and lysosomal enzyme systems (Trump et al. 1982; White et al. 1984). These degradative enzymes disrupt cellular regulatory functions with further compromise of cell membrane integrity and further loss of ion permeability barriers. The $[Ca^{++}]_i$ progressively overloads the cell via this putative pathway and sequentially inhibits mitochondrial oxidative phosphorylation, impairs Ca^{++} uptake-release functions of sarcoplasmic reticulum, and eventually culminates in cell death and necrosis. Evidence for this or an analogous series of pathophysiologic processes funneling to the common event of intracellular Ca^{++} overload has been derived from studies with various types of tissue, including heart, vascular muscle, and neurons (Trump et al. 1982; White et al. 1984). Calcium channel blocking drugs reduce the increase in $[Ca^{++}]_i$ by lowering the quantity of Ca^{++} influx, at least that component occurring through the Ca^{++} channels. Decreased $[Ca^{++}]_i$ then should reduce activation of Ca^{++}-dependent degradative enzymes, thereby preserving cell viability after ischemic-related injuries (Trump et al. 1982; White et al. 1984).

CLINICAL PRECAUTIONS. On the basis of the foregoing schema of physiologic and pathophysiologic roles for Ca^{++}, it is now possible to discuss three basic types of pharmacodynamic pathways incorporating Ca^{++} channel blocking drugs into cardiovascular therapeutics in veterinary medicine. First, by evoking arteriolar dilatation and lowering total peripheral vascular resistance, these drugs should improve blood flow-oxygen demand relationships during hypodynamic circulatory conditions such as heart failure. Second, these drugs should be able to restore hemodynamic stability in patients with cardiac arrhythmias caused by abnormal Ca^{++} influx patterns. Third, these drugs should directly prolong cell viability in various tissues during ischemic-related syndromes by modulating the cellular Ca^{++} overload cascade. Some essential issues remain unresolved, however, and several important precautions should be considered by the clinician before these drugs are accepted for routine therapeutic use.

PHARMACOLOGIC HETEROGENEITY. Although the Ca^{++} channel blockers share common cellular effects, they comprise chemically unrelated subgroups with somewhat disparate tissue and systemic pharmacologic profiles (Spedding 1985; Defeudis 1985). Nifedipine, e.g., directly reduces myocardial contractile strength and slows AV conduction in isolated cardiac tissues. However, these direct cardiodepressant effects of nifedipine may not be manifested in patients with normal myocardial contractile reserves, owing to more potent vasodilator actions and the resulting baroreflex-induced cardiac stimulation. In contrast, verapamil can induce direct myocardial contractile depression and antiarrhythmic responses at dosages that induce peripheral vasodilatation. Diltiazem is a potent vasodilator that also directly decreases sinus firing rate in dosages that usually spare cardiac contractile mechanisms. Dissimilarities in systemic pharmacologic profiles have clinical relevance because they indicate that the various Ca^{++} channel blockers should not be construed as being therapeutically interchangeable.

CARDIOVASCULAR SIDE EFFECTS. Because of the essential physiologic roles for Ca^{++} influx in activation of cardiovascular tissues, the Ca^{++} channel blocking agents can be likened to a "double-edged sword" relative to benefit-risk relationships. On the one hand, the negative inotropic effects and vasodilator actions of Ca^{++} channel blockade can benefit hemodynamics by reducing cardiac workload. On the other hand, if unexpected or unabated, these same cardiovascular depressant responses obviously carry the risk of exacerbating underlying abnormalities of the circulatory system.

Adverse circulatory side effects of Ca^{++} channel blockade include contractile depression of the heart, with reduced cardiac output and hypotension. This combination of effects can result in decompensation of preclinical or compensated heart failure, precipitation of pulmonary edema, and worsening of the primary ailment. Other potential side effects are sinus bradycardia and heart block attributable to direct depression of SA firing rate and AV conduction, respectively. The propensity for cardiovascular depression should be considered whenever Ca^{++} channel blocking drugs are used. This precaution is especially valid in patients with preexisting or suspected myocardial contractile failure.

CLINICAL APPLICATIONS

SUPRAVENTRICULAR TACHYARRHYTHMIAS. The clinical antiarrhythmic applications for Ca^{++} channel blockade mainly involve the use of verapamil and diltiazem for treatment of supraventricular tachyarrhythmias (Kittleson et al. 1986; Hamlin 1986; Johnson 1985; Adams 1986a; Novotny and Adams 1986). Verapamil and diltiazem are used for conversion of paroxysmal atrial tachycardia to sinus rhythm. Atrial fibrillation and flutter constitute other important indications (Wasman et al. 1981; Smith et al. 1981). Verapamil and diltiazem usually do not convert these high-frequency atrial patterns to sinus rhythm but effectively reduce AV conduction and thereby lower the ventricular rate response, as discussed in Chap. 24.

HEART FAILURE SYNDROMES. Initial studies with nifedipine, verapamil, and diltiazem indicated favorable results in human beings with chronic myocardial contractile failure, valvular insufficiencies, or obstructive cardiomyopathies (Katz 1985; Conti et al. 1985; Lorell 1985; Rosing et al. 1979). Beneficial effects were attributed to reduced cardiac workload; improved aortic blood flow, with reduced regurgitant fraction in valvular insufficiencies; enhanced diastolic compliance, with increased ventricular filling in obstructive heart disease; or a combination of these effects. The therapeutic use of Ca^{++} channel blockade in congestive cardiomyopathies with severe cardiac contractile failure is controversial (Colucci et al. 1985; Josephson and Singh 1985; Brooks et al. 1980; Packer 1985). Josephson and Singh (1985) suggested caution in the use of these agents in patients with impaired ventricular performance and stated that available data do not support the use of calcium antagonists as afterload-reducing agents in chronic heart failure. Packer (1985) cautioned that both verapamil and nifedipine may exert notable depressant effects on right ventricular performance in patients with impaired right ventricular function. Colucci et al. (1985) similarly warned that Ca^{++} channel blockade in the setting of severe left ventricular dysfunction can result in abrupt decompensation and development of overt pulmonary edema. In contrast, treatment with verapamil or nifedipine seemed particularly effective in human patients with hypertrophic cardiomyopathy (Lorell 1985; Rosing et al. 1979). Because of shared pathophysiologic similarities between human and feline obstructive hypertrophic heart conditions (Tilley et al. 1977), it is not surprising that Ca^{++} channel blocking drugs are useful in cats with hypertrophic heart disease.

HYPERTROPHIC CARDIOMYOPATHY. In contrast to the lack of clinical interest for Ca^{++} channel blockers in dilated cardiomyopathy, verapamil and especially diltiazem are being used increasingly in dogs and cats with hypertrophic cardiomyopathy (Bright 1992). Because of reduced propensity for side effects associated with cardiac contractile depression, diltiazem is commonly the preferred drug for this condition. Recommended doses range from 1.75 to 2.5 mg/kg orally BID to TID. As with any highly active cardiovascular drug, therapy with diltiazem or other Ca^{++} channel blocker should be implemented with careful patient monitoring.

CIRCULATORY SHOCK AND TRAUMA. Calcium channel blocking drugs have been tested for salutary pharmacologic effects in experimental models of hemorrhagic shock, traumatic shock, cerebral ischemia, cardiopulmonary resuscitation, and endotoxemic shock. Studies have involved various representatives of this drug group, including verapamil, diltiazem, lidoflazine, nimodipine, nisoldipine, nivadipine, and nitrendipine (Adams 1986a). Initial data favored the general conclusion that Ca^{++} channel blocking drugs can improve the short-or long-term outcome of various induced forms of shock and trauma. Other studies, however, have indicated that Ca^{++} channel blocking effects were not helpful in some forms of induced shock and ischemia (Denis et al. 1985; Lanza et al. 1984) and could result in further reductions in blood pressure and cardiac output. Ca^{++} channel blocking drugs are not used in emergency medicine dealing with circulatory shock and trauma (Adams 1986a).

Investigators in human medicine caution that higher than "optimal" dosages of Ca^{++} channel blocking drugs can nonspecifically alter Ca^{++}-dependent hemodynamic control mechanisms and thereby exacerbate the circulatory instability already underway in a patient with compromised cardiac function (Colucci et al. 1985; Josephson and Singh 1985; Brooks et al. 1980; Packer 1985). Because of the potential for serious cardiovascular side effects associated with Ca^{++} channel blocking drugs, the patient should be under diligent monitoring or hospitalized conditions during initial determination of therapeutic response. With this conservative approach, patients with preclinical, occult, or compensated heart failure will have the advantage of immediate care if cardiovascular depressant side effects intervene. These complexities should be assessed judiciously by the clinician when the Ca^{++} channel blocking agents are considered for use in veterinary medicine. Verapamil and especially diltiazem are rapidly finding a useful niche in veterinary therapeutics dealing with supraventricular tachyarrhythmias and hypertrophic cardiomyopathies.

Other Vasodilators. Several other vasodilator drugs have been studied and employed therapeutically in humans with heart failure, including nitroprusside, nitroglycerin, isosorbide dinitrate, and Ca^{++} entry-blocking drugs. Clinical trials with these compounds are lacking in veterinary medicine. Indeed, with the notable exception of a few outstanding studies (Kittleson et al. 1983, 1985a,b; Knowlen et al. 1983; Ettinger et al. 1994), controlled clinical drug trials in spontaneous congestive heart failure in animal patients are almost nonexistent. This is in sharp contrast to human medicine, where literally dozens of double-blind, placebo-controlled drug trials appear almost annually in the cardiovascular literature. Until such studies are done in animals with spontaneous cardiac disease, cardiovascular drug therapy in veterinary internal medicine will involve a somewhat empiric approach and should be implemented carefully, with close supervision of each patient.

ANCILLARY THERAPY IN CONGESTIVE HEART FAILURE. The basic goal of therapeutic management of patients with congestive heart failure is to adjust cardiac output to meet bodily needs and, importantly, vice versa. In addition to improving mechanical performance of the heart with digitalis, other procedures helpful in attaining this goal include reducing oxygen demand by the tissues, improving oxygen uptake into the pulmonary capillary bed, decreasing pulmonary capillary pressure, reducing respiratory froth, and reducing salt intake. Except for dietary changes, all these goals theoretically can be achieved by effective drug therapy and its attendant hemodynamic improvement; however, other interventions may be necessary. This is particularly relevant in emergency situations when time may not be available for the full effects of digitalis to become manifested. Several clinical aspects concerning emergency management of congestive failure patients have been reviewed by Adams (1981).

Oxygen Demands and Delivery. In animals with mild stages of congestive failure to be treated as outpatients, severe restriction of physical exertion may be adequate to decrease oxygen needs. The owner of the animal should be advised that reduced physical activity will in all likelihood be necessary throughout the remainder of the animal's life. Initial therapy of severe cases of congestive failure includes complete inactivity in a well-oxygenated cage, especially if acute cardiac decompensation is presented. An oxygen mask, nasal catheter, or even endotracheal tube may be necessary in severe episodes of cardiogenic pulmonary edema; intermittent positive pressure ventilation is sometimes required if fluid accumulation in the lungs is overwhelming.

Diuretics. Use of potent loop-acting diuretics usually is indicated in congestive failure, and some clinicians believe these agents are drugs of choice in this condition (Hamlin et al., 1973). However, sole therapy with diuretics alone should be carefully monitored. Pronounced diuresis could reduce blood volume to the extent that ventricular filling would be inadequate. A reduced ventricular filling pressure is good on the one hand because it reduces wall tension and myocardial oxygen demand and propensity for edema. Conversely, excessive loss of venous return without concurrent positive inotropic effects may well lead to reduced cardiac output. Most cardiologists advocate the use of diuretics in conjunction with positive inotropic drugs.

Morphine. Morphine has been advocated as an agent of choice, second only to effective delivery of oxygen, in managing pulmonary edema (Davis 1979). Morphine purportedly exerts beneficial effects by three actions: sedation and relief of anxiety; conversion of rapid, violent ventilatory patterns to slow, deep respirations by depressing the respiratory centers; and dilation of splanchnic vasculature, thereby diverting blood volume from the pulmonary to the systemic circuit. IV administration of small quantities of morphine (0.05-0.1 mg/kg) can be made every 3-6 minutes while the patient's progress is monitored closely.

Inasmuch as morphine substantially reduces coronary blood flow in the dog, the question arises whether it is efficacious in treatment of cardiac dyspnea.

Other Procedures. Bronchodilating drugs (e.g., aminophylline) have been strongly advocated in treatment of congestive failure (Bolton 1977). Aminophylline and other xanthines are potent bronchodilators, but they also have direct stimulatory activity on the heart, some diuretic activity, and vasodilator effects. A usual dose of aminophylline is 10 mg/kg given orally or parenterally 2 to 3 times a day. IV administrations should be infused slowly, preferably in dilute solution. A large number of bronchodilatory antitussive-expectorant preparations have been used in congestive failure, but the potential for unexpected drug interactions should be considered. Nebulization of a 20% solution of ethanol into the respiratory tract may be of some help in reducing foaming of respiratory fluids in acute cases. Sodium intake should be restricted on a long-term basis to reduce the potential for edema formation. Low-salt dog foods are available commercially.

An arrhythmia is an abnormality in the rate, regularity, or site of origin of the cardiac impulse or a disruption in impulse conduction such that the normal sequence of atrial and ventricular activation is changed. Although numerous drugs have been identified that suppress cardiac rhythm disturbances, relatively few antiarrhythmic drugs have found strong clinical use in veterinary medicine. This chapter focuses on the more common antiarrhymic agents along with their principal pharmacodynamic actions on cardiac rate and rhythm.

RHYTHMICITY OF THE HEART. Normal cardiac rhythmicity is maintained by (1) dominance of a single pacemaker discharging regularly with the highest frequency, (2) rapid and uniform conduction through normal routes of impulse conduction, and (3) long and uniform duration of the action potential and refractory period of cardiac myofibers. In addition, duration of the Purkinje fiber action potential normally outlasts that of the ventricular muscle, thus providing a safety factor preventing reentry and reexcitation of the Purkinje system by the muscle action potential. A disturbance in any of the preceding factors can be arrhythmogenic, e.g., an inappropriate increase in automaticity of normally latent pacemaker cells, abbreviation of the refractory period, slowing of conduction velocity, or disparate refractory periods of adjacent fibers.

Arrhythmias often are associated with imbalance of the parasympathetic and sympathetic branches of the autonomic nervous system; changes in serum electrolyte concentrations, especially potassium and calcium ions (K^+ and Ca^{++}); hypoxemia; acidosis; changes in concentration of carbon dioxide; excessive stretch of cardiac tissue; mechanical trauma; myocardial disease states such as congestive heart failure and viral myocarditis; numerous drugs; and ischemia and infarction of the heart muscle.

Hemodynamic instability occurring during cardiac arrhythmias results from alterations in heart rate, changing the regularity of heartbeats, and losing atrial assistance in ventricular filling. Electromechanical synchrony of the cardiac chambers is thereby lost, culminating in ineffectual filling and ejection of the ventricles and hemodynamic deterioration of the patient. Antiarrhythmic drugs suppress arrhythmias and help restore hemodynamic stability by altering basic electrophysiologic processes in the heart.

Electrophysiologic Properties of Cardiac Cells. The classification system for clinically useful antiarrhythmic drugs is based mainly on the predominant pharmacologic effects of a drug on the action potential of cardiac cells (Vaughn Williams 1984; Adams 1986). Accordingly, a useful understanding of antiarrhythmic drug actions and affiliated nomenclature depends first on a good comprehension of basic bioelectric properties of the heart. An overview of salient features of this topic is outlined below relative to action potentials of cardiac cells and types of cardiac arrhythmogenesis.

ACTION POTENTIALS OF CARDIAC CELLS. The electrical activity of individual heart muscle cells can be recorded with a microelectrode capable of entering the intracellular space of a single cell, as shown schematically in Fig. 24.1. Some of the common terms used to describe the configuration and ionic determinants of cardiac action potential components are defined below (Adams 1986):

1. Membrane potential is the voltage difference across the cell membrane, i.e., the difference in electrical voltage between the intracellular and extracellular spaces. By convention, the resting membrane potential is defined as the charge inside the cell relative to the extracellular side, in which case the resting potential is a negative charge. An increase in resting membrane

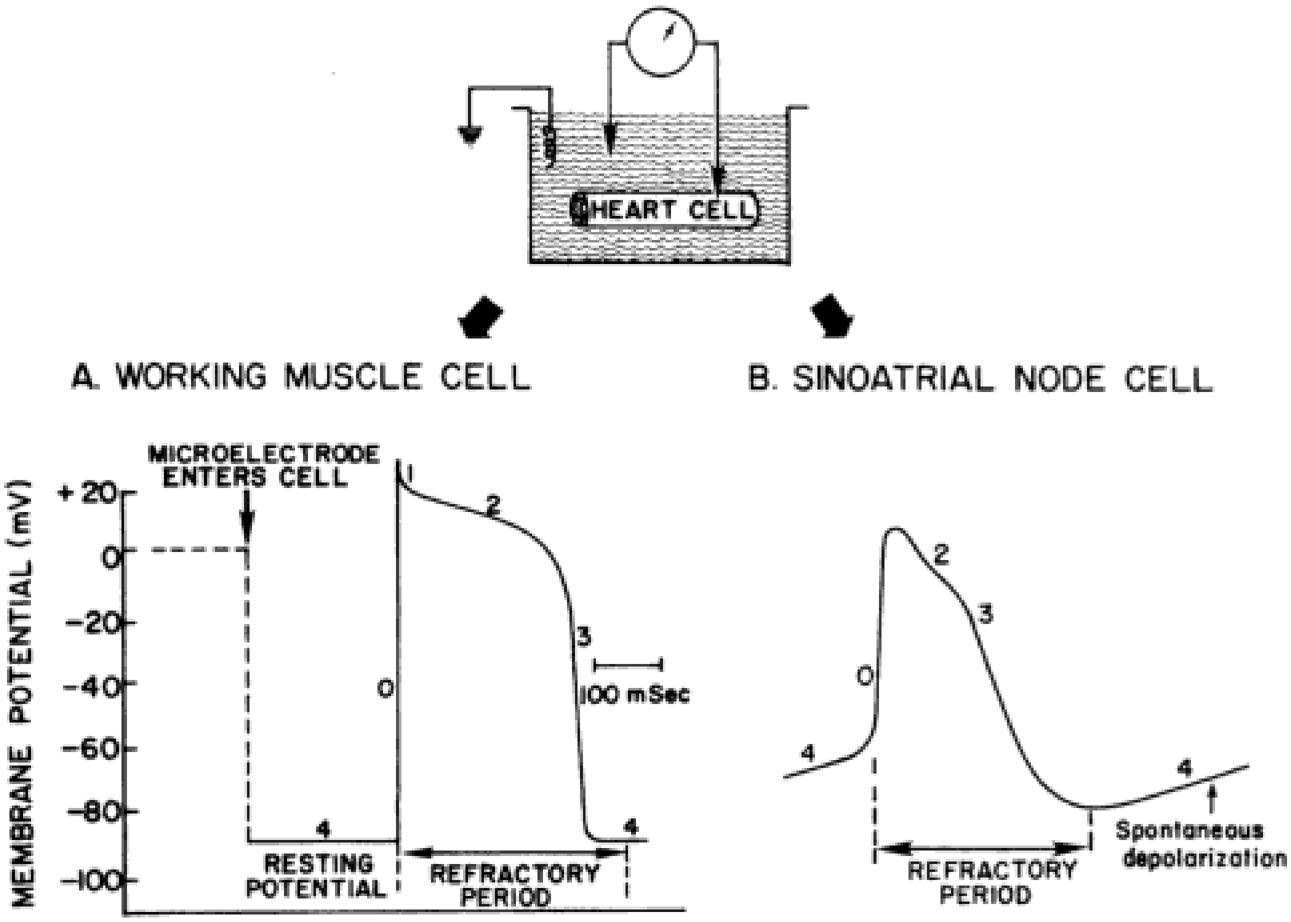

FIG. 24.1—Cardiac action potentials recorded from a working myocardial cell (A) and a sinoatrial pacemaker cell (B). The nonautomatic working muscle cell (A) exhibits a constant phase 4 resting potential during diastole, whereas the automatic cell (B) undergoes spontaneous depolarization during phase 4, leading to threshold and spontaneous excitation. The cell is inexcitable or poorly responsive to additional stimuli during much of the action potential, and this refractory period helps prevent premature excitation. See text for further details. (Source: Adams 1986.)

potential would therefore designate a more negative intracellular charge (e.g., an increase from −70 to −90 mV), while a decrease in resting membrane potential would designate a less negative intracellular charge (e.g., a decrease from −70 to −50 mV).

2. Depolarization is the loss or decrease in electronegativity of the intracellular space, e.g., a decrease in membrane potential from −90 to −50 mV (partial depolarization) or from −90 to 0 mV (complete depolarization).

3. Hyperpolarization is an increase in electronegativity of the intracellular space.

4. Inward current is the change in electrical charge across the cell membrane that results from influx of positively charged ions or, alternatively, from efflux of negatively charged ions.

5. Spontaneous depolarization of automatic cells is a physiologic and progressive decrease in resting potential during diastole, leading spontaneously to threshold and automatic firing.

6. Threshold potential is the membrane potential required for excitation of the cell, initiating the action potential and affiliated cellular responses.

7. Phase 0 is the rapid depolarization phase of the action potential of the excited cell, mediated by a rapid inward current carried by Na^+ through fast sodium channels of the cell membrane.

8. Phase 1 is the initial early repolarization phase of the action potential.

9. Phase 2 is the plateau phase of the action potential, mediated in part by a slow inward current carried by Ca^{++} through slow calcium channels of the cell membrane.

10. Phase 3 is the rapid repolarization phase of the action potential, returning membrane potential to the diastolic level.

11. Phase 4 is the membrane potential during diastole; it is constant in working muscle cells but undergoes spontaneous depolarization in cells with automaticity.

12. Refractory period is that early and late interval of the action potential during which excitability of the cell is essentially absent (functional refractory period) or depressed (relative refractory period) respectively.

13. Depressed fast sodium ion (Na^+) responses are slowly rising phase 0 depolarizations due either to

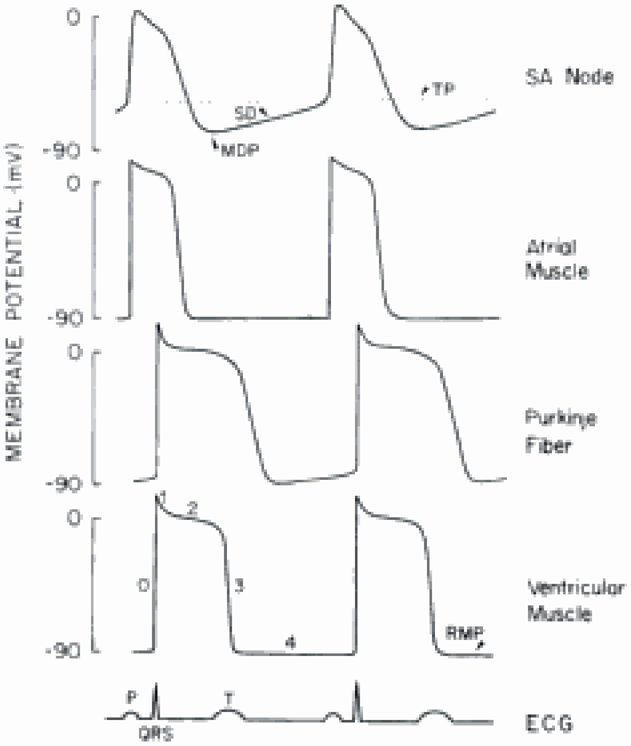

FIG. 24.2—Schematic diagrams demonstrating the temporal relationships between transmembrane action potentials recorded from cells of the sinoatrial node (SA), atrial muscle, Purkinje fibers, and ventricular muscle (see text for discussion). (Modeled after Trautwein 1963. Source: Adams 1986.)

premature excitation during the relative refractory period of normal cells or excitation of sick cells with low diastolic potentials; depressed fast Na^+ response action potentials develop cardiac impulses that propagate poorly with reduced conduction velocity.

14. Slow Ca^{++} responses are analogous to the slow inward Ca^{++} current during phase 2; this term is used to describe the very slowly rising phase 0 depolarizations mediated by Ca^{++} when the fast Na^+ channels are inoperative. Slow Ca^{++} action potentials develop cardiac impulses that propagate poorly with extremely slow conduction.

When a cardiac cell is stimulated, the electrical potential measured across the cell membrane undergoes a depolarization and repolarization cycle that can be differentiated into five interconnected components. These components are referred to as phases 0, 1, 2, 3, and 4 (Fig. 24.1). The precise morphology of the 5 phases of the cardiac action potential varies with the anatomic region of the heart. A schematic diagram illustrating the configuration of action potentials derived from SA tissue, atrial muscle (AM), Purkinje fibers (PF), and ventricular muscle (VM) is depicted in Fig. 24.2 along with corresponding waveforms of the electrocardiogram (ECG). Action potentials of a sinoatrial pacemaker cell (Fig. 24.1B) and a typical working heart muscle cell (Fig. 24.1A) will be addressed as examples of cardiac tissue with and without normal automaticity respectively.

WORKING HEART MUSCLE CELLS. Electrical diastole is designated by phase 4 of the action potential (Fig. 24.1A); during this period, the resting membrane potential of heart muscle cells is steady at about −90 mV. The interior of the cell is charged negatively relative to the extracellular space; this state of polarization across the cell membrane is maintained primarily because of the unequal distribution of K^+ inside and outside the cell. The Na^+,K^+-adenosine triphosphatase transport system maintains high intracellular K^+ relative to extracellular K^+, and the cell membrane is selectively permeable to K^+ during phase 4 diastole when compared to other ions such as Na^+ or Ca^{++}. When the cell is stimulated to its particular threshold level, however, the selective permeability characteristics of the cell membrane to K^+ are momentarily lost. Other ions now cross the sarcolemma and produce the typical depolarization-repolarization cycle that comprises the action potential (Fig. 24.1).

Phase 0 of the action potential reflects the extremely rapid depolarization spike produced by Na^+ rushing into the cell through specific "fast Na^+ channels" or passageways of the sarcolemma. As the permeability characteristics of the sarcolemma are reestablished, phase 0 is terminated as early (phase 1) and delayed (phase 3) repolarization occur, restoring the membrane potential to its resting diastolic level of phase 4 (Fig. 24.1). The cell is inexcitable or nonresponsive to additional stimuli during the early and intermediate phase of the action potential cycle; it is only partially responsive if stimulated prior to complete repolarization and return to normal phase 4 diastolic potential. This period of refractoriness provides a safety factor, preventing reexcitation by the initiating cardiac impulse itself.

Phase 2 is the plateau of the action potential (Fig. 24.1); it partially represents a brief anomalous delay in restoration of K^+ permeability. In addition, a critically important component of phase 2 comprises an influx of Ca^{++} through specific "slow Ca^{++} channels" or "slow cation channels" of the cell membrane. The plateau phase is important because this slow inward Ca^{++} current is the mechanism whereby membrane excitation is coupled to activation of the contractile elements of heart muscle cells (Parker and Adams 1977). The influx of Ca^{++} during phase 2 triggers a release of greater amounts of Ca^{++} from intracellular storage sites. The increased availability of cytosolic Ca^{++} directly and proportionately activates the contractile machinery of the myocardial cells. As will be addressed subsequently, the slow inward Ca^{++} current participates also in certain types of automaticity mechanisms and conduction disturbances.

SINOATRIAL PACEMAKER CELLS. Unlike working myocardial cells, automatic cells do not exhibit a clearly definable resting membrane potential during phase 4. Instead, phase 4 is characterized by a slow spontaneous depolarization to threshold potential (Fig. 24.1B), thereby discharging automatically and leading into the more rapid depolarization of phase 0. However, the slope of phase 0 depolarization of SA pacemaker cells is much less than that of working muscle cells (Figs. 24.1, 24.2). This distinction may be explained by a component of slow Ca^{++} influx in the genesis of phase 0 depolarization in these types of automatic cells (Adams 1986). In addition to SA pacemaker tissue, cells with normal automaticity (i.e., spontaneous phase 4 depolarization) also are found in specialized atrial conduction tracts, the distal region of the AV node, AV valves, and PF. Although working muscle cells do not normally develop spontaneous depolarization during phase 4 (Fig. 24.1A), they may generate aberrant automaticity during heart disease and thereby mediate or contribute to associated arrhythmogenic events.

Classification of Arrhythmogenic Mechanisms. Theories on the basic mechanisms involved in genesis of cardiac arrhythmias focus on abnormalities of impulse formation (i.e., arrhythmias caused by changes in automaticity), impulse conduction (i.e., arrhythmias caused by reentry phenomena), and a combination of automaticity and reentry (Singh et al. 1980; Binah and Rosen 1984; Boyden and Wit 1985).

DISTURBANCES IN AUTOMATICITY. The action potential from the SA node, AM, PF, and VM are shown in Fig. 24.2. The five phases of the action potential (0, 1, 2, 3, 4) are numbered in the first complex of VM. Notice spontaneous depolarization (SD), maximal diastolic potential (MDP), and threshold potential (TP) in the automatic cells of SA and PF. The resting membrane potential (RMP) is shown in the nonautomatic cells of the AM and VM. The P wave of the ECG corresponds to depolarization of SA and AM, while the QRS complex and T wave correspond to depolarization and repolarization respectively of ventricular cells (Fig. 24.2).

Automatic cells of the SA node normally are the dominant pacemaker, reaching threshold first with the resultant propagating impulse exciting all other potential pacemaker cells before they spontaneously attain threshold values (Fig. 24.2). If automaticity of the SA node is depressed or the spontaneous firing rate in some other tissue (latent pacemaker) is accelerated, regions of the heart other than the SA node may serve as the pacemaker and initiate ectopic impulses. Examples are shown in Fig. 24.3.

Automaticity is enhanced when the slope of phase 4 SD is increased (e.g., from a to b in I of Fig. 24.3); this decreases the time required to reach TP, thereby increasing the frequency of spontaneous discharge. The result is an increase in heart rate when the SA pacemaker is involved or emergence of ectopic beats if a normally latent pacemaker is involved. By decreasing the slope of spontaneous depolarization (e.g., from b to a or from a to c in I of Fig. 24.3), drugs can depress ectopic foci and restore normal sinus rhythm without affecting MDP or TP. If a drug raises TP to less negative values (e.g., from TP-a to TP-b in II of Fig. 24.3), additional time will be required to reach TP, thereby depressing automaticity. By increasing the MDP (e.g., from MDP-a to MDP-b in III of Fig. 24.3), a drug can suppress automaticity since additional time would be required before TP is attained.

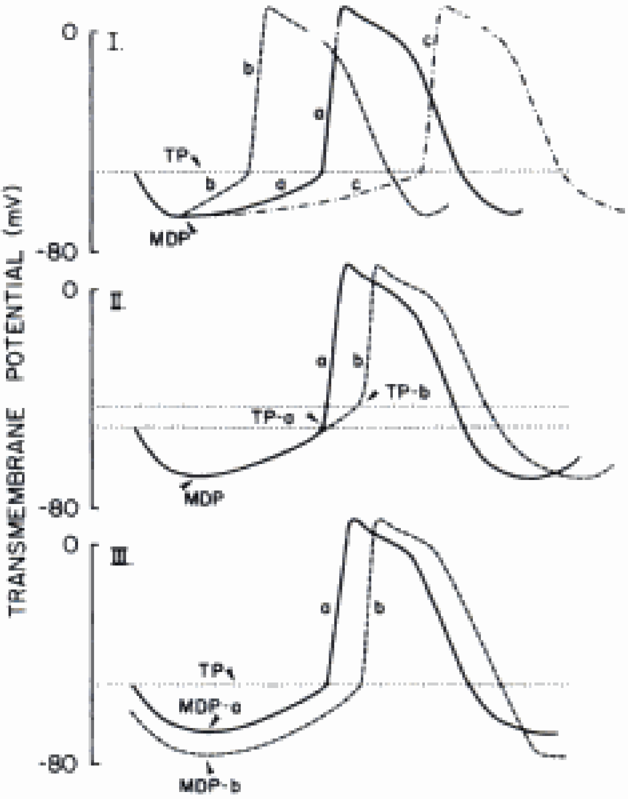

FIG. 24.3—Schematic representations of transmembrane action potentials of cardiac cells with the property of automaticity and potential mechanisms whereby antiarrhythmic drugs can influence automaticity (see text for discussion). (Modeled after Hoffman and Cranefield 1960; Mason et al. 1973.)

DISTURBANCES IN IMPULSE CONDUCTION. Arrhythmias caused by disturbances in impulse conduction are thought to be associated with a phenomenon of reentry or circus movement. The concept of reentry is based on very slow conduction velocity, an area of the heart demonstrating unidirectional block of impulse conduction and perhaps an abnormally brief refractory period (Schmidt and Erlanger 1929; Wit et al. 1972, 1974). This theory holds that a cardiac impulse can travel circuitously around an anatomic loop of fibers in which slowed conduction velocity and brief refractoriness permit the impulse to arrive at cells that are no longer refractory, thereby permitting perpetual reexcitation.

A schematic demonstration of impulse reentry at a junctional region between PF and ventricular muscle is shown in Fig. 24.4 (Adams 1986). Acceptance of this

FIG. 24.4—Schematic representations of potential mechanisms involved in cardiac arrhythmias caused by reentry phenomena.

I. Normal. The cardiac impulse (arrows) exits a main bundle branch (MB) of the Purkinje system and enters terminal Purkinje branches A and B. The impulse uniformly and rapidly excites a segment of ventricular muscle (VM) and would be extinguished within the VM due to refractoriness of the cells just excited.

II. Normal conduction and unidirectional block. Because of an area of damaged tissue (shaded area) that blocks antegrade conduction in branch A, the impulse traversing branch B and the VM will excite branch A. The impulse will traverse branch A and the area of unidirectional block through a retrograde pathway; however, since it is conducted at a normally fast speed, it will encounter refractory cells (open square) and be extinguished.

III. Slow conduction velocity and no block. Although the cardiac impulse may be conducted at an abnormally slow velocity (wavy arrows), the lack of unidirectional conduction block causes the impulse to arrive at refractory cells and extinguish.

IV. Slow conduction and unidirectional block. Same as II but the speed of impulse conduction through the area of unidirectional block (wavy arrows), and perhaps through B and VM as well, is so slow that the impulse encounters cells after their refractory period. Thus the impulse can reenter the conduction pathway, thereby establishing perpetual reexcitation. (Modeled after Cranefield 1973; Mason et al. 1973. Source: Adams 1986.)

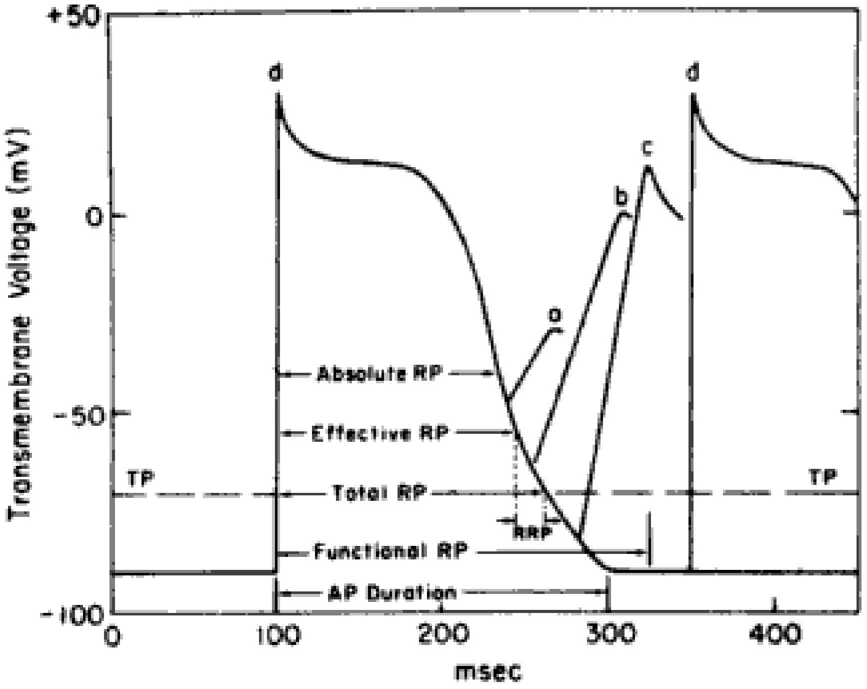

FIG. 24.5—Schematic diagram of transmembrane potentials (TMP) of a working ventricular muscle cell. The maximal rate of rise of phase 0 depolarization of the action potentials labeled a, b, c, and d depends on the magnitude of the TMP at the time of excitation. Thus the rate of depolarization is least at low levels of membrane potential (a), becomes progressively greater as TMP increases (b, c), and finally reaches a maximum at the resting potential (d). RP = refractory period, RRP = relative refractory period, AP = action potential, TP = threshold potential (Mason et al. 1973).

theory was delayed by difficulty in visualizing a decrease in conduction velocity adequate to comply with the value deemed necessary for establishing reentry phenomena. After all, the normal conduction velocity in PF can be as high as 2-4 m/sec, thus displaying a high safety factor for impulse propagation. As will be discussed in the following section, however, the velocity of impulse conduction can be diminished to as low as 0.01-0.1 m/sec by pathologic emergence of action potentials that demonstrate activation-deactivation kinetics that are remarkably slower than the normal fast responses.

Reentry theoretically could be controlled by a drug that either creates bidirectional block or bidirectional conduction through the region of cells causing the unidirectional block; accelerates speed of impulse conduction, thus returning the impulse to the site of reentry when cells are still inexcitable; prolongs action potential duration of normal cells, thereby extending their refractory period; or exhibits a combination of the above actions.

It should be appreciated also that other forms of cardiac electrophysiologic disturbances, in addition to primary abnormalities of impulse conduction and automaticity, may be important. Examples would include abnormal excitability, early afterdepolarizations, delayed afterdepolarizations, triggered electrical activities, and perhaps others. However, genesis of these types of abnormalities may overlap mechanistically with disturbances of automaticity and impulse conduction. Thus arrhythmias arising from primary automaticity and conduction abnormalities are adequate for modeling the classes of antiarrhythmic drugs relative to their effects on cardiac action potential characteristics and arrhythmogenesis.

FAST AND SLOW RESPONSES AND CONDUCTION. Phase 0 depolarization of a spontaneously active PF, and also of nonautomatic muscle cells in the atria and ventricles, represents the transmembrane potential change caused by a rapid influx of Na^+ through "fast Na^+ channels" of the cell membrane (see Figs. 24.1A, 24.2). There is increasing evidence that phase 0 of automatic SA and AV nodal cells is dependent upon a slow influx of Ca^{++} through "slow cation channels" of the cell membrane that are quite distinct from the fast Na^+ passageways. Under pathophysiologic influences, cells that normally exhibit fast Na^+ currents can develop slow Ca^{++}-dependent currents leading to conduction disturbances.

Conduction of a cardiac impulse through the different regions of the heart is dependent upon bioelectric characteristics of the individual cells in each region. The velocity of impulse conduction varies directly with magnitude of the maximal rate of depolarization of the cardiac cell (V_{max}), which is determined in turn by magnitude of the transmembrane voltage at the instant of excitation (Fig. 24.5). If the intracellular potential is reduced to less negative voltages, V_{max} and conduction velocity decrease proportionately (Fig. 24.5).

TABLE 24.1—Comparison of properties of fast Na^+ and slow Ca^{++} inward currents in cardiac muscle

Electrophysiologic property	Fast current (fast response)	Slow current (slow response)
Activation-inactivation kinetics	Rapid	Slow
Dependent on extracellular concentration of:	Na^+	Ca^{++}
Blocked by:	Tetrodotoxin	Verapamil, D600
Threshold	–60 to –70 mV	–30 to –40 mV
Diastolic membrane potential	*–80 to –90 mV*	*–40 to –70 mV*
Conduction velocity	*0.5 to 3.0 m/sec*	*0.01 to 0.1 m/sec*
Overshoot	+20 to +35 mV	0 to +15 mV
V_{max}	*100 to 1000 V/sec*	*1 to 10 V/sec*
Safety factor for conduction	*High*	*Low*
Relationship to nodal tissues	Probably none	May mediate pacemaker potentials
Catecholamines	Little effect	Significant enhancement

Note: Particularly important differences are italicized.

It now seems that many cardiac diseases and disturbances can cause the diastolic potential of myocardial cells to become less negative, i.e., they become partially depolarized (Boyden and Wit 1985). As the diastolic potential approaches about –60 mV, the fast Na^+ channels normally responsible for the rapid influx of Na^+ during phase 0 depolarization become progressively inactivated. If the fast Na^+ channels are completely inoperative owing to a resting potential less than –60 to –55 mV, cells may generate action potentials with an extremely slow rate of depolarization (i.e., a low $\dot{V}_{max}$) caused entirely by a slow current flowing through the slow cation channels of the cell membrane. Such an action potential is called a slow response and thought to be carried predominantly by Ca^{++}. It is now believed that slow responses and associated irregularities of impulse conduction may be involved in the genesis of different types of arrhythmias (Cranefield 1975). Some comparisons between fast and slow inward currents and their associated electrophysiologic properties are provided in Table 24.1.

ANTIARRHYTHMIC DRUGS

Classification. Investigators have attempted to classify antiarrhythmic drugs according to their electrophysiologic actions, but disagreements have arisen owing to lack of consensus over which drug-induced changes in the transmembrane potential are responsible for antiarrhythmic activity. The classification system advocated by Vaughn Williams (1984) and co-workers has become the standard nomenclature model for antiarrhythmic drugs. This system is rather straightforward; it is based on the observation that most antiarrhythmic drugs have one dominant electrophysiologic action on the myocardial cell, which may be influenced by the drug's subsidiary myocardial effects as well as its extracardiac activities (Adams 1986). Antiarrhythmic drugs are divided into Class I to IV in this system, as summarized in Table 24.2.

CLASS I DRUGS. Class I drugs are potent local anesthetics for nerves as well as the myocardial cell membrane, but this activity is generally more pronounced in the heart than in nerve fibers. The dominant electrophysiologic action of this group is a reduced maximal rate of depolarization of cardiac fibers. This decrease occurs without a significant change in the resting membrane potential. This activity is associated in turn with an increase in the threshold of excitability, a decrease in conduction velocity, and in some instances prolongation of the effective refractory period. These alterations invariably are associated with an inhibition of the spontaneous diastolic depolarization in automatic cells. The effect on pacemaker cells, especially ectopically active ones, seems to be more prevalent than effects on conduction velocity or excitability. Thus by inhibiting spontaneous diastolic depolarization, Class I drugs can control arrhythmias caused by enhanced automaticity. Also, by prolonging the refractory period, these agents are likely to be effective in abolishing reentrant tachyarrhythmias.

Since quinidine is the original and prototypical Class I drug, compounds in this group often are referred to collectively as the "quinidine-like" antiarrhythmic agents. Some important dissimilarities exist, however, relative to the precise effects of the different Class I drugs on phase 0 depolarization in normal and abnormal cells, action potential duration, and length of refractoriness. These differences prompted Keefe et al. (1981) to place Class I agents into three subdivisions: Class IA, IB, and IC.

Class IA includes quinidine, procainamide, and disopyramide. Their distinguishing features include a consistent reduction of the rate of phase 0 depolarization in normal and injured cardiac cells. Class IA agents also uniformly prolong the cardiac action potential duration and especially the affiliated refractory period.

Class IB drugs include lidocaine, phenytoin, tocainide, mexiletine, and aprindine. Although some controversy exists, a distinguishing feature of Class IB

TABLE 24.2—Classification and mechanisms of action of antiarrhythmic drugs

Class	Drug	Depression of fast Na^+ $\dot{V}_{max}$	Action potential duration	β–Blockade	Depression of slow responses	Extracardiac effects
I	*Local anesthetic agents—membrane stabilizers*					
	Quinidine	4+	Lengthen +	Slight	0	Anticholinergic
	Procainamide	4+	Lengthen +	0	0	Anticholinergic
	Lidocaine	4+[a]	Shorten +	0	0	Local anesthetic
	Phenytoin	4+[a]	Shorten +	0	0	Anticonvulsant
	Disopyramide	4+	Lengthen	0	0	Anticholinergic
	Aprindine	4+	0	0	0	Anticonvulsant
	Tocainide	4+	0	0	0	Local anesthetic
II	*β blockers*					
	Propranolol	+	Shorten +	4+	0[b]	Slight
	Oxyprenolol	+	Shorten +	4+	0[b]	Slight
	Alprenolol	+	Shorten +	4+	0[b]	Slight
III	*Agents that prolong action potential duration*					
	Bretylium	0	Lengthen 4+	Neuron blockade	0	Hypotension
	Amiodarone	0	Lengthen 4+	0	0	Coronary vasodilator
IV	*Ca^{++} channel blockers*					
	Verapamil	0	Lengthen phase 1 and 2+	0	4+	Coronary vasodilator

Note: 4+ = principal electrophysiologic action; + = subsidiary action; 0 = little or no effect in presumed therapeutic plasma concentrations.

[a] May decrease Na^+ conductance in injured, rather than normal, cells (see text for subclassification of IA, IB, and IC).

[b] May indirectly inhibit slow responses that are initiated by catecholamines.

drugs pertains to their reduction of phase 0 depolarization and conduction velocity in injured cardiac tissue but much less effect on these variables in normal cells (Table 24.2). Another feature of the Class IB compounds is their minimal shortening effect on action potential duration and refractory period (Table 24.2). This is quite different from quinidine and other Class IA drugs that reliably prolong action potential duration and refractoriness.

Three principal members of Class IC are encainide, lorcainide, and flecainide. These drugs, like the quinidine Class IA group, markedly depress the maximal rate of phase 0 depolarization in normal as well as abnormal cardiac cells. The Class IC agents, however, exert little effect on refractoriness and action potential.

Although the antiarrhythmic drug classification system facilitates an understanding of the various agents, the clinical importance of the subdivision of Class I drugs remains to be established.

CLASS II DRUGS. Class II drugs are defined as agents that exert antiadrenergic activity in the heart. Clinically useful Class II drugs are β-blocking agents; these compounds are discussed in Chap. 6. Propranolol is the prototype of Class II; newer agents include oxyprenolol, alprenolol, metoprolol, timolol, and pindolol. The basis for classifying agents that block cardiac sympathetic stimulation into a separate category derives from the fact that hyperactivity of the sympathetic nervous system is an important factor in pathogenesis of different types of arrhythmias, especially tachyarrhythmias associated with ectopic pacemaker foci. By reducing sympathetic input, β-blocking drugs obviously would be effective in controlling arrhythmias associated with sympathoadrenal discharge.

In addition, propranolol and some other β-blocking agents exert local anesthetic activity. They have been classified by some investigators as quinidine-like agents rather than being placed in a separate antiadrenergic category. At this time, however, it seems that β-adrenoceptor blocking agents in therapeutically effective concentrations act primarily and perhaps exclusively by β-adrenergic blockade; their local anesthetic properties, apparent in high concentrations, may be unimportant in control of cardiac arrhythmias (Singh et al. 1980).

CLASS III DRUGS. Class III drugs produce a "pure" prolongation of the action potential, thereby extending the refractory period. Development of this concept is based on the observation that cardiac arrhythmias are frequent in hyperthyroid states, which exhibit brief action potentials, but infrequent in hypothyroid conditions, which exhibit prolonged action potential duration. An antianginal drug, amiodarone, was found to exert antiarrhythmic activity associated with a prolonged action potential duration without effect on resting membrane potential. Bretylium, an adrenergic neuronal-blocking agent (Chap. 6), has Class III activity.

CLASS IV DRUGS. Class IV drugs are generally classified as calcium antagonists or Ca^{++} channel blockers; they exert little local anesthetic activity on fast Na^{+} responses but have relatively specific inhibitory effects on Ca^{++}-dependent slow responses. Because of slow Ca^{++} current participation in AV nodal conduction, Ca^{++} blockers slow AV conduction and thereby have application for controlling supraventricular arrhythmias that involve AV reentry pathways (Allert and Adams 1987). Action potentials may also arise from cells with pacemaker activity on the basis of slow Ca^{++} inward currents. Thus blockade of slow Ca^{++} responses may control both ectopic and reentry arrhythmias when such disturbances are dependent on slow response activity. Verapamil is the prototype drug of Class IV.

Autonomic Drugs. With exception of the β-adrenoceptor blocking agents, autonomic drugs usually are not included in classic groupings of antiarrhythmics. However, the clinician should not overlook the fact that during the actual practice of medicine, drugs other than the classic antiarrhythmic agents generally are preferred in controlling arrhythmias associated with uncomplicated autonomic imbalance. Atropine, e.g., would be an obvious choice when severe sinus bradycardia or sinus arrest is presented secondary to vagal discharge and accumulation of acetylcholine (ACh). Epinephrine is indicated in attempts to restart the heart after cardiac arrest, isoproterenol is useful in reversing AV block, and both can be effective in increasing heart rate if sinus bradycardia associated with impaired sympathetic drive is diagnosed (Adams 1981; Tilley 1985). Pharmacologic actions of the autonomic drugs are covered in Chaps. 5-7.

Digitalis. The pharmacologic action of digitalis, a quite useful antiarrhythmic agent for controlling ventricular rate in atrial tachyarrhythmias, is discussed in Chap. 23. It should be remembered that irrespective of the presenting arrhythmia, digitalis glycosides generally are the agents of choice if congestive heart failure is involved.

Quinidine Sulfate. *Quinidine Sulfate,* USP (Quinidex, Quinicardine), is the dextrorotatory isomer of quinine. Both compounds are present in cinchona bark, and their use as antiarrhythmic drugs can be traced to Wenckebach in 1914. This Viennese cardiologist learned that quinine, used to treat malaria, could also control irregular pulse rates in patients with atrial fibrillation. Subsequent investigation indicated that quinidine was more effective than quinine, and the former became a drug of choice in controlling atrial fibrillation.

Quinidine has both direct and indirect effects on cardiac rhythmicity. Like other Class I agents (Table 24.2), quinidine decreases the maximal rate of phase 0 depolarization of cardiac cells. This activity is demonstrable in atrial, ventricular, and Purkinje fibers; it reflects a direct depressant effect on Na^{+} permeability or the relationship between resting membrane potential and Na^{+} conductance (see Fig. 24.5). Quinidine also decreases the slope of spontaneous depolarization of Purkinje fibers but usually spares automaticity of the SA node except when excessive amounts are administered. Thus careful use of quinidine can control ectopic automaticity with less effect on firing frequency of normal pacemaker cells.

Clinically useful doses of quinidine prolong the effective refractory period of atrial and ventricular muscle with relatively less effect on the refractory period of normal pacemaker cells. Quinidine is subtyped as a Class IA drug owing to its characteristic prolongation of the refractory period. The capability of quinidine to directly prolong the refractory period of atrial fibers is thought to account for its effectiveness in converting atrial fibrillation to sinus rhythm.

As a subsidiary action, quinidine exerts an atropine-like vagolytic effect and therefore antagonizes the cardiac actions of vagally released ACh. This activity contributes to the effectiveness of quinidine in controlling atrial tachyarrhythmias because the action of ACh to shorten the atrial refractory period would be antagonized. Thus quinidine not only directly lengthens the refractory period, it also acts indirectly to lengthen this parameter by its anticholinergic action (Moss and Patton 1973). An adverse result of the atropine-like activity of quinidine, however, is improved AV conduction. Accordingly, an untoward effect of quinidine in treating supraventricular tachyarrhythmias is a sometimes pronounced increase in ventricular rate before the atrial dysrhythmia itself is controlled. This characteristic seems to be particularly prevalent when quinidine is administered by the intravenous (IV) route.

To avoid the potentially dangerous acceleration of ventricular rate by quinidine, it is traditional to first pretreat with a digitalis glycoside. The latter slows AV conduction and can thereby provide control of ventricular rate in atrial fibrillation and flutter (see Chap. 23). However, care should be exercised in the concomitant use of digoxin and quinidine, since the latter may substantially increase the plasma concentration of the former (Leahey et al. 1978).

Acute quinidine toxicoses is characterized by hemodynamic changes due largely to nonselective depression of various electromechanical functions of the heart. Impulse conduction through the AV node can be depressed to the extent that AV block develops. SA block and even ventricular fibrillation may also occur. Hypotension, decreased cardiac output, decreased myocardial contractility, and prolongation of the PR, QRS, and QT intervals of the ECG can result if large amounts of quinidine are administered intravenously. IV administration is not advocated because of potential dangers. Quinidine and other Class I agents usually are considered to be contraindicated in AV block or intraventricular block.

Quinidine is absorbed efficiently and rapidly when administered by the oral or intramuscular (IM) route. After IV administration, quinidine rapidly passes from the blood and distributes in tissues; distribution equilibrium is complete within 30 minutes (Neff et al. 1972). Approximate plasma half-life values in hours are: dogs (5.5), swine (5.5), ponies (4.4), cats (1.9), and goats (0.9). Protein binding varies from 82 to 92%. A large portion of quinidine undergoes metabolic degradation in the liver, and less than 40% is excreted in urine. Dissimilar rates of biotransformation and elimination probably account for species differences with this drug.

CLINICAL ASPECTS. Quinidine has generally been less successful in treatment of atrial fibrillation in small breeds of dogs (Detweiler 1957) than in large breeds such as the Great Dane, St. Bernard, and Newfoundland (Pyle 1967; Bohn et al. 1971). Apparently, atrial fibrillation can occur in large dogs with less extensive cardiac pathology than in small breeds.

Some of the inconsistencies about the effectiveness of quinidine in controlling supraventricular tachyarrhythmias in dogs may be explained partially by the differences in doses used by different investigators. Detweiler (1977) indicated that 50-100 mg may be given orally as a test dose in dogs with atrial fibrillation, followed several hours later or on the following day by 6.6-13.2 mg/kg every 2 hours for 4-5 doses daily. Hilwig (1976), in contrast, listed 3-10 mg quinidine by mouth 2-3 times daily in managing supraventricular tachycardias, without designating body weight of the patient. Tilley (1979) listed 6-20 mg/kg by the oral route every 6-8 hours. Suggested doses for IM injection of quinidine also have varied: 2-6 mg/kg every 6-8 hours (Tilley 1979) and 0.6-2 mg/kg every 6-8 hours (Hilwig 1976). In view of the limited amount of well-controlled data actually available about clinical use of quinidine in treating spontaneous arrhythmias in animals, dosage recommendations are somewhat provisional. Care is necessary in individual management of each patient, and dosage should be adjusted according to initial results after institution of a conservative regimen.

Quinidine has been used in the treatment of atrial fibrillation in horses (Detweiler and Patterson 1963); the following dose schedule for oral administration by capsule or stomach tube has been recommended (Detweiler 1977):day 1, 5 g (test dose); day 2, 10 g 3 times daily at 3-hour intervals; day 3, 10 g 4 times daily at 2-hour intervals; day 4, 10 g 4 times daily at 2-hour intervals.

Adverse effects of quinidine in horses include urticarial wheals, digestive disturbances, inflammation of the nasal mucosa with respiratory difficulty, laminitis, cardiovascular dysfunction, and even sudden death (Detweiler 1977). IV administration of quinidine has been employed by some clinicians, but this route is more hazardous than oral therapy. An IV preparation is available (*Quinidine Gluconate*, USP), but none of the quinidine products have been approved by the U.S. Food and Drug Administration for use in animals.

Procainamide Hydrochloride. *Procainamide Hydrochloride*, USP (Pronestyl), is a derivative of procaine containing an amide linkage in place of the ester linkage in the procaine molecule. This structural modification prolongs the biologic half-life of procainamide to 3-4 hours, making it more useful than the shorter lasting procaine.

The pharmacologic actions of procainamide, a Class IA agent, are qualitatively similar to those of quinidine (Table 24.2). In general, procainamide is considered more effective in controlling ventricular arrhythmias than atrial arrhythmias.

Huisman and Teunissen (1963) recommended IV infusion of procainamide at the rate of 100 mg/min when used in controlling dangerous ventricular tachycardias in dogs. Ettinger and Suter (1970) employed doses of 250 mg injected intramuscularly as frequently as every 2 hours in dogs weighing 11-16 kg (i.e., about 15-20 mg/kg). Hilwig (1976) listed the dose of procainamide as 4-8 mg/kg when given by IV injection or 25-50 mg/min by IV drip. Tilley (1979) listed an oral dose of procainamide as 125-500 mg every 6-8 hours (not to exceed 33 mg/kg/day), an IM dose as 8-16 mg/kg every 3-6 hours, and an IV dose as 1-2 mg/kg every 5 minutes to effect or to signs of intoxication (not to exceed 1 g).

Signs of procainamide toxicosis include greater than 50% widening of the QRS complex of the ECG, additional arrhythmias, bradycardia, tachycardia, or hypotension. Ideally, the ECG and blood pressure should be monitored during administration of procainamide, especially if given by a parenteral route.

Phenytoin Sodium. *Phenytoin Sodium*, USP (Dilantin, Diphenytoin), originally referred to as diphenylhydantoin, is a primary anticonvulsant drug used in humans and animals for control of epileptic seizures (see Chap. 16). Phenytoin also exerts antiarrhythmic activity in the heart, but this characteristic has a narrow spectrum of therapeutic application. Studies in isolated cardiac tissues have shown convincingly that phenytoin exerts direct antiarrhythmic actions similar in some respects to those of quinidine. Thus phenytoin usually is classified as a "local anesthetic-like" antiarrhythmic belonging in the Class I group (Table 24.2). Because it minimally shortens the refractory period, phenytoin is subtyped as a Class IB drug. Under some circumstances, phenytoin actually may enhance membrane responsiveness and increase conduction velocity, thereby improving impulse conduction through damaged tissue; however, the clinical significance of these activities is uncertain (Singh et al. 1980).

In general, phenytoin is considered to be effective in controlling digitalis-induced arrhythmias of all types; it also is useful in treating ventricular arrhythmias from other causes but is relatively ineffective in abolishing atrial dysrhythmias unless they are related to digitalis toxicosis (Hayes 1972). When administered slowly by the IV route, the usual dose of phenytoin for dogs is approximately 5-10 mg/kg at an infusion rate of about 25-50 mg/min. This appears to be effective in treatment of digitalis-induced arrhythmias without depressant effect on myocardial contractile function (Helfant et al. 1967; Scherlag et al. 1968; Damato 1969). Tilley (1979) and Hilwig (1976) have used 4 mg/kg phenytoin for slow IV administration in dogs. Data pertaining to phenytoin use in cats are lacking; in view of the remarkably long plasma half-life of phenytoin in this species (Roye et al. 1973), much smaller doses than those used in dogs should be considered.

The complete pharmacokinetic disposition of phenytoin has not been determined, but studies in dogs indicate that the drug is absorbed somewhat poorly from the gastrointestinal (GI) tract (approximately 40%) and has a short serum half-life (approximately 3 hours) (Sanders and Yeary 1978). Furthermore, an oral dose of 10 mg/kg phenytoin in this same study yielded serum concentrations that did not exceed 2 µg/mL. If therapeutically effective serum concentrations of phenytoin are accepted as approximately 10 µg/mL, the oral dose of phenytoin may have to be increased over the usual recommendations of approximately 5-10 mg/kg. Sanders and Yeary (1978) proposed that 35 mg/kg of phenytoin administered three times daily (i.e., a total daily dose of 105 mg/kg) may be necessary to achieve plasma concentrations likely to be therapeutically effective in controlling convulsions or cardiac arrhythmias in dogs.

Phenytoin is metabolized in dogs by the microsomal enzymes of the liver, and pharmacokinetic-based drug interactions are likely. Dogs receiving phenytoin were reported to develop signs of phenytoxin toxicosis (postural ataxia and hypermetric gait) when chloramphenicol was added to the therapeutic regimen; this adverse drug interaction was attributed to the inhibitory effect of chloramphenicol on phenytoin metabolism (Adams 1975; Sanders et al. 1979).

Lidocaine Hydrochloride. *Lidocaine Hydrochloride*, USP (Xylocaine), is a local anesthetic drug found to exert antidysrhythmic action that has therapeutic application in treating ventricular tachyarrhythmias. Lidocaine is classified as a Class IB agent. Lidocaine is not recommended for controlling supraventricular arrhythmias but is considered to be useful primarily in reverting ventricular dysrhythmias that develop during general anesthesia, surgery, ischemia, and other forms of trauma. In humans it also is used following myocardial infarction. Lidocaine has been advocated in cardiac emergencies to antagonize the profibrillatory activity of epinephrine (Clark 1977). Experimentally, lidocaine shares an efficacy similar to phenytoin in controlling digitalis-induced arrhythmias, but it has received little clinical use for this purpose.

Therapeutic assets of lidocaine in emergency situations are its rapid onset and short duration of action after IV injection. However, it is not useful for maintenance therapy because of ineffective absorption after oral administration and short duration of action. In large doses, lidocaine can produce hypotension and exert negative chronotropic and inotropic actions on the heart.

Tilley (1979) lists the following dose schedules for IV administration of lidocaine in dogs: 2-4 mg/kg over 1-2 minutes, 0.5-2 mg/kg every 20-60 minutes by slow injection, or 0.025-0.060 mg/kg/min by constant infusion with ECG monitoring. Rapid IV administration of more than approximately 4 mg/kg lidocaine is likely to cause CNS seizures.

Propranolol Hydrochloride. Drugs that exhibit β-adrenoceptor blocking properties have an established place in treating and preventing cardiac dysrhythmias in humans but have received less clinical use in animals. In view of the effectiveness of β-blocking agents in controlling a wide variety of dysrhythmias, it seems likely that these drugs will be used increasingly in animals with spontaneous cardiac arrhythmias.

Propranolol Hydrochloride, USP (Inderal), is the prototype; newer agents include oxprenolol, metoprolol, timolol, alprenolol, pindolol, and practolol. Experimental evidence in animals and clinical studies in humans support the view that β blockade is the primary determinant of the antiarrhythmic activity of this group of drugs. Their local anesthetic or quinidine-like activities currently are considered to be less important (perhaps unimportant) in most clinical situations (Table 24.2). The efficacy of β-blocking agents in preventing various cardiac dysrhythmias emphasizes the importance of autonomic imbalance, particularly sympathetic overactivity, in the genesis of different rhythm disturbances in the heart.

Propranolol slows the rate of spontaneous discharge of the SA and ectopic pacemakers and slows both antegrade and retrograde conduction through anomalous pathways of the heart. Thus propranolol can provide relief from arrhythmias associated with disturbances of automaticity, reentry phenomena, or both. Propranolol increases the refractory period of the AV node, which has therapeutic application in slowing ventricular rate during atrial fibrillation or flutter. During the latter conditions, propranolol usually does not slow the fibrillatory or flutter frequency of the atria and only rarely does it restore sinus rhythm. However, the slowing of ventricular rate by propranolol often is effective and is reported to be useful in some cases that are refractory to other antiarrhythmic agents.

Propranolol and other β blockers are effective in reducing frequency of paroxysmal supraventricular tachycardia, especially in the Wolff-Parkinson-White syndrome (Singh and Jewitt 1974). Tachyarrhythmias associated with digitalis intoxication and physical exertion respond well to β-blocking agents. Arrhythmias evoked during inhalation anesthesia with halogenated hydrocarbon anesthetics often can be prevented or reversed by propranolol administration prior to or during anesthesia respectively.

Propranolol is well absorbed from the gut and is eliminated largely from portal blood by the liver before it reaches the systemic circulation. Because of this large "first-pass effect," six to ten times larger doses are necessary when propranolol is administered by mouth as compared to the IV route (Weidler et al. 1979). The order of plasma clearance for propranolol in different species is: rat > dog > cat > human > monkey.

In a study in cats, a two-step IV infusion technique was found to be more effective in attaining and maintaining steady-state plasma concentrations of propranolol than IV bolus injection. The two-step technique involved the following schedule: continuous IV infusion first at a rapid rate of approximately 8-11 μg/kg/min for 15 minutes, than a slow rate of approximately 1-4 μg/kg/min for 4 hours (Weidler et al. 1979). Steady-state plasma concentrations of propranolol achieved with this schedule were 60-80 ng/mL. Application of such techniques to clinical management of arrhythmias probably would be useful depending upon severity of the dysrhythmia and whether the animal is ill enough or tractable enough to allow prolonged IV infusions.

In the dog, suppression of catecholamine-induced arrhythmias by propranolol requires smaller IV doses (0.1-1 mg/kg) than abolition of ouabain-induced arrhythmias (3-5 mg/kg). Relatively large IV doses of propranolol (3 and 5 mg/kg) are toxic in dogs subjected to myocardial infarction after ligation of the anterior descending branch of the left coronary artery (Shanks and Dunlop 1967). Care must be exercised when β-blocking agents are administered to animals with reduced cardiac reserve.

Importantly, rapid bolus injections of large amounts of propranolol can produce nonspecific cardiovascular depressant effects. Ideally, blood pressure and the ECG should be monitored closely when β blockers are administered intravenously. Oral doses of propranolol in animals vary from approximately 2 mg/kg to as high as 40 mg/kg 2 or 3 times daily (Hilwig 1976; Tilley 1979).

Metoprolol Tartrate, USP (Lopressor), is considered to be a cardioselective β-blocking agent; i.e., it is relatively more effective in blocking β_1 receptors of the heart than β_2 receptors of vascular and bronchiolar smooth muscles (see Chap. 6). This selectivity is important, because a limiting side effect of propranolol and other nonselective β blockers is airway obstruction owing to a block of adrenergically regulated dilation of bronchioles. Thus metoprolol or other β_1 selective blockers may well be the β-blocking agents of choice in patients with a history of chronic obstructive airway disease.

PRECAUTIONS. Beta-blocking agents should be administered with caution in patients with reduced cardiac reserve (e.g., congestive heart failure). Under such pathophysiologic conditions, cardiac function is characterized by increased dominance of the sympathetic nervous system as part of the compensatory attempt to maintain cardiac output (see Chap. 23). Blockade of sympathetic input to the heart by propranolol, particularly if sudden, can precipitate cardiac decompensation and all the associated problems that entails (Kittleson and Hamlin 1981). This warming is valid despite the suggestion that propranolol, by reducing myocardial oxygen consumption, is a potential adjunct to treating aged dogs with heart failure (Hamlin 1977).

Verapamil and Diltiazem. Verapamil (Isoptin) is a systemic and coronary vasodilator that also exerts important antiarrhythmic action (Allert and Adams 1987). Early data were interpreted as evidence that verapamil either blocked β-adrenergic receptors (i.e., a Class II propranolol action) or exerted quinidine-like local anesthetic properties (i.e., Class I). However, verapamil and its methoxy derivative D600 were discovered to inhibit transmembrane fluxes of Ca^{++} in various excitable tissues. In the heart, studies demonstrated that verapamil has a unique cellular action in selectively inhibiting transmembrane influx of Ca^{++} (and perhaps Na^{+}) through the aforementioned slow cation channels of the cardiac sarcolemma. Since this action seems crucial to the antiarrhythmic effects of these drugs, verapamil and diltiazem are placed in a separate category (i.e., the calcium antagonists or Ca^{++} channel blockers of Class IV) (Table 24.2).

Arrhythmias caused by disturbances in either impulse formation (automaticity) or impulse conduction (reentry) are theoretically amenable to verapamil if their origin is associated with the emergence of slow response depolarizations (see Table 24.1). In addition, verapamil depresses SA and AV nodal discharge rates and conduction velocity, because slow Ca^{++}-dependent events are normal characteristics of automaticity in these tissues (Spedding 1985). Thus verapamil has application in certain types of atrial arrhythmias and in aborting supraventricular tachycardias that depend on continuous reentry of impulses utilizing the AV node as part of the reentrant pathway (Singh et al. 1980).

In veterinary medicine the clinical antiarrhythmic applications for Ca^{+} channel blockade mainly involve use of verapamil and diltiazem for treatment of supraventricular tachyarrhythmias (Allert and Adams 1987; Kittleson et al. 1988). Verapamil is used in human medicine for short-term conversion of paroxysmal atrial tachycardia to sinus rhythm. Atrial fibrillation and flutter constitute other important indications. Verapamil and diltiazem usually do not convert these high-frequency atrial patterns to sinus rhythm but effectively reduce AV conduction and thereby lower the ventricular rate response. Primary ventricular arrhythmias generally are unresponsive to Ca^{++} channel blockade, unless they are secondary to myocardial ischemia. Nifedipine has little clinical antiarrhythmic utility because reflex cardiac stimulation evoked by this drug's systemic vasodilator effects usually nullifies any direct Ca^{++}-dependent antiarrhythmic properties.

Few clinical trials have examined the antiarrhythmic efficacy of Ca^{++} channel blockade in animals with cardiac disease. Verapamil was reported to be effective in converting paroxysmal or chronic atrial fibrillation to sinus rhythm in only 3 of 7 dogs tested (Johnson 1985). Further, one of the 3 responding dogs developed ventricular tachycardia within 1 day after verapamil treatment was started. Verapamil was discontinued and replaced effectively by combination therapy with quinidine and propranolol. Clinical details were presented for only 2 dogs in the study, and apparently other cardioactive agents (e.g., digoxin, milrinone) were routinely administered along with verapamil. Thus it is difficult to determine whether improvement or lack of improvement in cardiac rhythmicity could be ascribed solely to verapamil.

Results from two additional clinical studies with verapamil use in dogs have been presented (Kittleson et al. 1988; Hamlin 1986). In one study, verapamil was successful in terminating supraventricular tachycardia in 12 of 14 dogs when administered intravenously in 1 to 3 doses at the rate of 0.05 mg/kg (Kittleson et al. 1988). One nonresponding dog developed a transient hypotensive crisis after a total verapamil dose of 0.15 mg/kg.

A second study involved 27 dogs with either atrial tachycardia (17 dogs) or atrial fibrillation with rapid ventricular rate responses (10 dogs) (Hamlin 1986). A qualification for subjects in that study was the absence of overt heart failure, as evidenced by lack of dyspnea and severe cardiomegaly. Verapamil was administered orally at a dose of 0.5 mg/kg every 6 hours, but greater doses were used for some dogs at the beginning of the study. Seven dogs retained their arrhythmia after verapamil, 5 dogs with atrial fibrillation had a reduction in ventricular rate of more than 50 beats/min, and 9 dogs with supraventricular tachycardia converted to sinus rhythm (Hamlin 1986). Thus about 50% of the dogs with supraventricular tachyarrhythmia responded favorably to verapamil. Importantly, however, 6 dogs died within 2-3 hours after the initial dosing of verapamil. Five of these dogs were treated at the rate of 1.5-2.5 mg/kg. Because the deaths occurred so rapidly, they probably were attributable to verapamil rather than to natural progression of the disease. Cardiovascular depressant effects resulting from these relatively large doses of verapamil may have exacerbated underlying cardiac dysfunction, thus evoking acute decompensation of preexisting subclinical heart failure.

A combination of Wolff-Parkinson-White syndrome and atrial fibrillation may constitute a serious precaution or even a contraindication to verapamil treatment. Clinical reports in human medicine have indicated that when these conditions exist simultaneously, verapamil may paradoxically evoke an increase in ventricular rate and lead to fatal ventricular fibrillation (Jacobs et al. 1985). Perhaps episodes of ventricular tachycardia or mortality associated with verapamil therapy in dogs with atrial fibrillation (Johnson 1985; Hamlin 1986) might have involved occult Wolff-Parkinson-White or analogous syndromes.

Adverse circulatory side effects of Ca^{++} channel blockade include contractile depression of the heart, with reduced cardiac output and hypotension. This combination of effects can result in decompensation of preclinical or compensated heart failure, precipitation of pulmonary edema, and worsening of the primary ailment. Other potential side effects are sinus bradycardia and heart block attributable to direct depression of SA firing rate and AV conduction respectively. The propensity for cardiovascular depression should be considered whenever Ca^{++} channel blocking drugs are used. This precaution is especially valid in patients with preexisting or suspected myocardial contractile failure (Allert and Adams 1987).

Newer Drugs. Data are generally insufficient to provide information about clinical use in animals of most of the newer antidysrhythmic drugs. Practical applications are likely in the future, however, because some of these offer potential advantages over the older agents, as summarized below.

BRETYLIUM. Bretylium tosylate (Bretylol) is a bromobenzyl quaternary ammonium compound originally introduced as an antihypertensive agent in humans. This drug is broadly classified as an adrenergic neuronal-blocking agent because it inhibits release of norepinephrine from adrenergic nerve endings (see Chap. 6). Although bretylium is no longer considered useful as an antihypertensive agent, subsequent studies have shown that it exerts direct antiarrhythmic actions in the heart. This characteristic is thought to reside with a relatively "pure" prolongation of action potential duration. Thus bretylium is designated a Class III agent (Table 24.2).

Bretylium lengthens the action potential duration as well as the refractory period in ventricular muscle cells and PF in a homogeneous manner; however, this characteristic effect is not manifested in the atria. Accordingly, bretylium is particularly effective in controlling ventricular arrhythmias, but supraventricular tachycardias are poorly responsive to the drug. Bretylium has received little clinical application in animals, but it has been approved for management of refractory and recurrent ventricular tachycardia or fibrillation in humans (Koch-Weser 1979; Singh et al. 1980).

Bretylium has been reported to bring about defibrillation in clinical episodes of ventricular fibrillation in humans and in experimental episodes in dogs (Koch-Weser 1979). Conflicting data have been presented, however, as Breznock et al. (1977) reported that bretylium (6-24 mg/kg) did not induce chemical defibrillation in dogs when administered by the IV or intracardiac route. Furthermore, bretylium did not seem to stabilize ventricular irritability nor facilitate resuscitation by electrical defibrillation. Additional work is needed in both the clinic and laboratory before therapeutic applications of bretylium are identified in animals with spontaneous cardiac dysrhythmias.

Administration of bretylium to animals anesthetized with halogenated hydrocarbon anesthetics may be contraindicated, since a study demonstrated severe and long-lasting ventricular arrhythmias under such circumstances in cats (Condouris et al. 1979). These anesthetics are known to sensitize the heart to the arrhythmogenic activities of the catecholamines. Because bretylium initially causes a release of catecholamines from adrenergic nerves prior to neuronal blockade, the ventricular arrhythmias evoked by the drug may have been secondary to release of norepinephrine.

The pharmacokinetics of bretylium are not fully elucidated, but it is effective after parenteral (IM, IV) or oral administration. Absorption from the GI tract is somewhat poor and erratic; bretylium is not biotransformed to a significant extent and is excreted essentially unchanged in urine, accounting for its long elimination half-life (Hurley et al. 1960).

DISOPYRAMIDE. Disopyramide is a Class IA agent. The spectrum of electrophysiologic actions and the range of therapeutic effectiveness of disopyramide basically resemble respective characteristics of the other two Class IA drugs, procainamide and quinidine (Novotny and Adams 1986). Although efficacy in controlling supraventricular arrhythmias has been reported, most data indicate that disopyramide is therapeutically effective mainly against tachyarrhythmias of ventricular origin. In this respect, clinical applications for disopyramide more closely resemble those for procainamide than for quinidine.

Although disopyramide was approved recently for antiarrhythmic therapy in humans, adverse side effects and pharmacokinetic characteristics may limit the use of this drug in veterinary medicine. First, disopyramide is absorbed quickly after oral administration, but it undergoes metabolism and clearance almost as rapidly. The biological half-life in dogs is only 2-3 hours, which would necessitate multiple daily administrations (Bonagura and Muir 1985). Second, disopyramide has pronounced atropine-like side effects and can elicit an alarming increase in ventricular rate responses in patients with atrial fibrillation or flutter. Last, and perhaps most important, disopyramide exerts rather potent negative inotropic effects in the heart. The latter characteristic is a potentially critical limitation because it is especially pronounced in patients with preexisting myocardial disease. Indeed, disopyramide was reported to exacerbate congestive heart failure in over one-half of human patients who had preexistent left ventricular dysfunction. Because of pharmacokinetic disadvantages and limiting side effects, Bonagura and Muir (1985) indicated that disopyramide may prove to have limited application in veterinary medicine.

TOCAINIDE. Tocainide is a Class IB antiarrhythmic drug; it was discovered as a structural congener of lidocaine that shared basic electrophysiologic and antiarrhythmic actions with the parent compound. Tocainide has distinct pharmacokinetic advantages because it is effective after oral administration and has a long duration of action. Like lidocaine, tocainide is a narrow spectrum antiarrhythmic drug with clinical efficacy against ventricular arrhythmias.

Patients that respond to parenterally administered lidocaine usually respond to oral tocainide. Reports in the human literature often concern patients whose arrhythmias were refractory to other antiarrhythmic agents before tocainide was tried, so the actual efficacy of tocainide as an initial antiarrhythmic drug may be higher than some studies would indicate.

Tocainide may have clinical usefulness in veterinary medicine. It has potential application in cases where ventricular arrhythmias are initially responsive to IV lidocaine or tocainide, but refractory to the older oral antiarrhythmic agents such as quinidine or procainamide. Lidocaine itself is inappropriate for oral therapy because it is rapidly metabolized after absorption from the GI tract. Plasma concentrations of tocainide in the dog are maintained in the therapeutic range for up to 12 hours after oral administration, making tocainide suitable for administration only 2 times a day.

A slightly different chemical structure from lidocaine protects tocainide from rapid first-pass hepatic metabolism, markedly improving its bioavailability when compared to lidocaine. Metabolism occurs in the liver, but in humans as much as 50% of the drug can be excreted unchanged in the urine. Similar hepatic and renal mechanisms of drug elimination are believed to be found in dogs. The side effects anticipated with tocainide are similar to those seen with lidocaine, but in studies in humans the side effects are usually minor, well tolerated, and generally eliminated by dosage adjustment.

MEXILETINE. Mexiletine is a Class IB drug that exerts electrophysiologic and antiarrhythmic actions similar to those of lidocaine and tocainide (Novotny and Adams 1986). As with tocainide, mexiletine was developed for its lidocaine-like effectiveness in treating serious ventricular arrhythmias in a formulation suitable for oral administration. Mexiletine undergoes minimal first-pass metabolism by the liver after nearly complete absorption from the GI tract. As with tocainide, mexiletine may find its greatest clinical utility in controlling ventricular arrhythmias that are found to be lidocaine-sensitive and when continued outpatient therapy by the oral route is desirable. In one clinical study involving a small group of dogs (Bonagura and Muir 1985), success was limited when mexiletine was administered orally 2 or 3 times daily at doses of 1-2 mg/kg, but as with tocainide, more extensive clinical trials are necessary.

APRINDINE. Aprindine is a Class I agent that shares basic electrophysiologic actions with lidocaine, except that aprindine seems to have a somewhat broader spectrum of antiarrhythmic efficacy. Aprindine is effective against premature ventricular beats and ventricular tachycardias but also has potential for suppressing supraventricular premature beats. Aprindine is less effective and is not used in the settings of atrial fibrillation, atrial flutter, or supraventricular paroxysmal

TABLE 24.3—Suggested antiarrhythmic drugs of choice in treating canine arrhythmias

Note: For each arrhythmia the drug or procedure of first choice (response excellent) is indicated by + + +; of second choice (response good) by + +; of third choice (response fair and rarely indicated) by +; and contraindicated by 0. Combination antiarrhythmic therapy is often based on this table, with first- and second-choice therapies used concurrently.

tachycardia. Aprindine may accelerate AV conduction and precipitate increased ventricular rate responses. Aprindine's usefulness in humans has been somewhat limited, owing to a rather narrow toxic-therapeutic ratio; leukopenia, agranulocytosis, and hepatotoxicosis are potential side effects. Dose-related and reversible untoward reactions include hypotension, ataxia, nausea, seizures, transient depression of myocardial contractile function, and prolongation of the PR, QRS, and QT intervals (Novotny and Adams 1986).

Aprindine underwent clinical trial in 20 dogs with spontaneous ventricular arrhythmias (Muir and Bonagura 1982); 17 of the dogs had failed to respond to treatment with quinidine, procainamide, lidocaine, propranolol, or a combination of these drugs. Aprindine was administered by IV infusion at a dose of 0.1 mg/kg/min for 5 minutes and repeated at 10-minute intervals until the arrhythmia was controlled or signs of intoxication intervened. The subsequent oral dose was 1-2 mg/kg, 3 times daily. Aprindine was effective with this schedule in converting ventricular tachycardia to sinus rhythm in 15 of the dogs and in slowing ventricular rate in 4 others; one dog had an increased ventricular rate. Antiarrhythmic efficacy in 19 of 20 dogs is an impressive success rate. Aprindine likewise was effective in controlling ventricular tachycardia in another clinical trial involving Doberman Pinschers with congestive cardiomyopathy (Calvert et al. 1982).

These findings suggest that aprindine may be an alternate strategy for controlling ventricular arrhythmias in dogs resistant to standard antiarrhythmic therapy. Further study is warranted to substantiate the utility of aprindine, and to evaluate therapeutic-toxic ratios in animals. Because of the potential of aprindine for leukopenia and hepatotoxicosis, this drug may be reserved for ventricular arrhythmias resistant to other drugs. Interestingly, indecainide is a new aprindine congener purported to have fewer side effects and six times the potency of aprindine.

ENCAINIDE, FLECAINIDE, AND LORCAINIDE. Encainide, flecainide, and lorcainide are Class I members discovered and characterized during a search for drugs with efficacy against arrhythmias resistant to standard treatment regimens. They share basic Na^+ conductance-blocking properties with quinidine; however they are distinct from other quinidine-like drugs because they do not prolong the refractory period. Because of this spectrum of electrophysiologic actions, encainide, flecainide, and lorcainide are subgrouped as Class IC antiarrhythmic drugs (Novotny and Adams 1986).

As a general rule, Class IC agents seem to be effective against ventricular tachycardias and premature beats of either ventricular or atrial origin. These compounds are less effective and perhaps clinically ineffective in controlling atrial fibrillation and flutter. Encainide, flecainide, and lorcainide are absorbed after oral administration, but more work is needed with each compound before clinical recommendations can be made relative to their use as alternative approaches to drug-resistant ventricular arrhythmias in animals. Indeed, recent clinical studies in human medicine have indicated these drugs may increase the incidence of serious ventricular arrhythmias after myocardial infarction.

AMIODARONE. Amiodarone has been in clinical use in human medicine for several years in Europe and more recently in the United States. Few reports are available about the use of amiodarone in animals with heart disease. As a Class III antiarrhythmic agent, amiodarone selectively prolongs the action potential and refractory period; this is expressed clinically as a prolongation of

TABLE 24.4—Dose recommendations for drugs used to treat cardiac arrhythmias in dogs

Drug	Dose and route of administration	Indications
Atropine sulfate, 1/200 g tablets; 0.4 mg/ml injectable	Oral: 0.04 mg/kg every 6–8 hours SC, IM, IV: 0.04 mg/kg every 4–6 hours	Sinus bradycardia, AV block, SA arrest
Calcium chloride*	IV, IC: 0.05–0.10 ml/kg of 10% solution	Ventricular asystole (to increase cardiac irritability), electrical-mechnical dissociation
Digoxin (Lanoxin), 0.125, 0.25, and 0.50 mg tablets; 0.05 mg/ml oral elixir; 0.25 mg/ml IV	Oral: 0.1–0.2 mg/kg in 4 divided doses over 48 hours or to effect (rapid method); 0.02 mg/kg average daily maintenance divided into 2 doses IV: 0.02–0.03 mg/kg in 4 divided doses over 4 hours or to effect	Congestive heart failure, APCs, atrial tachycardia, atrial fibrillation, atrial flutter, sick sinus syndrome (after pacemaker insertion)
Epinephrine hydrochloride* (Adrenalin), 1:1000 solution; 1 mg/ml injectable	IC: 6–10 μg/kg IV: 0.1–0.3 mg of 1:10,000 dilution	Ventricular asystole, changing fine ventricular fibrillition to coarse fibrillation
Isoproterenol (Proternol), 15 and 30 mg tablets; (Isuprel), 0.2 mg/ml injectable	Oral: 15–30 mg 4–6 times daily SC, IM: 0.1–0.2 mg every 4 hours IV: 1 mg/500 ml 5% dextrose/water and titrate to effect	Sinus bradycardia, complete AV block, to initiate heartbeat
Lidocaine (2% without epinephrine) (Xylocaine), 20 and 40 mg/ml injectable	IV: 2–4 mg/kg as bolus over 1–2 min, 0.5–2.0 mg/kg every 20–60 min (slow injection), 25–60 μg/kg/min with monitoring (constant infusion)	Ventricular tachycardia, ventricular premature complexes (especially multiform)
Phenytoin (diphenylhydantoin) (Dilantin), 30 and 100 mg capsules; 125 mg/5 ml syrup; 50 mg/ml injectable	Oral: 4–8 mg/kg divided 3–4 times daily IV: 4 mg/kg slowly once	Ventricular arrhythmias, digitalis-induced arrhythmias
Procainamide (Pronestyl), 250, 375, and 500 mg capsules or tablets; 100 mg/ml injectable	Oral: 125–500 mg every 6–8 hr (not to exceed 33 mg/kg day) IM: 8–16 mg/kg every 3–6 hr IV: 1–2 mg/kg/5 min to effect or toxicity (>50% widening of QRS), not to exceed 1 g	Ventricular premature complexes, ventricular tachycardia
Propranolol (Inderal), 10, 20, and 40 mg tablets; 1 mg/ml injectable	Oral: 2.5–40 mg 2–3 times daily unless desired effect at lower dose or toxicity IV: 0.05 to 0.15 mg/kg slowly to effect or toxicity	Sinus tachycardia, digitalis-induced atrial arrhythmias, supraventricular tachycardias and ventricular arrhythmias, preexcitation arrhythmias, and with digoxin for atrial fibrillation
Quindine sulfate (short-acting form) 3 g tablets; quinidine sulfate (Quinidex Extentabs) (long-acting form), 300 mg tablets; quinidine gluconate injectable (IM), 80 mg/ml; quinidine gluconate (Quinaglute Duratabs) (long-acting form), 5 g tablets; quinidine polygalacturonate (Cardioquin) (long-acting form), 3 g tablets	Oral: 6–20 mg/kg every 6–8 hours (short-acting form), 8–12 hours (long-acting form) IM: 2.0–6.0 mg/kg every 6–8 hours	Ventricular premature complexes, ventricular tachycardia, maintenance therapy after electroconversion of atrial fibrillation and/or flutter, Wolff-Parkinson-White syndrome

Note: IV = intravenous, IM = intramuscular, SC = subcutaneous, IC = intracardiac, AV = atrioventricular, SA = sinoatrial, APC = atrial premature contraction.

*Drugs for cardiac arrest.

AV nodal conduction time and an increase in atrial and ventricular refractory periods (Novotny and Adams 1986). Its use in human medicine has been largely in patients with conditions refractory to other antiarrhythmic agents, including conditions such as paroxysmal atrial tachycardia, atrial flutter and fibrillation, and a recurrent ventricular tachycardia and fibrillation. Amiodarone has a long biologic half-life; days to weeks may be required to gain steady-state plasma concentrations with oral administration.

Clinical Indications. Important clinical uses of antiarrhythmic drugs were summarized when appropriate in the preceding sections on individual drugs. Data shown in Table 24.3 provide a listing of drugs of choice for several common arrhythmias and also point out relevant contraindications (Tilley 1979, 1985). Tables 24.4 and 24.5 provide schedules for approximating doses of several drugs in dogs and cats respectively. The fact remains, however, that although several antiarrhythmic drugs routinely are advocated for control of

TABLE 24.5—Dose recommendations for drugs used to treat cardiac arrhythmias in cats

Drug	Dose and route of administration	Indications
Atropine sulfate, 0.4 mg/ml injectable	SC, IM, IV: 0.04 mg/kg every 4–6 hours	Sinus bradycardia, AV block
Calcium chloride*	IC, IV: 0.05–0.10 ml of 10% solution/kg	Ventricular asystole (to increase cardiac irritability), electrical-mechanical dissocation
Digoxin (Lanoxin), 0.125 mg tablets; 0.25 mg/ml IV	Oral: 0.008–0.01 mg/kg, average daily maintenance divided into 2 doses (e.g., ¼ of a 0.125 mg tablet twice daily for 6 kg cat) IV: 0.02–0.03 mg/kg in 4 divided doses over 4 hours or to effect	Congestive heart failure, APC, atrial tachycardia, atrial fibrillation, atrial flutter
Epinephrine hydrochloride* (Adrenalin), 1:1000 solution; 1 mg/ml injectable	IC: 6–10 μg/kg IV: 0.05–0.1 mg of 1:10,000 dilution	Ventricular asystole, changing fine ventricular fibrillation to coarse fibrillation
Isoproterenol (Isuprel), 0.2 mg/ml injectable	IV: 0.5 mg/250 ml 5% dextrose/water and titrate to effect	Sinus bradycardia, complete AV block
Propranolol (Inderal), 10 mg tablets; 1 mg/ml injectable	Oral: 2.5 mg every 8–12 hours for average 5 kg cat; higher doses to effect IV: 0.25 mg diluted in 1 ml of saline, given as 0.2 ml boluses to effect	Sinus tachycardia, supraventricular tachycardia and ventricular arrhythmias, preexcitation arrhythmias, and with digoxin for atrial fibrillation

spontaneous arrhythmias in animals, well-controlled clinical data on the subject generally are lacking. Dosage recommendations by different investigators often vary widely in the same species, necessitating careful judgment in the clinical setting.

The clinician should integrate basic knowledge about the pharmacologic control of arrhythmias into a rational clinical approach to managing cardiac dysfunction in patients. A precise classification of individual drugs is of less importance to the clinician than a basic understanding of their pharmacodynamic and therapeutic applications. Initial therapy should be directed at correcting specific etiologies; e.g., if serum electrolyte abnormalities are responsible, obviously these should be corrected before a potent antiarrhythmic drug is introduced into the animal. Arrhythmias secondary to congestive heart failure may respond to restitution of cardiac compensation, and initial treatment with a primary antiarrthythmic drug may intensify rather than reverse the disease. Use of physical maneuvers such as ocular pressure, massage of the carotid sinus region, or a blow to the chest should not be disregarded (Ettinger and Suter 1970; Hilwig 1976; Tilley 1979, 1985).

TABLE 25.1—Units of measure and conversions commonly used in fluid therapy

Term	Abbreviation	Description and conversion
Molecular (formula) weight	MW	Sum of atomic weights of all elements in a chemical formula
Millimole	mmol (mM)	Molecular (formula) weight of a substance in mg, equals 1 mM
Milliequivalent	mEq	Weight, in mg, of an element that combines or replaces 1 mg (1 mmol) of hydrogen (H^+)
Milliosmole	mOsm	Always contains 6.0×10^{23} molecules and equals 1 mmol of a nondissociable substance
Milliequivalent per liter	mEq/L	= mmol/L × valence = [(mg/dL × 10)/MW] × valence

COMPOSITION AND DISTRIBUTION OF BODY FLUIDS

Units of Measure. The units of measure commonly utilized in discussion of fluid balance are presented in Table 25.1. Ions or electrolytes combine according to valence (charge) rather than molecular weight. Hence in the case of univalent ions, 1 mM = 1 mEq. One mM of a divalent ion provides 2 mEq. By expressing most electrolyte concentrations in milliequivalents per liter (mEq/L), and comparing the concentration of cations to anions in the body, it becomes clear that electroneutrality exists. Although extracellular cations are often more completely documented in the course of clinical investigations, anions, particularly chloride and bicarbonate, are the electrical counterbalance. Some electrolytes are measured in millimoles per liter (mM/L) because they exist in variable states of protein binding or valence. An example is total calcium, because protein binding confounds any simple assessment of ionized fraction. Phosphorus exists in variable proportions of phosphate and monohydrogen and dihydrogen phosphate, so no valence can be assigned and calculation of milliequivalence is therefore inaccurate. Since mEq/L are the most common and informative unit of comparison for most electrolytes, conversion formulas are also provided in Table 25.1.

Solutes exert an osmotic effect in solution that is dependent only on the number of particles in solution, not on molecular weight or valence. Hence for nondissociable substances, 1 osmole contains 1 mole of substance. If a substance dissociates in solution, the number of osmoles is increased according to the number of particles generated per mole of dissociated substance. For example, each mmol of a completely dissociated NaCl solution yields 2 mOsm. Osmolarity refers to the number of osmoles per liter, and osmolality indicates the number of osmoles per kilogram of solvent (Rose 1989). In physiological systems the difference between these two is usually small. The concept of osmolality explains why solutions of diverse chemical and electrical composition (e.g., 5% dextrose, 0.9% NaCl, and 1.3% sodium bicarbonate) can all be considered isotonic. For mammals, isotonic solutions equal approximately 300 mOsm.

Body Fluid Compartments. Semipermeable membranes separate most body compartments, allowing the free passage of water and selected solutes. The effective osmolality, or tonicity, of a solution is related to the ability of a solute to attract water and to sustain an increase in osmotic pressure as a result of water movement. For example, two substances with equal ability to attract water down a concentration gradient and across a semipermeable membrane may have very different effects on osmotic pressure, depending upon the movement of the substance itself through the semipermeable membrane. While the measured osmolality of a solution includes all osmoles, whether effective or ineffective, tonicity of a solution relates only to effective osmolality. For example, a solution containing 300 mOsm of nonpenetrating NaCl and 100 mOsm of urea, which can cross plasma membranes, would have a total osmolarity of 400 mOsm and would be hyperosmotic. However, if one put red blood cells in this solution, they would not shrink or swell, because the urea would diffuse into the cells and reach equilibrium inside and outside the cells. Thus, both extracellular and intracellular solutions would have the same osmolarity. There would be no difference in the water concentration across the membrane and no change in cell volume. The solution is therefore considered isotonic.

Ultimately all fluids within the body are in dynamic equilibrium, but it is helpful during fluid therapy to consider body water as existing in several compartments since critical fluid shifts can and do occur. Determination of the volumes of these compartments is problematic, as can be deduced from the large number of different methods that have been used to estimate these volumes (Kohn and DiBartola 1992). The most common method for assessment of volume in body fluid compartments depends upon intravenous administration of a known amount of a dye or radioisotope-tagged substance that distributes only in the compartment of interest. This is followed by assessment of dye or radioisotope concentration in the compartment. Ideally, the indicator substance must distribute rapidly and homogeneously, remain in the space to be measured, not be metabolized or bound, and be nontoxic. The volume of distribution (Vd) of a drug, or in this case a volume marker, may be derived according to the same principles of pharmacokinetics described elsewhere in this text.

Total body water (TBW) is approximated at 60% of body weight, but this figure varies from 50 to 75% depending upon age, lean body mass, and individual

TABLE 25.2—Approximate volumes of selected fluid compartments in the dog

Compartment	% Body weight (BW)	Method
Total body water (TBW)	60	Indicator substance
ECF	20–27	Indicator substance
Red blood cells (RBC)	3	Counted + calculations
Plasma volume (PV)	5	Indicator substance
Total blood volume (BV)	5.7–10	Calculated: RBC volume + PV
Interstitial lymph fluid	15	Calculated: ECF – BV
Transcellular fluid	1–6	Estimated
Bone and dense connective tissue	5	Estimated
ICF	33–40	TBW – ECF

Source: Estimated from data collected in multiple studies as detailed in Kohn and DiBartola 1992, 5–7.

TABLE 25.3—Approximate values for blood volumes of various animals expressed as percentages of body weight

Species	Total blood volume	Plasma volume	RBC volume
Dogs	8.5	4.5	4.0
Cats	6.7	4.7	2.0
Chickens	6.5	4.5	2.0
Cattle	5.7	3.8	1.9
Goats	7.0	5.4	1.6
Horses			
Draft	7.0	4.0	3.0

animal variations. Since fat is lower in water content than lean tissue, obesity is associated with decreased TBW (approximately 50%). To avoid overhydration of obese patients, fluid requirements are best estimated based on lean body mass. Very young animals are about 70–75% water, with TBW declining with advancing age. Table 25.2 provides estimates of selected volumes in dogs. TBW is broadly divided into two types: intracellular (ICF) and extracellular fluid (ECF). The ECF is further divided into four subcompartments: plasma volume, interstitial lymph fluid, transcellular fluid, and fluid present in dense connective tissue and bone. Table 25.3 provides experimentally derived blood volumes as percentages of body weight for various species.

Transcellular fluid is found in diverse locations, including cerebrospinal fluid, pleural cavity, gastrointestinal tract, bladder, synovia, aqueous humor, and peritoneal cavity. Transcellular volumes vary greatly from monogastrics (1–6%) to horses and ruminants (10–15%), dependent largely upon the amount of fluid sequestered in the gastrointestinal tract. Transcellular volumes are not readily mobilized during volume deficits but are of importance in terms of drug disposition and equilibrium. In certain disease processes, transcellular fluids may accumulate, causing ascites, hydropericardium, hydrothorax, synovitis, or other conditions, depending on the location of fluid accumulation.

Fluid and Electrolyte Distribution. Body solutes are not distributed homogeneously throughout TBW. Like drugs, every solute has a defined space or volume of distribution that can be assessed experimentally. As with estimation of body compartment volumes, determination of solute distribution is limited by the features of the labeled solute used. Because normal vascular endothelium is largely impermeable to formed blood elements and plasma protein, these cells and solutes are usually limited to the plasma. Vascular endothelium is freely permeable to ionic solutes, and the concentration of these ions is almost the same in interstitial as in plasma fluid. Table 25.4 provides estimations of ion composition in plasma of normal mammals.

The volume of ICF and ECF compartments is determined by the number of osmotically active particles in each space. ECF osmolality can be estimated from the following formula:

$$\text{ECF osmolality (mOsm/kg)} = 2\left(\left[\text{Na}^+\right]+\left[\text{K}^+\right]\right)+\frac{\text{glucose}}{18}+\frac{\begin{array}{c}\text{blood urea}\\ \text{nitrogen}\\ \text{(BUN)}\end{array}}{2.8}$$

(Rose 1989). Because cell membranes are permeable to urea and K^+, these substances contribute only ineffective osmoles, as described earlier. At normal blood glucose concentrations, Na^+ is the primary determinant of effective ECF osmolality. Because Na^+ is the most abundant and osmotically active ECF cation, maintenance of an extracellular-to-intracellular sodium gradient is critical and is accomplished by the cell membrane Na^+,K^+-adenosine triphosphatase (ATPase) pump. This pump is also responsible for maintaining appropriate concentrations of intracellular K^+. Because K^+ is the most abundant intracellular cation, the ratio of intracellular-to-extracellular K^+ concentration is the major determinant of the resting cell membrane potential (–70 to –90 mV). Because all body fluid spaces are isotonic with one another, the effective osmolality of the ICF, and indeed TBW, must be equal to that of the ECF. Acute addition or loss of fluid and/or solutes from the body inevitably results in alterations in

TABLE 25.4—Approximate average concentrations of cations and anions in plasma in normal mammals

Cations	mEq/L	Anions	mEq/L
Sodium	135–160	Chloride	110–125
Potassium	3–5	Bicarbonate	18–22

*Phosphate exists in variable proportions of phosphate and monohydrogen and dihydrogen phosphate, so no valance can be identified and the number of mEq/L is therefore an estimate (Gross 1994).

compartment volumes and tonicity. Homeostatic shifts of fluid between compartments must then occur to return the system to isotonicity.

The critical distribution of water between the plasma and the interstitium is maintained by the colloidal osmotic pressure of plasma protein (oncotic pressure). This is the force that draws water into the capillaries and balances the hydrostatic pressure driving water out. These so-called Starling forces describe the capillary balance between forces that favor filtration of water from plasma and those that retain vascular volume:

$$\text{Net filtration (NF)} = K_f\,[(P_{cap} - P_{if}) - (\pi_p - \pi_{if})]$$

where K_f represents permeability of the capillary wall, P represents hydrostatic pressure in the capillaries (P_{cap}) (blood) or tissues (P_{if}) (interstitial fluid), and π represents oncotic pressure generated by plasma protein (π_p) or filtered proteins and glycosaminoglycans in the interstitium (π_{if}). Applying Starling's relationships yields the prediction that hypoproteinemia (decreased π_p) will increase loss of vascular fluid and that water depletion (with a relative increase in π_p and a decrease in P_{cap}) will promote reabsorption of interstitial fluid into the vasculature (Kohn and DiBartola 1992). The volume of intracellular water in a given tissue is maintained by intracellular protein. As plasma water decreases, plasma protein competes with intracellular protein for water, resulting in cellular dehydration. Clinical alterations in plasma osmolality may be assessed by comparing measured osmolality in a patient to calculated serum osmolality as determined using Na^+, K^+, glucose, and BUN measurements (see the ECF osmolality equation provided above). Observed changes in the osmolal gap (difference between measured osmolality and the osmolality calculated from normal concentrations) may be useful in determining the presence of unmeasured osmoles associated with toxic substances such as ethylene glycol. The osmolal gap may also be useful in assessing shifts in plasma sodium concentration (Kohn and DiBartola 1992).

The number of cations in the ECF must equal the number of anions in order to maintain electroneutrality. In practice, only selected cations and anions are routinely measured in a clinical setting. Calculation of the difference between the commonly measured cations and anions in ECF yields the unmeasured anions, or anion gap (Oh and Carrol 1977; Emmett and Narins 1977). The anion gap calculation can be useful in assessing the etiology of metabolic acidosis and will be discussed in this context subsequently.

WATER, SODIUM, AND CHLORIDE

Homeostasis. Daily intake of water, nutrients, and minerals is normally balanced by daily excretion of these substances. *Water turnover* is the term used to describe input and output of body water over a given period of time. Values for water turnover, per 24 hours, in various domestic animals resting in cages or stalls range from about 40 to 132 mL/kg/day. The range is influenced by species, age, and physiologic state (Adolph 1939; Smith 1970). Extremes of temperature, psychologic state, disease, and other variables may change water demands markedly. Water turnover in mature dogs is approximated as 40–60 mL/kg/day, while immature and lactating animals may turn over approximately twice this amount (Muir and DiBartola 1983). Maintenance fluid needs are defined as the volume of fluid required daily to maintain an animal in zero fluid balance, that is, no net gain or loss of water.

Normal water intake occurs in response to thirst, which is stimulated by plasma hypertonicity and/or contracted ECF volume. Plasma hypertonicity, the primary stimulus, prompts osmoreceptors in the supraoptic and paraventricular nuclei of the hypothalamus to release vasopressin, also called antidiuretic hormone (ADH), which is released into the circulation at the level of the pituitary neurohypophysis. Binding of vasopressin to receptors in the distal nephron and renal collecting duct cells activates adenylyl cyclase and increases intracellular cyclic AMP. A protein kinase cascade initiated by activation of protein kinase A results in opening of luminal water pores in the tubule cell. Permeability of the collecting duct to water and reabsorption of water increase. Sustained release of vasopressin depends additionally upon calcium cycling across the plasma membrane and activation of protein kinase C–dependent pathways. Prostaglandins inhibit the renal response to vasopressin. Drugs with anticyclooxygenase activity that inhibit prostaglandin synthesis thereby enhance the action of endogenous vasopressin. Fig. 25.1 summarizes the effects of selected drugs and electrolytes on vasopressin release and action.

If ECF volume and renal perfusion decrease, volume receptors in the renal juxtaglomerular apparatus respond, causing the secretion (or release) of renin, which converts angiotensinogen to angiotensin I. This is the rate-limiting step in the renin-angiotensin sys-

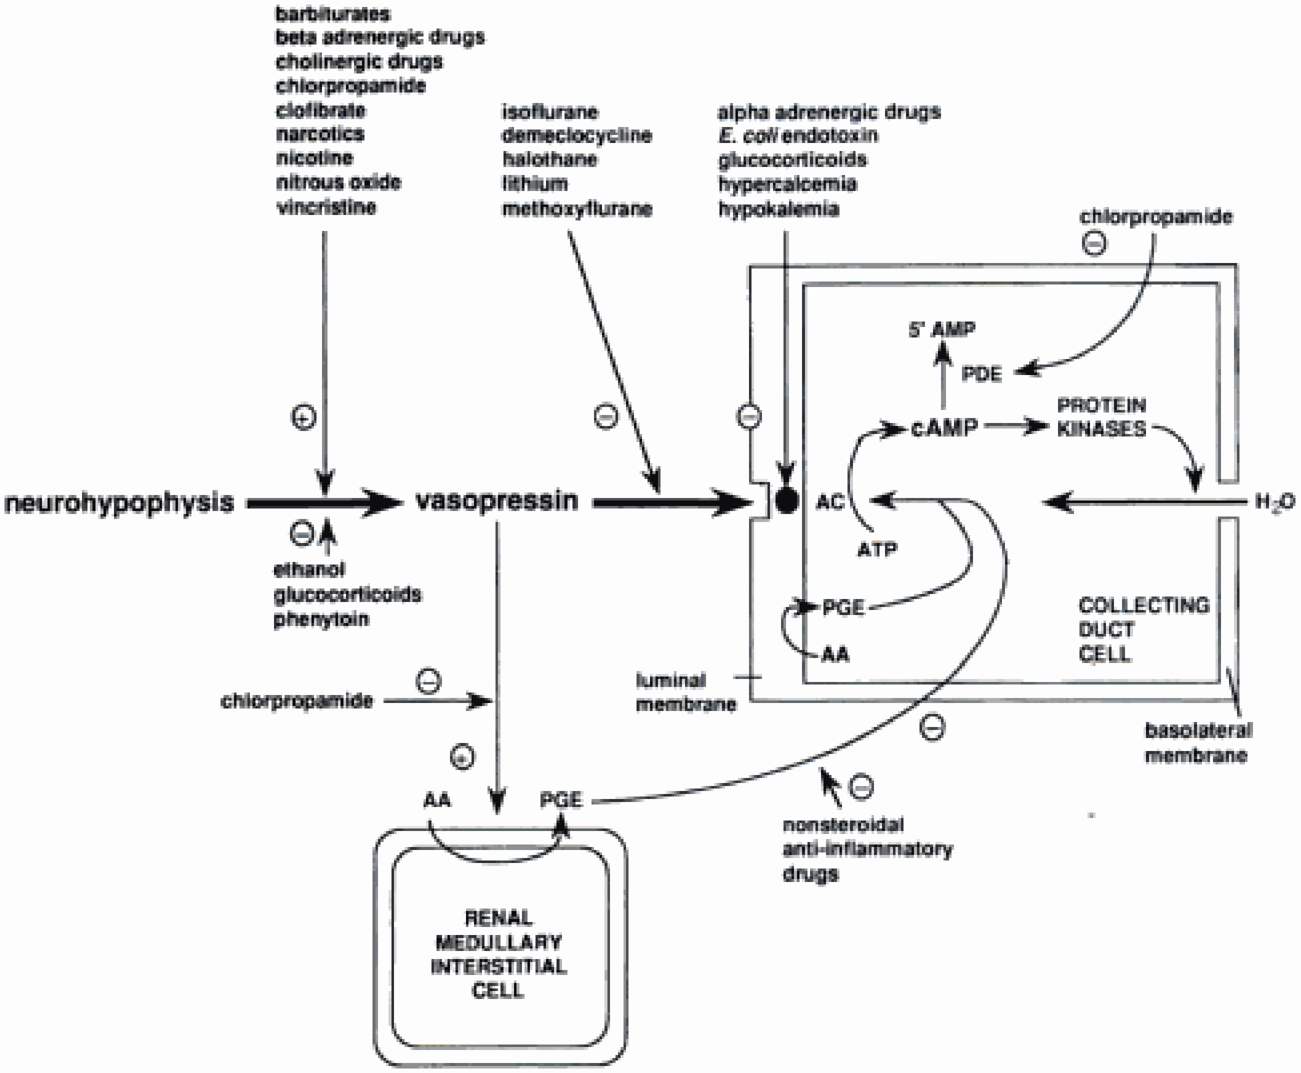

FIG. 25.1—Effects of drugs and electrolytes on vasopressin release and mechanisms of cellular action. AA = arachidonic acid; AC = adenylyl cyclase; ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; PDE = phosphodiesterase; PGE = prostaglandin E. (Adapted from DiBartola 1992c, Fig. 3-3.)

tem. Angiotensin I is activated to the potent vasoconstrictor angiotensin II in the lung and in endothelial cells throughout the body by angiotensin-converting enzyme (ACE). Angiotensin II stimulates the zona glomerulosa of the adrenal cortex to secrete aldosterone, which, in turn, causes increased reabsorption of sodium from the distal nephron with excretion of K^+ and H^+. Due to the increased concentration of sodium, plasma becomes hypertonic, causing vasopressin release and water retention.

Water intake occurs in response not only to thirst but also to hunger. Water content of food may be as low as 10% (dry food) or as high as 90% (succulent green pasture). Canned pet foods generally contain more than 70% water, and semimoist foods are intermediate (20–40% water) (Lewis and Morris 1987). Intake of dietary water is governed centrally by appetite control mechanisms rather than by fluid and electrolyte homeostasis. In addition to water intake related to eating and drinking, metabolic water is produced endogenously by catabolism of proteins, fats, and carbohydrates (approximately 5 mL/kg/day) and represents about 10–15% of total water intake in dogs and cats (Anderson 1983).

Normal water loss occurs via urine, fecal water, and saliva (sensible loss), with insensible losses occurring via evaporation from cutaneous and respiratory epithelia. Insensible losses account for TBW elimination of about 15–30 mL/kg/day in healthy, sedentary animals in a thermoneutral environment (Kohn and DiBartola 1992).

Metabolic rate, and therefore a portion of daily water turnover, are directly proportional to the ratio of body surface area to total volume. For example, the surface area to volume ratio in a puppy is much larger than in an adult dog and the puppy has a higher basal metabolic rate. Both lead to a much greater evaporative loss of water from the skin per unit volume. Hence, daily water turnover per unit body weight may be nearly twice that of the adult animal. Small, immature animals are therefore at greater risk for insensible water loss than large, mature animals.

The most important and predictable loss of water in healthy, sedentary animals, in a thermoneutral environment, occurs via the urine. Urinary losses can vary from 2 to 20 mL/kg/day. Daily urinary water losses may be divided into obligatory water loss and free water loss (Kohn and DiBartola 1992). Obligatory water loss represents water eliminated in order to excrete the daily renal solute load. The renal solute load is derived from dietary sources of protein and minerals and consists of urea, Na^+, K^+, Ca^{++}, Mg^{++}, NH_4^+, and other cations; and PO_4^{3-}, Cl^-, SO_4^{2-}, and other anions. Hence, daily renal solute load is a function of the quantity and composition of food ingested. Urea accounts for two-thirds of the urinary solute load in dogs (O'Connor and Potts 1969).

In normal animals increased urine solute load is eliminated by an increase in urine volume (obligatory water loss) rather than a marked increase in urine osmolality. Hence, urine osmolality is not generally maximized in order to accomplish steady-state elimination of solutes. Obligatory renal water loss is clinically important for removal of renal solutes but also because this type of water loss will continue even in states of relative water deficit. Free water loss represents water excreted unaccompanied by solute. Excretion of free water is controlled by vasopressin and increases during relative water excess or hypotonicity and decreases during water deficit or hypertonicity. Obligatory fecal water loss occurs in order to excrete fecal solutes. Fecal losses ordinarily account for 2–5% of TBW losses and vary with the species. Feces typically contain 50–80% water (Kohn and DiBartola 1992).

Renal Regulation of Sodium, Chloride, and Water Excretion. Elimination or conservation of body water and solutes via the kidneys depends upon the processes of glomerular filtration and renal tubular reabsorption and secretion. A major mechanism for conservation of water is urine concentration. The canine kidney can concentrate urine to as much as 2400 mOsm, compared to 1200–1400 mOsm achieved in human urine. Elimination of substances via the urine depends upon renal clearance of each substance from the plasma. The volume of plasma that must be filtered each minute to account for the amount of substance appearing in the urine each minute under steady-state conditions defines renal clearance of that substance.

As much as 20% of cardiac output is directed to the kidneys, with blood entering a renal glomerulus through an afferent arteriole and leaving through an efferent arteriole. Resistance changes in afferent and efferent capillaries regulate glomerular filtration rate (GFR). For discussions of normal and abnormal renal physiologic function the reader is referred to any standard physiology text. An understanding of the complexities of renal function is crucial to the understanding of water, acid-base, and electrolyte balances.

As glomerular filtrate flows through the tubules, most of the water (greater than 90%) and varying amounts of solute are reabsorbed into the peritubular capillaries. The composition of the tubular reabsorbate closely approximates that of ECF. Reabsorption is largely achieved by transport of electrolytes and other solutes in two steps: (1) absorption of solutes from tubular fluid into tubular cells and (2) movement of solutes from tubular cells into the ECF. Several types of transport account for tubular reabsorption of solutes, including passive transport (simple diffusion), facilitated diffusion, active transport, and cotransport. These mechanisms are discussed in more detail in the context of diuretic drugs (Chap. 26) and summarized in Fig. 26.2. Fig. 25.2 depicts some of the functional processes for regulation of salt and water transport in different segments of the nephron.

As much as 60–65% of filtered solute is reabsorbed in the proximal tubule accompanied by osmotically proportional amounts of water. The tubular fluid at the distal portion of the proximal tubule becomes slightly hypoosmotic. Passive reabsorption of substances, especially sodium and chloride, continues in the thin segment of the loop of Henle. The thick ascending limb of the loop of Henle and the distal convoluted tubule are relatively impermeable to water but actively reabsorb solute. Sodium and chloride enter tubular cells in the thick ascending limb of Henle's loop by crossing the luminal membrane coupled to potassium in a proportion of 1 Na^+:1 K^+:2 Cl^-. Sodium is then actively extruded across the basolateral membrane to maintain intracellular sodium at low levels. Potassium and chloride leave the tubular cell passively. Two consequences of this are decreased concentration of sodium and chloride in the tubular lumen and increased concentration of each in interstitial fluid. A concentration gradient across the tubular epithelium is established, and this becomes multiplied in a longitudinal direction by the countercurrent mechanism. The collecting ducts are responsive to vasopressin, and in its presence the ducts become highly permeable to water. Tubular fluid equilibrates with hyperosmotic interstitium, and hypertonic (concentrated) urine results. In the absence of vasopressin, the ducts are relatively impermeable to water. In this case, sodium and chloride have been reabsorbed proximally to the collecting ducts, tubular fluid is hypoosmotic, and voided urine is dilute (Thier 1987).

Renal reabsorption of sodium in the distal nephron is increased by aldosterone, a mineralocorticoid synthesized in the zona glomerulosa of the adrenal cortex. Aldosterone is produced and released in response to stimulation by angiotensin II, hyperkalemia, and by a decrease in dietary sodium intake. Adrenocorticotropic hormone (ACTH) and hyponatremia play permissive roles in promoting aldosterone secretion. Increased dietary sodium and atrial natriuretic peptide (ANP) decrease aldosterone production. ANP is a polypeptide released from atrial and ventricular myocytes in response to atrial distention asso-

ciated with volume expansion. ANP causes vascular smooth muscle relaxation, inhibits production of aldosterone in the adrenal glands, and blocks the production of angiotensin II. Study results suggest that parathyroid hormone (PTH) is required for augmented ANP secretion in response to acute volume loading in rats. PTH may play an important role in the regulation of fluid homeostasis via control of ANP (Geiger et al. 1992).

In general, chloride is reabsorbed with sodium throughout the nephron. As previously noted, chloride is exchanged in a ratio of 1 Na^+:1 K^+:2 Cl^- in the thick ascending limb of Henle's loop during sodium reabsorption. Because the cotransporter in this exchange has a very high affinity for both Na^+ and K^+, luminal Cl^- concentration is normally the rate-limiting step in NaCl entry into the cell (Gregor and Velazquez 1987). Additional active and passive processes contribute to proximal Cl^- reabsorption in the renal tubules. Chloride exchange for formate appears to occur via an anion exchanger in the luminal membrane. Low concentrations of filtered formate combine with H^+ to form formic acid (HF) in the tubular lumen. Because HF is uncharged, it moves freely into the tubular cell. Two additional mechanisms set the stage for conversion of HF back to formate and H^+. First, basolateral Na^+,K^+-ATPase pumps maintain a low intracellular sodium concentration, and this, in turn, allows for the continued exchange of Na^+-H^+ across the luminal membrane. As Na^+ is reabsorbed and H^+ is secreted, the interior of the cell is left with a lower $[H^+]$ than the tubular lumen. Under these conditions HF is converted back to H^+ and formate, providing for continued chloride-formate exchange. Reabsorbed chloride is returned to the ECF across the basolateral membrane by selective Cl^- channels and a K^+-Cl^- cotransporter (Rose 1994). Additional transport mechanisms in type B intercalated cells in the cortical collecting tubule may exchange bicarbonate for chloride. The favorable inward concentration gradient for chloride (lumen concentration greater than inside the cell) presumably provides the energy for bicarbonate secretion via this mechanism (Bastani et al. 1991).

Disorders of Water, Sodium, and Chloride Balance

TYPES OF DEHYDRATION. Dehydration may be considered in three general categories: hypertonic, isotonic, and hypotonic. Pure water loss and loss of hypotonic fluid lead to hypertonic dehydration. As pure water is lost from the ECF, fluid shifts from the intra- to the extracellular compartment in response to increased osmolality. The resulting proportionate distribution of volume loss results in fewer clinically detectable signs of volume depletion in the patient. Causes of dehydration associated with pure water deficit include

TABLE 25.5—Physical findings in dehydration

Percent dehydration	Clinical signs
4 or less	History of fluid loss, mucous membranes still moist, evidence of thirst
5–6	Subtle loss of skin elasticity, slight delay in return of skin to normal position, hair coat dull, mucous membranes slightly dry but tongue still moist
7–8	Definite delay in return of skin to normal position, both mucous membranes and tongue may be dry, eyeballs may be soft and sunken, slight prolongation of capillary refill time
9–11	Tented skin does not return to normal position, definite prolongation of capillary refill time, eyes definitely sunken in orbits, all mucous membranes dry, may be signs of shock such as tachycardia, cool extremities, rapid and weak pulses
12–15	Definite signs of shock and circulatory collapse, death is imminent.

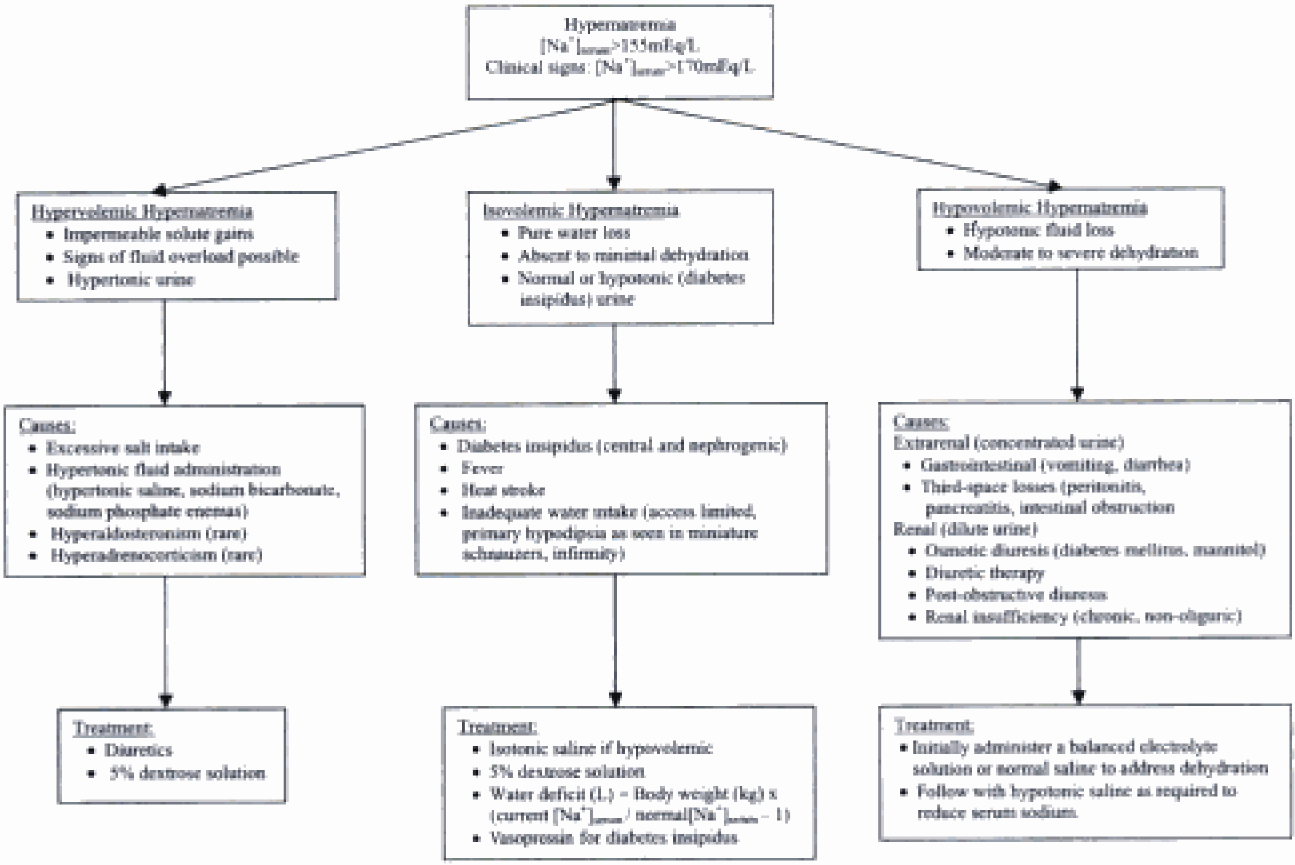
hypodypsia due to neurologic disease, diabetes insipidus, respiratory losses during exposure to elevated temperatures, fever, and inadequate access to water.

Loss of hypotonic fluid, as compared to pure water, results in a greater depletion of ECF volume since there is less osmotic drive to pull volume from the intracellular space. Hypotonic fluid losses are common and have been subclassified as extrarenal and renal. Extrarenal losses could include gastrointestinal (e.g., vomiting or diarrhea) or third-space loss (e.g., pancreatitis, peritonitis, as a result of surgery or cutaneous injury). *Third spacing* is a term used to describe extravasation of fluid from the vascular compartment into extravascular spaces. As tonicity of lost fluid approaches or exceeds normal plasma osmolality (about 300 mOsm/kg), disproportionate depletion of ECF causes more evident clinical signs of dehydration. Volume depletion would likely be the most clinically apparent in cases of hypertonic fluid loss.

Estimations of percent dehydration based on clinical signs are given in Table 25.5. Skin elasticity is a useful indicator of hydration status. However, age of the animal, body condition, and the technique used for evaluating elasticity may affect hydration assessment. With advancing age or cachexia, loss of fat and protein may account for decreased skin elasticity unrelated to hydration. Conversely, obese animals are likely to retain skin elasticity longer in the face of dehydration. Possibly as a result of variations in elastin content of skin, some species display smaller changes in elasticity for a given degree of dehydration. This may be clinically important in the horse. While dry mucous membranes can indicate dehydration, open-mouthed breathing associated with respiratory disease may cause misleading mucous membrane dryness. Degree of enopthalmos is considered a very useful parameter in assessment of dehydration in large animals. For example, the measured gap between the eyeball and orbit has been included as a guideline for assessment of dehydration in neonatal calves. A gap less than 0.5 cm is correlated with 9–10% dehydration, and a gap greater than 0.5 cm suggests 11–12% loss of hydration (Naylor 1996). A recent study evaluated several clinical and laboratory parameters to determine which were most useful in assessment of dehydration in diarrheic calves. Factors assessed included extent of enophthalmos, skin-tent duration on neck, thorax, and upper and lower eyelids, heart rate, mean central venous pressure, peripheral (extremities) and core temperatures, packed-cell volume, and hemoglobin and plasma protein concentration. The best predictors of degree of dehydration were extent of enophthalmos, skin elasticity on neck and thorax, and plasma protein concentration (Constable et al. 1998). Laboratory parameters such as hematocrit, plasma protein, and osmolality are often useful, but assessment should include consideration of possible preexisting derangements, such as anemia or hypoproteinemia, that could confound interpretation. If an accurate previous body weight is known, serial changes in weight are considered a very useful and accurate measurement in determining degree of dehydration.

HYPERNATREMIA. As the most important and abundant ECF cation, sodium is essential for proper maintenance of membrane potentials, initiation of action potentials, and, according to strong ion difference theory, maintenance of acid-base balance. Plasma sodium concentration and plasma osmolality generally vary in parallel since sodium and its associated anions account for greater than 95% of plasma osmolality. Plasma sodium concentration reflects the ratio of body sodium ion concentration to TBW. Total body sodium content, however, is independent of plasma sodium concentration and may be increased, decreased, or unchanged in the presence of hyper- or hyponatremia.

Clinical signs associated with alterations in serum sodium are more related to the rapidity of change rather than to the magnitude of sodium increase or decrease. Hypernatremia (e.g., >155 mEq sodium/L in dogs) and ECF hypertonicity can be caused by a loss of pure water, a loss of hypotonic fluid (extrarenal or renal), or a gain of impermeable sodium-containing solute (see Fig. 25.3). Clinical signs of hypernatremia are usually observed in dogs and cats as sodium concentration approaches and exceeds 170 mEq/mL. The signs seen are related to the osmotic movement of water out of cells. Negative effects of cellular dehydration are most pronounced in the brain and lead to the characteristic neurologic deficits associated with hypernatremia. These deficits include abnormal behavior and mentation, ataxia, seizures, and coma. The more rapidly water shifts out of brain cells, the greater the chance that decreased brain volume will lead to rupture of



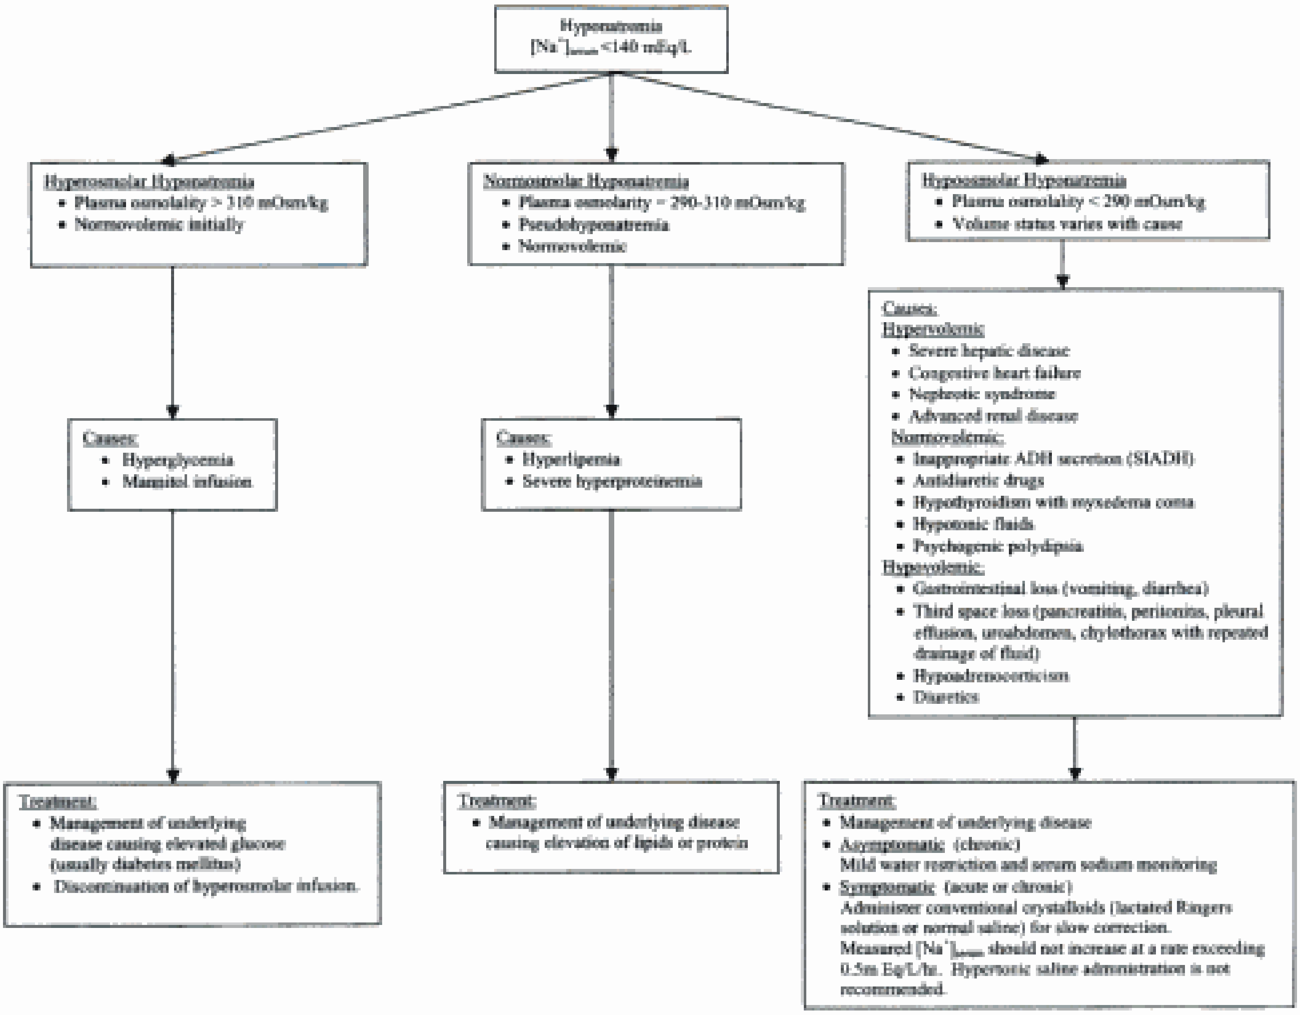
Hyperatremia
[Na⁺]serum>155mEq/L
Clinical signs: [Na⁺]serum>170mEq/L
Hypervolemic Hypernatremia
• Impermeable solute gains
• Signs of fluid overload possible
• Hypertonic urine
Isovolemic Hypernatremia
• Pure water loss
• Absent to minimal dehydration
• Normal or hypotonic (diabetes insipidus) urine
Hypovolemic Hypernatremia
• Hypotonic fluid loss
• Moderate to severe dehydration
Causes:
• Excessive salt intake
• Hypertonic fluid administration (hypertonic saline, sodium bicarbonate, sodium phosphate enemas)
• Hyperaldosteronism (rare)
• Hyperadrenocorticism (rare)
Causes:
• Diabetes insipidus (central and nephrogenic)
• Fever
• Heat stroke
• Inadequate water intake (access limited, primary hypodipsia as seen in miniature schnauzers, infirmity)
Causes:
Extrarenal (concentrated urine)
• Gastrointestinal (vomiting, diarrhea)
• Third-space losses (peritonitis, pancreatitis, intestinal obstruction
Renal (dilute urine)
• Osmotic diuresis (diabetes mellitus, mannitol)
• Diuretic therapy
• Post-obstructive diuresis
• Renal insufficiency (chronic, non-oliguric)
Treatment:
• Diuretics
• 5% dextrose solution
Treatment:
• Isotonic saline if hypovolemic
• 5% dextrose solution
• Water deficit (L) = Body weight (kg) x (current [Na⁺]serum / normal[Na⁺]serum – 1)
• Vasopressin for diabetes insipidus
Treatment:
• Initially administer a balanced electrolyte solution or normal saline to address dehydration
• Follow with hypotonic saline as required to reduce serum sodium.

FIG. 25.3—Summary of classification, causes, and treatment of hypernatremia. See text for additional details of treatment.

cerebral vessels and focal hemorrhage (Arieff and Guisado 1976). If sodium concentration or concentration of sodium-containing impermeable solute increases slowly, the brain attempts to adapt to the hypertonic state by production of intracellular solutes (e.g., sugars, amino acids) known as "idiogenic" osmoles. Production of these osmotically active substances protects the cell by retaining intracellular volume and preventing cellular dehydration. In addition to neurologic deficits, other clinical signs of hypernatremia include thirst, anorexia, lethargy, vomiting, and muscle weakness. If hypernatremia is related to hypotonic fluid loss, then clinical signs of dehydration (as previously described) may be present. If a gain of sodium has caused the hypernatremia, volume overload may be a problem, especially in patients with cardiac disease.

Restoration of ECF volume and tonicity is of primary importance in treatment of hypernatremia. Volume replacement must be accomplished slowly to avoid rapid shifts in plasma osmolality. In general, the rate of fluid administration is determined by the rate of onset of the hypernatremia. When treating chronic hypernatremia, the serum sodium concentration should drop at a rate that does not exceed 0.7 mEq/L/hr (O'Brien 1995). If plasma osmolality drops quickly, water may be attracted intracellularly by idiogenic osmoles, resulting in development of cerebral edema. In the case of pure-water loss, volume can be replaced with 5% dextrose in water over a 48- to 72-hour period. Since the dextrose ultimately enters cells and is metabolized, 5% dextrose administration is essentially replacement with pure water. Use of a 1:1 mixture of normal saline with 5% dextrose solution yields an isotonic solution of 2.5% dextrose, 0.45% saline that has also been utilized. This solution decreases plasma tonicity more slowly and decreases the chance for cerebral edema. Hypotonic fluid losses should generally be replaced with an isotonic crystalloid solution. If hypernatremia has resulted from addition of sodium or sodium-containing impermeable solute, then administration of 5% dextrose and water should be accomplished cautiously to avoid pulmonary edema. Diuretics may be useful in promoting saluresis (sodium excretion) as ECF volume is restored (Marks 1998).

HYPONATREMIA. Causes of hyponatremia (<135–140 mEq sodium/L) are best categorized if two additional variables, osmolality and hydration, are also considered. As indicated in Fig. 25.4, the more common causes of hyponatremia are accompanied by decreased plasma osmolality (<290 mOsm/kg) with or without volume depletion. If volume depletion exists with hyponatremia, then loss of body sodium has exceeded water loss. Physiologic responses to hypovolemia lead to impaired water excretion and a relative dilution of



Hyponatremia
$[Na^+]_{serum}$ <140 mEq/L
Hyperosmolar Hyponatremia
• Plasma osmolality > 310 mOsm/kg
• Normovolemic initially
Normosmolar Hyponatremia
• Plasma osmolarity = 290-310 mOsm/kg
• Pseudohyponatremia
• Normovolemic
Hypoosmolar Hyponatremia
• Plasma osmolality < 290 mOsm/kg
• Volume status varies with cause
Causes:
• Hyperglycemia
• Mannitol infusion
Causes:
• Hyperlipemia
• Severe hyperproteinemia
Causes:
Hypervolemic:
• Severe hepatic disease
• Congestive heart failure
• Nephrotic syndrome
• Advanced renal disease
Normovolemic:
• Inappropriate ADH secretion (SIADH)
• Antidiuretic drugs
• Hypothyroidism with myxedema coma
• Hypotonic fluids
• Psychogenic polydipsia
Hypovolemic:
• Gastrointestinal loss (vomiting, diarrhea)
• Third space loss (pancreatitis, peritonitis, pleural effusion, uroabdomen, chylothorax with repeated drainage of fluid)
• Hypoadrenocorticism
• Diuretics
Treatment:
• Management of underlying disease causing elevated glucose (usually diabetes mellitus)
• Discontinuation of hyperosmolar infusion.
Treatment:
• Management of underlying disease causing elevation of lipids or protein
Treatment:
• Management of underlying disease
• Asymptomatic (chronic)
Mild water restriction and serum sodium monitoring
• Symptomatic (acute or chronic)
Administer conventional crystalloids (lactated Ringers solution or normal saline) for slow correction.
Measured $[Na^+]_{serum}$ should not increase at a rate exceeding 0.5m Eq/L/hr. Hypertonic saline administration is not recommended.

FIG. 25.4—Summary of classification, causes, and treatment of hyponatremia. See text for additional details of treatment.

the sodium remaining in body fluids. Hypovolemia causes decreased renal perfusion and GFR, leading to a decline in water excretion. Slower movement of filtrate through renal tubules enhances isosmotic reabsorption of salt and water in the proximal tubules and decreases presentation of tubular fluid at distal diluting sites. Additionally, hypovolemia prompts vasopressin release, further impairing water elimination. Finally, thirst related to hypovolemia results in consumption of low-sodium fluids that also dilute existing plasma sodium (DiBartola 1992c).

Hyponatremia accompanied by hypervolemia and low plasma osmolality occurs in clinical disorders where there is a physiological perception of volume depletion by in vivo volume detectors. The physiological response is volume expansion. For example, in congestive heart failure, decreased cardiac output is sensed as volume depletion by baroreceptors. Release of vasopressin impairs water excretion, leading to expanded vascular volume. Decreased effective circulating volume and decreased renal perfusion also lead to activation of the renin-angiotensin-aldosterone system. Enhanced renal retention of sodium contributes to expanded vascular volume. In cirrhosis and the nephrotic syndrome, hypoalbuminemia and decreased oncotic pressure may contribute to decreased effective circulating volume and, ultimately, vasopressin release and volume expansion. Other features of hepatic and renal disease also contribute to decreased circulating volume and/or impaired water excretion (DiBartola 1992c).

Hyponatremia is relatively less common when associated with increased plasma osmolality. The most frequent cause of sodium decreases in the presence of increased plasma osmolality is the increased circulating glucose levels associated with diabetes mellitus. Each 100 mg/dL increase in glucose results in a measured decrease of serum sodium by 1.6 mEq/L (Katz 1973). In response to the increased concentration of serum glucose, water shifts from the intracellular to the extracellular compartment, resulting in dilution of measured sodium. Serum osmolality remains high due to elevated glucose concentrations.

Hyponatremia associated with normal plasma osmolality is referred to as pseudohyponatremia. The decreased sodium concentrations are spurious and are almost universally related to technical difficulties in sodium measurement when plasma lipid or protein concentrations are high.

As with hypernatremia, clinical signs of hyponatremia are more severe if sodium concentration changes rapidly than if it changes over a more prolonged period of time. If sodium concentrations and plasma osmolality decrease quickly, water shifts out of the ECF and into cells. The central nervous system (CNS) is most affected by a rapid fluid shift, which, in hyponatremia, results in development of cerebral edema. If onset of hyponatremia is slow, the brain can adjust cell volume by decreasing intracellular osmolality and preventing influx of water from the ECF. Patients with chronic hyponatremia will also adjust intracellular osmolality to an extent that clinical signs may not be obvious even though sodium concentrations are quite low.

Treatment of hyponatremia varies with etiology of the disorder. The goals of therapy are to manage the underlying disease and, if necessary, to increase serum sodium and osmolality. Infusion with conventional crystalloid solutions (e.g., normal saline or lactated Ringer's solution) is reported to accomplish sodium and volume replacement in hyponatremic, hypovolemic patients (DiBartola 1992c). Use of hypertonic saline solutions is not recommended since overly rapid correction of hyponatremia may do more harm than good. Chronic hyponatremia, in which the brain has adjusted to the decrease in osmolality and sodium, must be handled cautiously to avoid brain dehydration and injury, including osmotic demyelination syndrome. This syndrome, often occurring several days after correction of hyponatremia, results from areas of demyelination caused by treatment-induced increases in serum sodium concentration. Dogs with asymptomatic chronic hyponatremia are best treated by mild water restriction and monitoring of serum sodium. Chronic, symptomatic dogs should be treated such that the rate of increase of serum sodium does not exceed 10–12 mEq/L/day (0.5 mEq/L/hr) (DiBartola 1998). Again, the most important therapeutic goal in management of hyponatremia should be treatment of the underlying disease.

HYPERCHLOREMIA. Fluid loss associated with small bowel diarrhea often results in greater loss of HCO_3^- than chloride due to loss of alkaline pancreatic secretions and bile and HCO_3^- secretion in exchange for Cl^- in the ileum. The resulting hyperchloremic metabolic acidosis is characterized by a normal anion gap. Additional causes and treatment for hyperchloremic metabolic acidosis will be considered subsequently under the heading of metabolic acidosis. Please refer to the discussion of hypernatremia for treatment of hyperchloremia associated with loss of free water.

HYPOCHLOREMIA. Hypochloremia may be seen in patients with fluid losses due to vomiting or excessive diuretic administration. Hypochloremic metabolic alkalosis may develop in these cases because an excess of chloride is lost, leading to decreased filtered Cl^- in the renal tubules. As previously noted, activity of the Na^+-K^+-$2Cl^-$ cotransporter in the luminal membrane of the macula densa cell is primarily determined by the availability of Cl^-. In hypochloremia, less Cl^- is delivered, resulting in less NaCl reabsorption, promotion of renin release leading to secondary hyperaldosteronism, and increased distal H^+ secretion. If further Na^+ reabsorption does occur, then Na^+ must be accompanied by an anion other than chloride, usually bicarbonate, or must be exchanged for a secreted cation, either H^+ or K^+. In addition, bicarbonate secretion in exchange for chloride, which is thought to occur in intercalated cells of the cortical collecting tubule, will decrease since this process is presumably driven by a favorable inward gradient for Cl^-. As luminal $[Cl^-]$ decreases, the gradient is dissipated and bicarbonate is retained in the system. All of the foregoing mechanisms promote retention of base and excretion of H^+, leading to a hypochloremic metabolic alkalosis (Rose 1994). Treatment with chloride-replete fluid such as normal saline is usually adequate to resolve chloride-responsive alkalosis. As will be discussed below, potassium depletion may also promote a metabolic alkalosis and should be addressed as needed by addition of potassium chloride to fluids.

POTASSIUM

Homeostasis. As the major intracellular cation, potassium concentrations inside (145 mEq/L) and outside (3.5–5.5 mEq/L) the cell are maintained by the Na^+,K^+-ATPase pump. Under normal circumstances each pump actively transports three sodium ions out of and two potassium ions into the cell, but the ratio can change depending upon the circumstances. The ratio of intra- to extracellular concentration of potassium $([K^+]/[K^+]_o)$ is the major determinant of resting membrane potential. Resting membrane potential is crucial to normal membrane excitability associated with cardiac conduction, muscle contraction, and nerve impulse transmission.

The normal dietary intake of potassium is much more than the body requires. About 90% of this intake is excreted in the urine, with the remainder of what is not required eliminated in the stool. Plasma potassium concentration is determined by the movement of potassium into or out of cells. Two important factors stimulating the transport of potassium into cells are insulin and β-adrenergic stimulation (Clausen and Flatman 1987). Aldosterone is the primary determinant of potassium secretion across renal tubular epithelial surfaces.

Renal Regulation of Potassium Excretion. Most filtered potassium (60–80%) is reabsorbed in the proximal tubule. In the early proximal tubule, potassium enters the tubular cell at the luminal surface by active transport. The intracellular concentration of potassium is high, and the lumen of the tubule is negatively charged relative to the interior of the early proximal tubular cell. Potassium passively exits the basolateral membrane of the tubular cell down a favorable chemical concentration gradient. In the mid-to-late proximal tubule, the tubular lumen is relatively more positively charged than the tubular cell interior. This favors the passive reabsorption of potassium. Potassium again exits on the basolateral side of the tubular cell down a concentration gradient. Potassium reabsorption by intercalated cells in the distal nephron is similar to the process in the early proximal tubule and involves active transport at the luminal cell membrane followed by passive diffusion from the cell at the basolateral membrane.

Tubular secretion of potassium is aldosterone mediated and occurs in the distal nephron (late distal tubule or connecting tubule of the collecting duct system) primarily in the "principal" cells of the collecting tubules. Additional information on mechanisms of collecting duct system reabsorption and secretion is given in Chap. 26 (Fig. 26.2). Principal cells are rich in Na^+,K^+-ATPase and respond to aldosterone by increasing the number and activity of Na^+,K^+-ATPase pumps in the basolateral membrane. The increasing luminal membrane permeability to sodium causes greater lumen negativity relative to the tubular cell interior and increases luminal permeability to potassium. This facilitates potassium secretion into the tubule lumen. Aldosterone-stimulated Na^+,K^+-ATPase actively pumps potassium out of the peritubular fluid through the basolateral tubular cell membrane. Movement of potassium from the tubular cell through the luminal membrane and into the tubule lumen is favored by relative negativity of the lumen compared to the interior of the distal tubule cell (Black 1993).

When plasma potassium concentration is low, secretion of potassium by the principal cells is reduced while hydrogen ion secretion may be increased. Active potassium reabsorption by intercalated cells in the distal nephron is also stimulated by a potassium deficit. An additional factor affecting the movement of potassium across tubular cells is related to tubular flow rate. A rapid flow of filtrate through the tubules maximizes the potassium concentration gradient between the tubular cell interior and the lumen of the tubule and enhances potassium excretion. A reduction of tubular flow slows secretion by allowing a relatively greater concentration of potassium to be maintained in the lumen of the distal tubule (DiBartola and Autran de Morais 1992).

Disorders of Potassium Balance. Disorders of potassium balance have marked effects on excitable membranes. The difference between the resting membrane potential and the membrane potential required for depolarization (threshold potential) determines the excitability of a cell. Hypokalemia makes the resting membrane potential more negative, thereby hyperpolarizing the cell and increasing the difference between resting and threshold potentials. Hyperkalemia causes the resting membrane potential to become more positive, hypopolarizing the cell and causing hyperexcitability. In hyperkalemia, if the resting potential decreases to less than the threshold potential, the cell depolarizes but is incapable of repolarizing, resulting in loss of cell excitability (DiBartola and Autran de Morais 1992). In cardiac muscle this results in diastolic arrest; in vascular smooth muscle hyperkalemia causes vasoconstriction.

Changes in pH affect the distribution of potassium between the ICF and the ECF. When acidosis is present, potassium moves out of cells in exchange for hydrogen, which moves intracellularly. In the distal tubule more hydrogen, and relatively less potassium, may be exchanged for sodium at the luminal membrane, leading to decreased potassium excretion. Based on these general principles, a clinical rule of thumb predicts that each 0.1 unit decrease in pH will be accompanied by a 0.6 mEq/L increase in serum potassium concentration.

Conversely, in alkalosis potassium tends to move into cells in exchange for extracellular movement of hydrogen. Hypokalemia has been thought to promote alkalosis because less potassium is available to be exchanged for sodium in the distal tubule. Instead, sodium exchanges for hydrogen at the luminal membrane, leading ultimately to reclamation of bicarbonate and increased systemic pH. At the same time that systemic pH is increasing, secreted hydrogen ions exchanged for sodium cause the urine pH to decline.

Although the principles outlined above are commonly stated and widely applied clinically, it is not clear that these explanations are adequate. In acidosis, the effect of pH changes on potassium translocation varies with the nature of the acid anion, blood pH and HCO_3^- concentration, osmolality, hormonal activity, and liver and renal function (DiBartola and Autran de Morais 1992). Although changes in serum potassium have been documented during acute mineral acidosis caused by HCl or NH_4Cl (Adrogue and Madias 1981), acute metabolic acidosis caused by organic acids did not increase serum potassium as predicted (Oster et al. 1980; Adrogue and Madias 1981). In certain conditions (e.g., diabetic ketoacidosis), hyperkalemia may be more directly associated with hyperosmolality and insulin deficiency than with the acidosis itself. In lactic acidosis, increased serum potassium concentration may be the result of release of intracellular potassium caused by cell breakdown associated with decreased peripheral perfusion (Black 1993). Metabolic acidosis associated with both mineral and organic acids may directly or indirectly stimulate aldosterone secretion. The effects of aldosterone facilitate excretion of the acid load and, presumably, potassium, although one study failed to show any changes in serum potassium concentration (Perez et al. 1980).

Early studies of the effects of hypokalemia on acid-base balance may have overlooked the key role of chloride depletion in causing metabolic alkalosis (DiBartola and Autran de Morais 1992). When pure potassium depletion is created iatrogenically in rats, metabolic alkalosis results. However, in dogs, potassium deficit with normal chloride levels leads to metabolic acidosis due, presumably, to a distal renal tubular acidification defect (Garella et al. 1979).

HYPERKALEMIA. Total body potassium may be normal, decreased, or increased with hyperkalemia. Clinical signs of hyperkalemia (>7.5 mEq/L) are generally associated with changes in membrane excitability and are more severe if the increase in potassium has been rapid. Muscle weakness, twitching, and irritability may occur. Electrocardiographically determined cardiac effects may include extrasystoles, intraventricular conduction blocks, high-peaked T waves, altered QT interval, widened QRS interval, decreased amplitude or disappearance of P waves, depressed ST segment, ventricular asystole, or fibrillation.

Causes of hyperkalemia are summarized in Table 25.6. The more common causes are related to decreased urinary potassium excretion. Pseudohyperkalemia related to hemolysis can occur in species that have high red cell potassium concentrations similar to humans. Dogs, sheep, and cattle can be divided into two groups based on Na$^+$,K$^+$-ATPase activity in red cell membranes. Those animals with high activity and high intracellular potassium concentrations are at risk for hyperkalemia caused by hemolysis. Animals with genetically determined low activity and low intracellular concentrations of potassium are unlikely to suffer from pseudohyperkalemia since the concentration of potassium in red cells resembles the concentration in the ECF (DiBartola and Autran de Morais 1992).

TABLE 25.6—Causes of hyperkalemia

Decreased excretion
- Urethral obstruction
- Ruptured bladder
- Anuric or oliguric renal failure
- Hypoadrenocorticism
- Gastrointestinal diseases (e.g., trichuriasis, salmonellosis, perforated duodenal ulcers)
- Chylothorax with repeated drainage of the pleural effusion
- Drugs
    - ACE inhibitors (e.g., captopril, enalapril)
    - Potassium-containing drugs (e.g., potassium chloride)
    - Potassium-sparing diuretics (e.g., spironolactone, amiloride, triamterene)
    - Nonsteroidal anti-inflammatory agents
    - Heparin

Translocation from the ICF to ECF
- Acute mineral acidosis (e.g., HCl or NH_4Cl administration)
- Insulin deficiency (e.g., diabetic ketoacidosis)
- Ischemia reperfusion
- Drugs (e.g., propranolol)
- Acute tumor lysis syndrome
- Hyperkalemic periodic paralysis (rare)

Increased intake (rare)

Pseudohyperkalemia
- Thrombocytosis
- Hemolysis

Source: Adapted from DiBartola and Autran de Morais 1992, 108, Table 4.6.

The effects of several different drugs may impact serum potassium concentration. Since potassium uptake by cells is mediated in part by catecholamines at β receptors, β blockers decrease intracellular potassium movement and increase ECF potassium concentrations. Angiotensin-converting enzyme (ACE) inhibitors may cause hyperkalemia by interfering with angiotensin II–mediated aldosterone secretion. Prostaglandin inhibitors, heparin, and selected potassium-sparing diuretics (e.g., spironolactone) increase serum potassium by decreasing the secretion of aldosterone or by blocking its activity. In many cases drugs alone may not have a marked effect on serum potassium concentration but if combined with a potassium load or decreased renal function may cause clinically significant hyperkalemia.

Treatment of hyperkalemia varies with the severity of the condition in terms of magnitude and rapidity of onset. Emergency treatment is indicated if potassium rises quickly and exceeds 6.0–8.0 mEq/L (Phillips and Polzin 1998). Serum potassium concentrations less than these do not typically induce life-threatening cardiotoxicity and can usually be managed with administration of potassium-free fluids. More aggressive treatment is necessary if electrocardiographic signs suggest toxicity. Additional measures that may be taken in treatment of severe hyperkalemia are summarized in Table 25.7. Some are directed toward increasing movement of potassium from the extracellular to the intracellular compartment (i.e., glucose, insulin, and sodium bicarbonate), while others are intended to decrease potassium from the ECF by enhanced renal excretion (e.g., diuretics) or decreased gastrointestinal absorption (i.e., orally administered potassium-binding resins such as sodium polystyrene sulfonate). Therapy with calcium gluconate is included as part of the emergency treatment of hyperkalemia because changes in membrane excitability associated with alterations in potassium may be exacerbated by abnormalities in

TABLE 25.7—Therapeutic considerations in the management of severe hyperkalemia

- Establish venous access and administer potassium-deficient fluids
- Discontinue potassium intake, including drugs that may promote hyperkalemia
- Administer the following as needed:
    - $NaHCO_3$ (0.5–1 mEq/kg, slowly IV) if animal is acidotic
    - Calcium gluconate (10% solution; 0.5–1 mL/kg slowly IV up to 10 mL maximum)
    - Glucose (20% solution; 0.5–1.0 g/kg IV)
    - Insulin (0.5 IU/kg) and glucose (20% solution; 1 g/kg; half given IV bolus and the remainder infused over 2 hours)
- Potassium-wasting diuretics (furosemide, chlorothiazide, hydrochlorothiazide)
- Sodium polystyrene (20 g with 100 mL 20% sorbitol) per os or 50 g in 100–200 mL tap water (retention enema)
- Peritoneal dialysis (last resort)

ionized calcium. Ionized calcium affects the threshold potential of a membrane and, when calcium is decreased, brings threshold closer to resting membrane potential, resulting in greater membrane excitability. An increase in ionized calcium has an opposing effect on membrane excitability by increasing the threshold potential and making depolarization more difficult. Hence, hypocalcemia exacerbates hyperkalemia while hypercalcemia counteracts hyperkalemia.

HYPOKALEMIA. Since 97% of total body potassium is intracellular, depletion can occur with no change in plasma potassium concentration or even with an increase if acidosis is present. Clinical signs of hypokalemia (<2.5–3.0 mEq/L) can include weakness of skeletal and respiratory muscles and intestinal smooth muscle loss of tone. As in hyperkalemia, cardiac changes occur as potassium concentration changes. Supraventricular and ventricular arrhythmias are most commonly observed in animals. ECG hallmarks of hypokalemia in humans are flattened or inverted T waves, depressed S-T segment, and the appearance of U waves. Prolongation of the QT interval and U waves have been reported in dogs but are not as consistently seen as they are in humans. Hypokalemia is increasingly recognized as an important clinical problem in cats, especially in association with chronic renal failure and geriatric animals (Phillips and Polzin 1998). Feline hypokalemic polymyopathy syndrome, characterized by generalized muscle weakness associated with hypokalemia, is often manifest in cats as ventroflexion of the head and a stiff, stilted gait.

Increased loss associated with the gastrointestinal or the urinary system is a common cause of hypokalemia, as indicated in Table 25.8. Differentiating gastrointestinal from urinary causes of hypokalemia is largely accomplished by clinical signs and physical exam, but fractional potassium excretion rates (FE_K) may also be useful. Fractional potassium excretion can be calculated using the following formula:

$$FE_K = (U_K/S_K)/(U_{CR}/S_{CR}) \times 100$$

where U indicates the urine concentration of potassium (K^+) or creatinine (CR), and S indicates the serum concentration.

Treatment of hypokalemia is indicated if significant potassium loss is expected based on history and clinical signs (e.g., vomiting, diarrhea, overzealous use of diuretics) or if clinical signs of hypokalemia are present. Appropriate potassium administration is often required with prolonged fluid therapy. If feasible, oral potassium supplementation is most desirable since this is the safest route of administration. If intravenous potassium supplementation is warranted, the amount administered should be based on clinical status of the animal and measured serum potassium values. Oral and parenteral products for potassium supplementation are discussed later in this chapter. Table 25.9 provides approximate potassium dosages for treatment of hypokalemia in small animals. Alternatively, a rule of thumb may be applied in which 20 mEq/L of potassium is supplemented with careful monitoring of changes in serum potassium. An important admonition in the administration of intravenous potassium is not to exceed a rate of 0.5 mEq/kg/hr. Parenteral potassium administration should always be monitored to ensure that rate of potassium addition does not exceed rate of potassium movement into cells.

TABLE 25.8—Causes of hypokalemia

Increased loss
- Gastrointestinal (FE_K < 4–6%)
    - Persistent vomiting of stomach contents
    - Diarrhea
- Urinary (FE_K > 4–6%)
    - Chronic renal failure in cats
    - Diet-induced hypokalemic nephropathy in cats
    - Renal tubular acidosis
    - Postobstructive diuresis
- Excess circulating mineralocorticoid
    - Hyperadrenocorticism
    - Primary hyperaldosteronism (hyperplastic or neoplastic)
- Iatrogenic (drug induced)
    - Diuretics (loop acting, thiazides and osmotic)
    - Antibiotics (penicillins, amphotericin B, aminoglycosides)

Translocation from ECF to ICF
- Alkalemia
- Overadministration of insulin and glucose-containing fluids
- Hyperthyroidism
- Hypokalemic periodic paralysis
- Possible complication of hypothermia

Decreased intake
- Unlikely as sole cause

TABLE 25.9—Potassium supplementation in treatment of hypokalemia

Serum potassium concentration (mEq/L)	Supplement fluids (mEq/L)*
3.5 to 4.5	20
3.0 to 3.5	30
2.5 to 3.0	40
2.0 to 2.5	60
<2.0	80

*Quantity of potassium to add per liter of fluid. Do not exceed administration rate of 0.5 mEq K^+/kg/hr.

PRINCIPLES OF ACID-BASE METABOLISM

Homeostasis. Blood pH is highly regulated and is normally maintained between 7.38 and 7.42. Pulmonary and renal functions are necessary for precise regulation of pH of all body fluids, blood, and extravascular tissues. An acid is defined by Bronsted and Lowry as a substance that can supply H^+ (protons), and a base is defined as a substance that can accept H^+. In aqueous solutions, H^+ are hydrated; therefore, H_3O^+ is considered an acid and is implied by the symbol H^+. Blood pH is the negative logarithm of the hydrogen ion concentration. Although hydrogen ion concentration cannot be measured directly, hydrogen ion activity is measured chemically using a pH electrode. In body fluids, the difference between activity of hydrogen ions and concentration of hydrogen ions is negligible; hence hydrogen ion concentration and pH are commonly referred to in acid-base discussions. The hydrogen ion concentration of blood at pH 7.4 is 40 nmol/L (nanoequivalents per L) and is therefore approximately a million-fold lower than the blood concentration of electrolytes such as sodium and potassium. Appropriate hydrogen ion concentration is critical in order to maintain body proteins in configurations required for enzymatic and structural function. An increase in hydrogen ion concentration with a decrease in blood pH is termed acidemia and can be caused by pathophysiologic processes that cause accumulation of acids in the body. As the concentration of hydrogen ions decreases, and blood pH increases, alkalemia occurs and can be associated with pathophysiologic processes that cause accumulation of alkali in the body. The disordered processes leading to acidemia and alkalemia are termed acidosis and alkalosis, respectively.

On a daily basis, an excess of acid (70–100 mEq) is generated in the body as a result of dietary intake and intermediary metabolism. Catabolism of carbohydrate, fat, and protein account for most of this as a result of oxidation of sulfur-containing amino acids to sulfuric acid; oxidation of phosphoproteins to phosphoric acid; incomplete oxidation of fats and carbohydrates to organic acid; production of lactate/lactic acid during anaerobic glycolysis; and conversion of carbon dioxide and water produced in the tricarboxylic acid cycle to carbonic acid. Buffers throughout the body minimize changes in blood pH associated with alterations of acid-base balance. The most effective physiological buffers have pK_a values between 6.1 and 8.4, with buffering capacity being maximal within one pH unit of the pK_a. Important extracellular buffers include bicarbonate, inorganic phosphates, and plasma proteins.

Most extracellular buffering occurs as a result of the bicarbonate-carbonic acid buffer pair ($pK_a = 6.1$). Equilibrium of this buffer pair is indicated below:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

The hydration of CO_2 is a rapid reaction in the presence of the enzyme carbonic anhydrase (CA), which is found primarily in red blood cells and renal tubular cells. The dissociation of any acid, in this case carbonic acid, can be described utilizing the concept that the velocity of a reaction is proportional to the product of the concentration of the reactants. In the case of the bicarbonate buffer system, the carbonic anhydrase–catalyzed hydration of CO_2 to form H_2CO_3 reaches equilibrium almost instantaneously, with the number of dissolved CO_2 molecules far exceeding the number of carbonic acid molecules. By defining dissociation constants and rearranging, the useful Henderson-Hasselbalch form of the dissociation equilibrium equation can be derived:

$$pH = pK_a + \log [HCO_3^-]/[H_2CO_3]$$

Gaseous CO_2 produced in the tissues, primarily via the tricarboxylic acid cycle, is soluble in water; the concentration of dissolved CO_2 in body fluids can be related to the partial pressure of CO_2 in the gas phase, PCO_2, by the following expression:

$$[\text{dissolved } CO_2] = 0.03 \times PCO_2$$

Hence the clinically useful form of this equation for the bicarbonate–carbonic acid buffer system becomes

$$pH = 6.1 + \log [HCO_3^-]/(0.03 \times PCO_2)$$

The bicarbonate–carbonic acid system is the most physiologically important extracellular buffer system because it is present in relatively high concentrations in the blood and because it can effectively buffer by rapid regulation of PCO_2 through alveolar ventilation. As carbonic acid is formed from the buffering of excess H^+ by HCO_3^-, this drives the dissociation equation of carbonic acid to the left, causing an increase in PCO_2. An increase in ventilation enhances CO_2 excretion and lowers the PCO_2.

Intracellular buffers also contribute to maintenance of body pH. The primary intracellular buffers are proteins, organic and inorganic phosphates, and, in the red cell, hemoglobin. Hemoglobin is an especially important buffer for carbonic acid since the primary extracellular buffer, the bicarbonate system, cannot buffer this acid. Bone also acts as a tissue-based buffer by exchanging surface Na^+ and K^+ for H^+ under conditions of acid load. Additionally, dissolution of bone mineral results in release of buffer compounds into the ECF.

Regulation of Hydrogen Ion, Carbon Dioxide, and Bicarbonate. Pulmonary and renal control of dissolved CO_2 and bicarbonate concentrations, respectively, is responsible for maintenance of body pH. The "tail" of the Henderson-Hasselbalch equation for the bicarbonate system (i.e., HCO_3^-/dissolved CO_2) provides a simplistic but useful means to consider pulmonary and renal adjustments during simple acid-base disturbances. Under normal physiological conditions, the ratio of HCO_3^- to dissolved CO_2 is 20:1. This ratio can be disturbed by addition or loss of CO_2 or bicarbonate to the system. Table 25.10 depicts changes in the tail of the bicarbonate–carbonic acid dissociation equation that might occur during simple acid-base disturbances. The respiratory component of acid-base regulation (the denominator of the tail, or dissolved CO_2) involves changes in respiratory rate and volume prompted by changes in PCO_2. Initiation of these processes requires only minutes.

The renal component of acid-base regulation (the numerator of the tail, or HCO_3^-) involves selective absorption of bicarbonate and secretion of H^+. During periods of acidosis, relatively more H^+ are secreted, while relatively more K^+, Na^+, and HCO_3^- are retained.

TABLE 25.10—Examples of changes in the "tail" of the Henderson-Hasselbalch equation occurring during simple acid-base disturbances

Respiratory acidosis (↓ CO_2 elimination) associated with inadequate ventilation:										
$\frac{20\ HCO_3^-}{1\ CO_2}$	+	$2\ CO_2$	→	$\frac{20\ HCO_3^-}{3\ CO_2}$	+	$40\ HCO_3^-$	→	$\frac{60\ HCO_3^-}{3\ CO_2}$	=	$\frac{20}{1}$
(Normal)		(↓ Ventilation)		(Uncompensated)		(Renal production)		(Compensated)		
Respiratory alkalosis (↑ CO_2 elimination) associated with hyperventilation:										
$\frac{20\ HCO_3^-}{1\ CO_2}$	−	$0.5\ CO_2$	→	$\frac{20\ HCO_3^-}{0.5\ CO_2}$	−	$10\ HCO_3^-$	→	$\frac{10\ HCO_3^-}{0.5\ CO_2}$	=	$\frac{20}{1}$
(Normal)		(↑ Ventilation)		(Uncompensated)		(Renal excretion)		(Compensated)		
Metabolic acidosis (bicarbonate deficit) associated with diarrhea:										
$\frac{20\ HCO_3^-}{1\ CO_2}$	−	$10\ HCO_3^-$	→	$\frac{10\ HCO_3^-}{1\ CO_2}$	−	$0.5\ CO_2$	→	$\frac{10\ HCO_3^-}{0.5\ CO_2}$	=	$\frac{20}{1}$
(Normal)		(Loss in feces)		(Uncompensated)		(Eliminated by ↑ ventilation)		(Compensated)		
Metabolic alkalosis (bicarbonate excess) associated with administration of alkali:										
$\frac{20\ HCO_3^-}{1\ CO_2}$	+	$20\ HCO_3^-$	→	$\frac{40\ HCO_3^-}{1\ CO_2}$	+	$1\ CO_2$	→	$\frac{40\ HCO_3^-}{2\ CO_2}$	=	$\frac{20}{1}$
(Normal)		(Alkali) administration)		(Uncompensated)		(Eliminated by ↓ ventilation)		(Compensated)		

During alkalosis, K^+ is secreted, while relatively more H^+ and less Na^+ and HCO_3^- are retained. This process requires hours to days to produce an effect. The kidney regulates acid-base balance by maintaining the appropriate HCO_3^- in the plasma. The kidney accomplishes this by reclaiming virtually all filtered HCO_3^- and excreting an amount of acid that equals the amount of ingested or endogenously generated nonvolatile acid. In the proximal tubule of the kidney, cytoplasmic carbonic anhydrase catalyzes the formation of H^+ and bicarbonate from cellular carbon dioxide and water, controlling the rate of hydrogen secretion and bicarbonate reabsorption. In the luminal membrane, carbonic anhydrase converts carbonic acid to carbon dioxide and water, increasing net bicarbonate reabsorption (Fig. 25.5, panel A). In the distal nephron, intercalated cells specialized for hydrogen secretion contain large quantities of carbonic anhydrase, again yielding hydrogen and bicarbonate. In this case, secreted H^+ serves to titrate buffers in the urine (phosphate buffering is shown in Fig. 25.5, panel B) and lower urinary pH. As titratable acidity of the urine reaches a maximum, another adaptation, increased ammonia (NH_3) production by tubular cells, contributes to excretion of acid loads. Fig. 25.5, panel C, shows production of freely diffusable NH_3 from glutamine moving into the tubular lumen, where it combines with H^+ to form ammonium (NH_4^+). Ammonium, in turn, combines with chloride for excretion as ammonium chloride. While this is an oversimplification of the physiological events, it is acceptable to consider ammonium chloride as a flexible mechanism for H^+ secretion based on the ability of the kidney to generate ammonia.

Assessment of Acid-Base Disturbances. Disorders of acid-base equilibrium can result from a primary disturbance in pulmonary regulation of the concentration of H_2CO_3 in body fluids via changes in alveolar ventilation and PCO_2 levels, from metabolic changes in concentration of bicarbonate, or from a combination of these mechanisms.

The partial pressure of CO_2 (PCO_2) is generally accepted as the best measure of respiratory disturbances. Assessment of PCO_2 depends upon availability of a blood gas analyzer and proper arterial sample collection. A blood gas analysis provides three measured parameters (pH, PCO_2, PO_2) and typically two calculated values (actual bicarbonate and base excess). Acidemia and alkalemia (using pH), eucapnia, hypercapnia or hypocapnia (using PCO_2), and hypoxemia (using PO_2 if the sample is arterial) may be directly assessed. In-house blood gas and electrolyte analyzers have become much more common in practice, making assessment of these parameters practical and economical. Results obtained with one hand-held analyzer appropriate for in-house testing were similar to those obtained from a standard chemistry analyzer with the exception of sodium concentration in canine samples and hematocrit in equine samples (Looney et al. 1998).

Actual bicarbonate values are useful in assessment of nonrespiratory disorders, but these values will vary with compensatory changes in alveolar ventilation and PCO_2. Bicarbonate values are derived using the Henderson-Hasselbalch equation and measured values for pH and PCO_2. Plasma bicarbonate values may also be estimated by measurement of total CO_2. Total CO_2 combines measurement of both the numerator and the

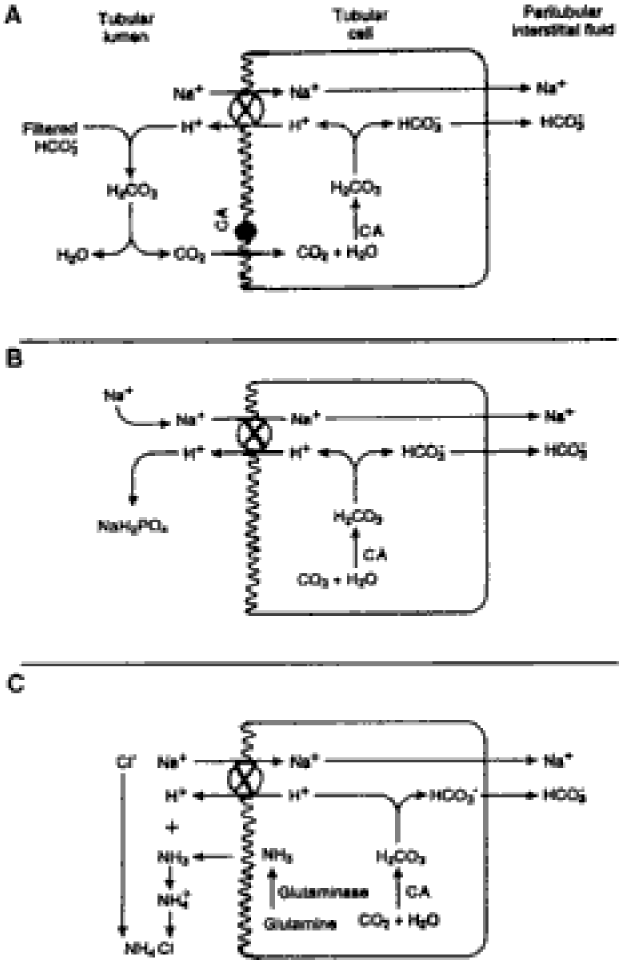

FIG. 25.5—Renal mechanisms for H^+ excretion. See text for explanation of each panel.

denominator of the tail of the Henderson-Hasselbalch equation ($[HCO_3^-]/[H_2CO_3]$) by converting both to measurable CO_2. Total CO_2 and plasma bicarbonate are used interchangeably in reporting plasma bicarbonate concentrations even though total CO_2 is actually plasma bicarbonate plus 1.1–1.3 mEq of H_2CO_3. As compared to actual plasma bicarbonate, standard bicarbonate is defined as the concentration of bicarbonate after fully oxygenated whole blood has been equilibrated with CO_2 at a PCO_2 of 40 mm Hg at 38° C; this measurement eliminates the influence of respiration on plasma HCO_3^-.

Standard base excess (BE) is the concentration of titratable base of ECF; this value may be calculated using a Siggaard-Anderson alignment nomogram that interrelates BE and total CO_2 and HCO_3^- when pH and PCO_2 are measured. Because this calculation is based on a constant oxygen saturation, error may be introduced by inclusion of air bubbles in a poorly handled blood sample. In veterinary medicine, error may also be inherent because the nomogram is based on human blood and excludes the effects of plasma protein and electrolytes on acid-base equilibrium. BE is useful because it accounts for the effects of CO_2 on carbonic acid equilibrium and identifies nonrespiratory causes of acid-base derangement. Base deficit is defined as the negative of base excess (Bailey and Pablo 1998).

Anion Gap. Further analysis, beyond pH, PCO_2, HCO_3^-, and BE, may be useful in assessment of complex acid-base disturbances. The anion gap (AG) is defined as the difference between the quantity of unmeasured cations (UCs) and unmeasured anions (UAs) in the blood. Major UAs include phosphates, sulfates, and organic acids (e.g., lactate, citrate, ketones), with chloride and bicarbonate being the measured anions. Major UCs include calcium and magnesium, with sodium and potassium being the measured cations. Calculation of the AG according to the following equations reflects the law of electroneutrality, according to which total cations must equal total anions (DiBartola 1992d).

$$[Na^+] + [K^+] + [UC] = [Cl^-] + [HCO_3^-] + [UA]$$

$$\text{Anion gap} = UC - UA = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-])$$

The normal AG varies with the species but is approximately 13–25 mEq/L in dogs and cats. AG is most often used to identify causes of metabolic acidosis. In organic acidoses, HCO_3^- buffers hydrogen ions that are generated from dissociation of organic acid (e.g., lactic acid). In theory, the measured $[HCO_3^-]$ should decrease as the concentration of the UA (the organic acid) increases. As long as $[Cl^-]$ remains unchanged (normochloremic metabolic acidosis), the gap will increase proportionately with the increase in acid. Several factors that may confound this simple relationship include the following: (1) other buffers besides HCO_3^- also respond to the influx of organic acid; (2) the volume of distribution of HCO_3^- may be different from that of the acid; and (3) the patient's AG baseline (prior to the presenting illness) is often not known. Hence the AG is useful but not fully predictable.

Increased AG often occurs in lactic acidosis, diabetic ketoacidosis, azotemic renal failure (due to increased phosphates and sulfates), and poisoning (ethylene glycol, salicylate). A recent study (Constable and Morin 1997) demonstrated a useful correlation between AG and serum creatinine concentration in calves with experimentally induced diarrhea and adult cattle with abomasal volvulus. Although the AG was not a useful predictor of all anion-associated changes (e.g., no correlation was found between AG and blood lactate levels), the AG could alert clinicians to the potential presence of uremic acidosis.

A normal AG usually occurs in metabolic acidosis related to diarrhea, renal tubular acidosis, excessive use of carbonic anhydrase inhibitors, or ammonium chloride administration and in iatrogenic expansion acidosis caused by excessive normal saline administration. The two most common causes of a decreased AG are hypoalbuminemia or dilution of plasma proteins caused by infusion of crystalloid solutions. In both cases the gap decreases as a result of a decreased concentration of net negative charges associated with plasma proteins. Each 1.0 g/dL decrease in albumin is associated with an approximately 2.4 mEq/L decrease in the AG (Gabow 1985).

Nontraditional (Stewart's) Acid-Base Analysis. An understanding of the traditional interrelationships between H^+, CO_2, and HCO_3^- is adequate to explain the behavior of aqueous solutions; however, it does not account for the effects of plasma proteins and electrolytes, particularly sodium and chloride, on acid-base status in biological systems. Stewart described a new approach to understanding acid-base physiology based on three fundamental concepts of electrolyte chemistry (Stewart 1978, 1983). First, electroneutrality must always be maintained. Hence, as with the concept of the AG, the sum of all positive charges must equal the sum of all negative charges. Second, mass must be conserved even though it may change in form within a solution. Finally, the dissociation or ionization of a substance in water is determined by its dissociation constant. Weak electrolytes relevant to acid-base physiology include proteins, water, and CO_2. In contrast, sodium and chloride are considered strong electrolytes because they are fully dissociated in water. Evaluation of acid-base status using the Stewart approach requires assessment of independent, or primary, variables; dependent, or unknown, variables; and dissociation constants of all variables. Values of independent variables are controlled externally and cannot be changed by processes occurring within the solution. Independent variables dictate the acid-base status of a solution.

The independent variables controlling acid-base status in biological solutions are strong ion difference (SID), PCO_2, and total weak acid concentration (A_{TOT}). The first variable, SID, is the sum of the strong cation concentrations minus the sum of the strong anion concentrations:

$$SID = ([Na^+] + [K^+]) - ([Cl^-] + [lactate^-] + [ketoacid])$$

Unless lactic acidosis or ketoacidosis is suspected in a given case, these terms may be eliminated from the equation since their values would be quite small. Likewise, $[K^+]$ is often dropped from the equation since it contributes a relatively small number to the total cation population. If PCO_2 and A_{TOT} remain constant, increases in SID suggest nonrespiratory alkalosis and decreases suggest nonrespiratory acidosis. Mean normal SID values are derived by each laboratory based on their reference population, and these values vary across species. The second independent variable, PCO_2, is an indication of the amount of CO_2 dissolved in plasma. As in traditional acid-base theory, an increase in PCO_2 shifts the dissociation equation for carbonic acid to the right, increasing the $[H^+]$ and making the solution more acidic. The final independent variable, $[A_{TOT}]$, is accounted for by plasma proteins (95%), primarily albumin, and inorganic phosphates (5%). A_{TOT} has been calculated for horses (Constable 1997) using the formula

$$[A_{TOT}]\ (mEq/L) = 2.25\ [albumin]\ (g/dL) + 1.4\ [globulin]\ (g/dL) + 0.59\ [phosphate]\ (mg/dL)$$

These three independent variables influence several dependent, or unknown, variables. Dependent variables are affected by processes occurring within the solution and do not change unless independent variables change. Values for dependent variables are thus the result, not the cause, of events in solution. Dependent variables include $[H^+]$, $[HCO_3^-]$, carbonate ion concentration ($[CO_3^{2-}]$), $[OH^-]$, concentration of dissociated weak acids ($[A^-]$), and concentration of nondissociated weak acids ($[AH]$). Values of dependent variables are not affected by the values of other dependent variables. Because the values for $[CO_3^{2-}]$ and $[OH^-]$ are so small, they are not measured or evaluated in a clinical setting. The variables for dissociated and nondissociated weak acids reflect the dynamic relationship between acid-base balance and protein ionization. The ability of proteins to function as enzymes, cell membrane pumps, ion channels, receptors, etc., depends upon their state of ionization, and this is directly affected by changes in independent variables (PCO_2, SID, and A_{TOT}). Likewise, the ratio of ionized to unionized calcium depends upon protein binding, which changes with alterations of A_{TOT} and pH.

Independent variables are controlled via respiration (PCO_2) and renal function (SID). As in traditional acid-base theory, rate and depth of respiration control retention or elimination of CO_2, which may lead to respiratory acidosis or alkalosis, respectively. Control of SID is primarily accomplished by the kidney with a smaller contribution from the gastrointestinal tract. Changes in SID via the kidneys are achieved much more slowly than respiratory changes and are on the order of hours to days. The kidney regulates SID by differential reabsorption of Na^+ and Cl^-. Since Na^+ reabsorption is strongly related to renal regulation of ECF volume, net Cl^- excretion relative to net Na^+ excretion is the primary mechanism for renal regulation of acid-base balance. Control of PCO_2 and SID is the primary determinant of acid-base balance because there is no evidence that the body alters the third independent variable, protein concentration $[A_{TOT}]$, in order to regulate acid-base balance.

In summary, the most important premise of Stewart's approach is that concentrations of HCO_3^- and H^+ are dependent on concentrations of primary, or independent, variables, notably CO_2, Na^+, and Cl^-. The complex equations derived by Stewart address the changes induced by independent variables and quantitate each potential influence by solving for the dependent variables. Much simplified versions of Stewart's formula have been adopted on a limited basis by clinicians who value Stewart's theories and believe that they provide a more complete picture of acid-base derangements. Table 25.11 summarizes the equations being applied for nontraditional analysis of nonrespiratory acid-base status (Russell et al. 1996). In brief, increases in SID suggest nonrespiratory alkalosis, whereas decreases

TABLE 25.11—Formulas for quantitative analysis of nonrespiratory acid-base status

I. Estimation of [SID]. (All values expressed as mEq/L.)

$[\text{SID approx.}] = [\text{Na}^+_{\text{mean normal}}] - [\text{Cl}^-_{\text{corrected}}]$

$[\text{Cl}^-_{\text{corrected}}] = [\text{Cl}^-_{\text{patient}}] \times ([\text{Na}^+_{\text{mean normal}}] / [\text{Na}^+_{\text{patient}}])$

II. Alterations in acid-base balance

A. Changes in acid-base balance due to weak acids

Δ albumin (mEq/L) = $3.7 \times ([\text{alb}_{\text{mean normal}}]$ (mg/dL) $- [\text{alb}_{\text{patient}}]$ (mg/dL))

Δ phosphorus:

$[\text{phos}_{\text{adjusted}}]$ (mg/dL) = $[\text{phos}_{\text{mean normal}}]$ (mg/dL) $- [\text{phos}_{\text{patient}}]$ (mg/dL)

phos_{adj} (mg/dL) $\times 0.3229$ = phos (mmol/L)

effective phos (mEq/L) = $1.8 \times$ phos (mmol/L)

B. Changes in acid-base balance due to alterations in [SID]. (All values expressed in mEq/L.)

Δ free water = $z([\text{Na}^+_{\text{patient}}] - [\text{Na}^+_{\text{mean normal}}])$

where $z = [\text{SID}] / [\text{Na}^+_{\text{mean normal}}]$

Δ chloride = $[\text{Cl}^-_{\text{mean normal}}] - [\text{Cl}^-_{\text{corrected}}]$

Δ unmeasured anions (UA) = BE − (Δ free water + Δ Cl^- + Δ phos + Δ albumin)

TABLE 25.12—Characteristics of primary acid-base disturbances

Disorder	pH	[H⁺]	Primary disturbance	Compensatory response
Metabolic acidosis	↓	↑	↓ $[\text{HCO}_3^-]$, ↓ [SID]	↓ $P\text{CO}_2$
Metabolic alkalosis	↑	↓	↑ $[\text{HCO}_3^-]$, ↑ [SID]	↑ $P\text{CO}_2$
Respiratory acidosis	↓	↑	↑ $P\text{CO}_2$	↑ $[\text{HCO}_3^-]$, ↑ [SID]
Respiratory alkalosis	↑	↓	↓ $P\text{CO}_2$	↓ $[\text{HCO}_3^-]$, ↓ [SID]

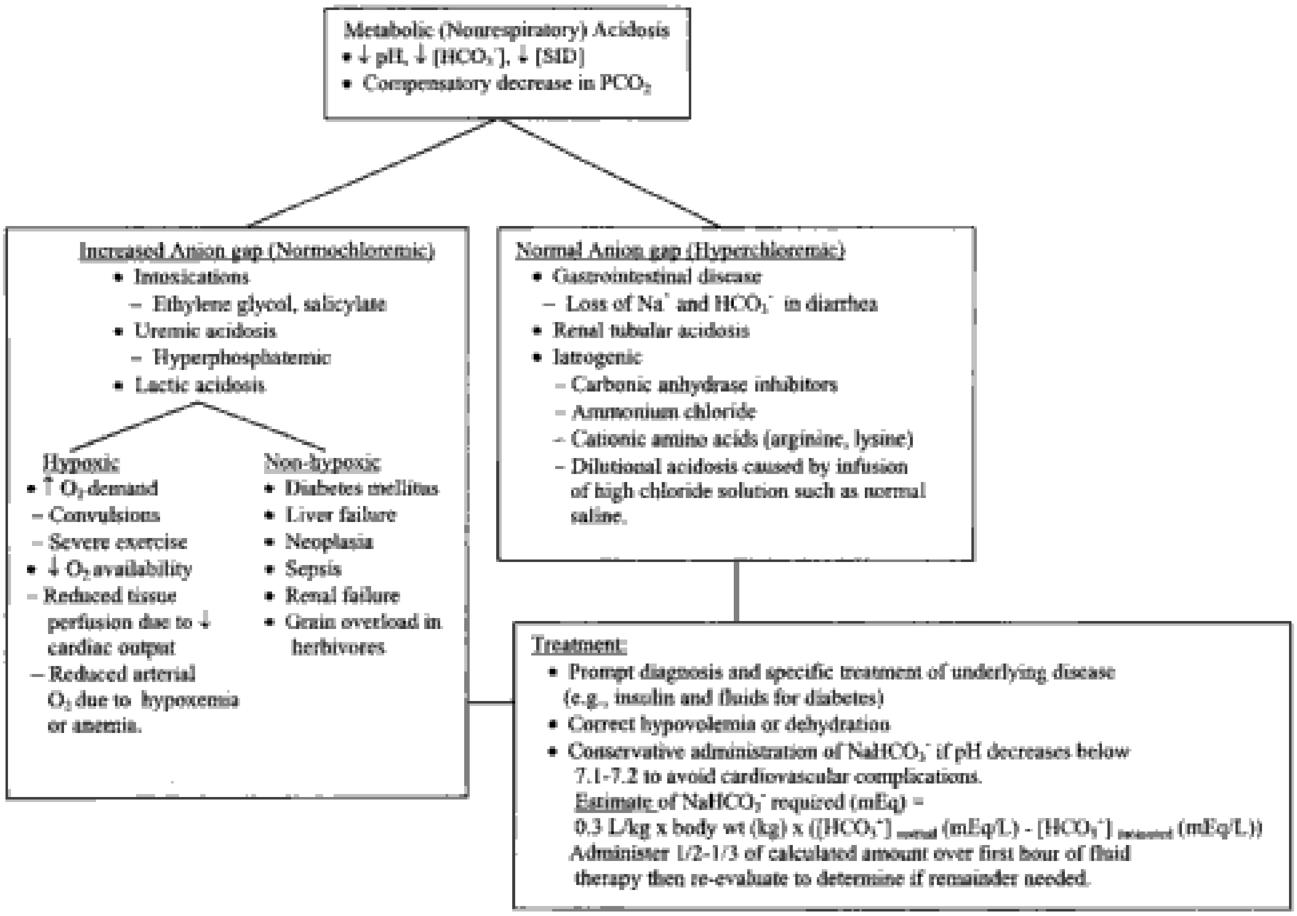
Source: Adapted from Rose 1994, 506.

suggest nonrespiratory acidosis. Negative values for Δ albumin suggest hyperproteinemic acidosis, whereas positive values reflect hypoproteinemic alkalosis. Negative values for Δ phosphorus suggest hyperphosphatemic acidosis. Negative changes in free water point to dilutional acidosis, and positive values suggest concentration alkalosis. Positive values for Δ chloride suggest hypochloremic alkalosis, and negative values suggest hyperchloremic acidosis.

While most clinicians still favor the traditional approach to evaluation of acid-base balance, modified applications of Stewart's theories broaden this scope and lend useful quantitative insights into the complexities of acid-base disturbances (Constable 1999).

DISORDERS OF ACID-BASE METABOLISM. Disorders of acid-base equilibrium can result from a primary disturbance in pulmonary regulation of the concentration of CO_2, from metabolic changes in strong ions and, dependently, bicarbonate, or from a combination of these mechanisms. An acid-base disturbance is considered simple if it is limited to a primary disturbance and an appropriate secondary or compensatory response. Primary disturbances and expected compensatory responses are modeled using the tail of the Henderson-Hasselbalch equation in Table 25.10 and summarized in Table 25.12. Mixed acid-base disturbances are suspected when the compensatory response to a primary disorder is not as expected or when the pH is changing in a direction opposite that predicted by the primary disorder. Mixed acid-base disturbances are characterized by two or more primary disturbances in the same patient.

Metabolic (Nonrespiratory) Acidosis. Metabolic acidosis may be characterized by a decrease in plasma HCO_3^- concentration, decreased pH, increased concentration of strong anions (such as chloride, lactic acid, or ketoacids), and decreased plasma sodium concentration associated with renal disease or diarrhea. The clinical signs most commonly associated with metabolic acidosis are hyperpnea and CNS depression. Laboratory analysis of blood and urine reveals a lowered urine and blood pH, decreased serum HCO_3^- (<20 mEq/L), decreased [SID], and a variable serum $P\text{CO}_2$ depending upon the degree of respiratory compensation. Fig. 25.6 summarizes causes of metabolic acidosis and provides general principles of treatment. Metabolic acidosis is the most common acid-base disorder in dogs, cats, and



Metabolic (Nonrespiratory) Acidosis
• ↓ pH, ↓ [HCO_3^-], ↓ [SID]
• Compensatory decrease in PCO_2
Increased Anion gap (Normochloremic)
• Intoxications
– Ethylene glycol, salicylate
• Uremic acidosis
– Hyperphosphatemic
• Lactic acidosis
Hypoxic
• ↑ O_2 demand
– Convulsions
– Severe exercise
• ↓ O_2 availability
– Reduced tissue perfusion due to ↓ cardiac output
– Reduced arterial O_2 due to hypoxemia or anemia.
Non-hypoxic
• Diabetes mellitus
• Liver failure
• Neoplasia
• Sepsis
• Renal failure
• Grain overload in herbivores
Normal Anion gap (Hyperchloremic)
• Gastrointestinal disease
– Loss of Na^+ and HCO_3^- in diarrhea
• Renal tubular acidosis
• Iatrogenic
– Carbonic anhydrase inhibitors
– Ammonium chloride
– Cationic amino acids (arginine, lysine)
– Dilutional acidosis caused by infusion of high chloride solution such as normal saline.
Treatment:
• Prompt diagnosis and specific treatment of underlying disease (e.g., insulin and fluids for diabetes)
• Correct hypovolemia or dehydration
• Conservative administration of $NaHCO_3^-$ if pH decreases below 7.1-7.2 to avoid cardiovascular complications.
Estimate of $NaHCO_3^-$ required (mEq) =
0.3 L/kg x body wt (kg) x ([HCO_3^-]$_{normal}$ (mEq/L) - [HCO_3^-]$_{measured}$ (mEq/L))
Administer 1/2-1/3 of calculated amount over first hour of fluid therapy then re-evaluate to determine if remainder needed.

FIG 25.6—Causes of metabolic acidosis and general treatment principles.

horses, and causes may be usefully subdivided into those conditions that increase the AG and those that do not.

Loss of Na^+ and HCO_3^- associated with diarrhea is the most common cause of normal AG (hyperchloremic) metabolic acidosis. Intestinal secretions replete in Na^+ and HCO_3^- may also be sequestered in lower obstructive bowel disease and paralytic ileus. Hypoadrenocorticism may also present with a non-gap metabolic acidosis, but these patients usually have hypochloremia as a result of impaired water excretion, lack of aldosterone, and poor renal function.

LACTIC ACIDOSIS. Production of lactic acid and accumulation of lactate, an unmeasured anion, decrease the [SID], resulting in a high AG metabolic acidosis. Lactic acid is the final product of anaerobic glycolysis in eukaryotic cells and is formed by the action of lactate dehydrogenase (LDH) on pyruvic acid with NADH as a cofactor.

$$\underset{\text{(pyruvate)}}{CH_3COO^-} + NADH + H^+ \underset{\text{LDH}}{\leftrightarrow} \underset{\text{(lactate)}}{CH_3CHOHCOO^-} + NAD^+$$

The direction of the LDH reaction depends upon the relative intracellular concentrations of pyruvate and lactate and on the ratio of reduced (NADH) to oxidized (NAD^+) nicotinamide adenine dinucleotide cofactor. Newly produced lactic acid is partially buffered by HCO_3^-, resulting in rapid generation of sodium lactate, which dissociates to lactate and sodium ions. Under aerobic conditions in the liver and the kidney, lactate is converted back to pyruvate, and pyruvate is metabolized through the tricarboxylic acid (TCA) cycle to yield HCO_3^-, CO_2, and H_2O. Alternatively, hepatic uptake of lactate and conversion to pyruvate can feed gluconeogenesis, a process that also regenerates HCO_3^-. In either case, the net result of aerobic lactate metabolism is production of alkalinizing equivalents in the form of HCO_3^-:

Conversion via the TCA cycle:

$$\text{lactate}^- + 3O_2 \rightarrow HCO_3^- + 2CO_2 + 2H_2O$$

Conversion via gluconeogenesis:

$$2\ \text{lactate}^- + 2H_2O + 2CO_2 \rightarrow 2HCO_3^- + \text{glucose}$$

If the ratio of NADH/NAD^+ in the cell shifts toward accumulation of NADH (e.g., in exercising muscle or poorly oxygenated tissues), more lactic acid accumulates, decreasing cellular pH. In the case of poorly oxygenated tissues, inability to oxidize NADH via the respiratory chain blocks oxidative phosphorylation and production of ATP. ATP depletion in lactic acidosis causes leaky ATP-dependent K^+ channels, leading to hyperpolarized membranes and decreased Ca^{++} influx via voltage-dependent Ca^{++} channels. Decreased intracellular Ca^{++} produces smooth muscle relaxation, vasodilation, and a potential decline in systemic blood pressure (Landry and Oliver 1992).

Causes of the two types of lactic acidosis, hypoxic (type A) and nonhypoxic (type B), are listed in Fig. 25.6. (Only L-lactate is metabolized by animals; hence the discussion that follows refers only to L-lactic acidosis and not D-lactic acidosis, a condition described in humans and associated with small bowel resection or short bowel syndrome.) Reduced tissue perfusion and hypoxia caused by cardiac arrest/cardiopulmonary resuscitation, shock, hypovolemia, left ventricular failure, low cardiac output, and acute pulmonary edema limit oxygen availability and force cells into anaerobic glycolysis. As NADH accumulates, the LDH reaction is pushed to the right, resulting in lactic acid accumulation. Successful management of most of these conditions involves returning tissue perfusion and oxygenation to normal, often with the aid of parenteral fluid administration. Reversal of circulatory failure decreases further lactate accumulation and, if the liver is well perfused, will result in conversion of accumulated lactate to HCO_3^-.

Administration of $NaHCO_3^-$ to animals suffering from lactic acidosis is controversial. Benefits could include improved tissue perfusion related to reversal of acidemia-induced vasodilation and an increase in [SID] (associated with Na^+ administration). Potential risks include overshoot metabolic alkalosis caused by the cumulative effect of $NaHCO_3^-$ administration and metabolism of the accumulated lactate into HCO_3^-. A recent study in rats (Halperin et al. 1996) concluded that $NaHCO_3^-$ therapy extended the period of survival during acute, hypoxic L-lactic acidosis. Hypoxia was induced in anesthetized, paralyzed rats ventilated with a lowered (5.5%) oxygen concentration, which was sufficient to cause a severe degree of L-lactic acidosis. Survival in rats receiving $NaHCO_3^-$ was close to twofold longer than in rats receiving no sodium bicarbonate or NaCl only. The rate of $NaHCO_3^-$ infusion was titrated to equal the rate of L-lactic acid appearance in the ECF of control hypoxic rats. Part of the benefit of alkali treatment was hypothesized to be increased anaerobic glycolysis, causing enhanced ATP and L-lactic acid production and a decreased oxygen consumption. Despite continued accumulation of L-lactic acid and a decrease in cardiac output that was greater than in control rats, availability of ATP for vital organs was considered critical to prolonged survival in alkali-treated animals. While results using this controlled model are not directly clinically applicable, they suggest that continued consideration of the advantages and disadvantages of alkali supplementation in L-lactic acidosis may be merited. Many clinicians favor a conservative therapeutic approach in which small amounts of $NaHCO_3^-$ are administered to keep the arterial pH above 7.1–7.2 and to avoid progressive decline in cardiovascular function (Rose 1994). In the absence of severely elevated concentrations of lactate, and in the presence of a well-perfused liver, the use of lactate-containing alkalinizing solutions is effective for volume restoration. Alternatives to lactate-containing solutions include $NaHCO_3^-$, sodium gluconate, sodium acetate, and an equimolar mixture of sodium carbonate and sodium bicarbonate. The latter product, referred to as "Carbicarb" (Cohen 1995), has been promoted as a method of preventing the increased CO_2 production and paradoxical intracellular acidosis that has been reported as a complication of $NaHCO_3$ treatment. It has been found, using a canine model of severe hemorrhagic shock, that Carbicarb, $NaHCO_3$, and hypertonic saline all possess similar abilities to improve hemodynamics, despite the buffering properties of $NaHCO_3$ and Carbicarb. However, correction of arterial pH did not appear to improve the responses to blood retransfusion in this model (Benjamin et al. 1994).

KETOACIDOSIS AND OTHER CAUSES. Metabolic acidosis associated with ketonemia and ketonuria occurs when the rate of formation of ketone bodies is greater than the rate of their use. This occurs most often in two conditions, diabetes mellitus and starvation. Excess acetyl coenzyme A (CoA) derived from fatty acid or pyruvate oxidation is diverted, primarily in the liver, to production of ketone bodies (acetoacetate, beta-hydroxybutyrate, acetone). Ketones can be transported in the blood and utilized as an energy source by peripheral tissues. In diabetes the lack of insulin increases lipolysis, and an excess of glucagon indirectly increases fatty acyl CoA entry into hepatic mitochondria for conversion to ketones. An elevation of ketones in the blood results in acidemia because the carboxyl group of the ketone body has a pK_a of about 4. At physiological pH the ketoacid is fully dissociated, losing a proton (H^+), which lowers blood pH. Addition of a UA, the ketoacid, decreases the [SID] driving an acidosis. Ketoacidosis is often complicated by dehydration associated with osmotic (glucose-driven) diuresis. The use of alkali to treat diabetic ketoacidosis is controversial and not generally recommended. Rehydration (usually with normal saline) and administration of insulin is the treatment of choice since circulating ketoacids will subsequently be metabolized to HCO_3^- and move plasma pH toward normal.

Renal failure typically produces a normochloremic, high-AG metabolic acidosis due to accumulation of phosphates, sulfates, and other organic anions, altered handling of chloride, and an inability to excrete the daily dietary acid load. Enhanced generation of ammonia by the renal tubular cells allows the kidney to respond, up to a point, to the chronic retention of fixed acid. Use of alkali to treat metabolic acidosis associated with renal failure is controversial. Three reasons cited in support of treatment are that treatment (1) spares depletion of bone serving as a H^+ buffer, (2) prevents the potentially catabolic effects of acidosis on muscle protein, and (3) limits complement-mediated tubulointerstitial damage that may occur in concert with increased ammoniagenesis. Oral administration of $NaHCO_3$ (0.5–1.0 mEq/kg/day) with the goal of maintaining plasma HCO_3^- at 15 mEq/L may be effective if the associated sodium load does not encourage fluid retention.

Metabolic (Nonrespiratory) Alkalosis. Metabolic alkalosis is characterized by an excess of HCO_3^- caused by a deficit of H^+ in the ECF. This state may be caused by excessive vomiting (especially from gastrointestinal obstruction), excessive alkaline therapy or use of diuretics that can create iatrogenic metabolic alkalosis, or excessive loss of potassium caused by hyperadrenocorticism or administration of large quantities of K^+-free solutions. Clinical signs of metabolic alkalosis are depressed breathing (slow and shallow), nervous excitement, including tetany, and even convulsions and muscular hypertonicity. Respiratory compensation is not as effective as respiratory compensation for metabolic acidosis.

Values for serum electrolytes usually reveal elevated $[HCO_3^-]$, lowered $[Cl^-]$, and variable $[Na^+]$. There is usually a low serum $[K^+]$ in this condition. A relationship exists between K^+ loss and metabolic alkalosis in that each can result in the other (positive feedback). In ruminants the situation is much more complex, and unlike in small animals, metabolic alkalosis is much more common. Compensation for metabolic alkalosis requires the kidneys to excrete HCO_3^- and retain H^+. Therapy for metabolic alkalosis involves treatment of the underlying disease and, potentially, use of acidifying solutions such as NaCl (0.9%), NH_4Cl (1.9%) (NH_4^+ is conjugated to urea in the liver, which frees H^+ and Cl^-), and Ringer's solution, which supplies Na^+, K^+, Ca^{++}, and Cl^-.

Respiratory Acidosis. Respiratory acidosis (Table 25.13) involves retention of CO_2 as a consequence of alveolar hypoventilation. The fall in pH is predictable from the Henderson-Hasselbalch equation. Impaired respiration can be caused by pneumonia, pulmonary edema, emphysema, pneumothorax, respiratory muscle paralysis, morphine, barbiturate, or anesthetic poisoning, airway occlusion, or, most commonly, hypoventilation during positive pressure ventilation (iatrogenic). Clinical signs include respiratory distress and CNS depression with progressive disorientation, weakness, and finally coma (CO_2 narcosis). Cyanosis is often present in the advanced stages. Laboratory analysis of blood and urine will show a decreased urine pH, decreased blood pH, increased serum HCO_3^- (from tissue buffers and renal reabsorption of HCO_3^-), and a decrease in serum Cl^- because of renal excretion. Hypoventilation results in CO_2 retention, an excess of H_2CO_3, and thereby an excess of H^+. The compensatory mechanism is for the kidneys to conserve HCO_3^- and excrete H^+. The most important treatment for this condition is proper ventilation of the animal. Use of alkalinizing solutions may aid in cases of lung disease when ventilation alone will not correct the condition. Whenever possible, therapy should be directed at removal of the causative factor.

TABLE 25.13—Causes of respiratory acidosis

- Inadequate mechanical ventilation
- Airway obstruction
- Respiratory center depression
    - Neurologic disease
    - Drugs (e.g., anesthetic agents, narcotics, sedatives)
- Cardiopulmonary arrest
- Neuromuscular defects
    - Myasthenia gravis
    - Tetanus
    - Botulism
    - Polyradiculoneuritis
    - Polymyositis
    - Tick paralysis
    - Hypokalemic periodic paralysis in Burmese cats
    - Hypokalemic myopathy in cats
    - Drugs (e.g., succinylcholine, pancuronium, aminoglycosides with anesthetics, organophosphates)
- Restrictive defects
    - Diaphragmatic hernia
    - Pneumothorax
    - Pleural effusion
    - Hemothorax
    - Chest wall trauma
    - Pulmonary fibrosis
    - Pyothorax
    - Chylothorax
- Pulmonary disease
    - Respiratory distress syndrome
    - Pneumonia
    - Severe pulmonary edema
    - Diffuse metastatic disease
    - Smoke inhalation
    - Pulmonary thromboembolism
    - Chronic obstructive pulmonary disease
    - Pulmonary fibrosis

Respiratory Alkalosis. Causes of respiratory alkalosis are indicated in Table 25.14. The most common cause of this disease in animals is overactive positive pressure ventilation during anesthesia (iatrogenic). Other causes include fever, stimulation of respiratory centers by encephalitis, salicylate intoxication, a deficiency of O_2 (hypoxia), heat prostration, hysteria, or conditions causing chronic hyperventilation (excessive blowing off of CO_2). Clinical signs include hyperpnea (with or without panting), hyperactive tendon reflexes, and CNS stimulation with or without convulsions. Laboratory analysis reveals increased urine pH, increased blood pH, and decreased serum HCO_3^-. Serum Cl^- is usually normal to slightly increased, and pathogenesis of the condition relates to excessive blowing off of CO_2. Compensation occurs by renal excretion of HCO_3^- and retention of H^+. Treatment for this condition should involve correcting the hyperventilation, when feasible, and use of the same acidifying solutions used for metabolic alkalosis. Underlying etiologic factor(s) must be eliminated.

Mixed Acid-Base Disturbances. The preceding discussion of acidosis and alkalosis has purposely dealt

TABLE 25.14—Causes of respiratory alkalosis

- Overzealous mechanical ventilation
- Hypoxemia (stimulation of peripheral chemoreceptors by decreased oxygen delivery):
  - Right-to-left shunts
  - Decreased PO_2 (e.g., high altitude)
  - Congestive heart failure
  - Severe anemia
  - Hypotension
  - Pulmonary diseases resulting in ventilation-perfusion mismatching:
    - Pneumonia
    - Pulmonary embolism
    - Pulmonary fibrosis
    - Pulmonary edema
  - Pulmonary disease resulting in stimulation of nociceptive receptors independent of hypoxemia:
    - Pneumonia
    - Pulmonary embolism
    - Interstitial lung disease
    - Pulmonary edema
- CNS-mediated hypocapnia with direct stimulation of medullary respiratory center:
  - Liver disease
  - Gram-negative sepsis
  - Drugs (e.g., salicylate intoxication, progesterone, xanthines)
  - Recovery from metabolic acidosis
  - Central neurologic disease
  - Heat stroke

with idealized, single etiologic processes in the genesis of acid-base abnormalities. Such states rarely exist in real life. Mixed disturbances usually occur, and treatment will often convert one type of acid-base disturbance into another. Proper therapy must include careful appraisal of repeated laboratory determinations and close observation of the clinical situation. Using these techniques, mixed disturbances can be identified, evaluated, and managed successfully. Examples of potential causes of mixed respiratory and metabolic disorders are noted in Table 25.15.

PRACTICAL ASPECTS OF FLUID THERAPY

Diagnosis and Monitoring. When fluid therapy is under consideration, the practitioner must ask the following six questions: (1) When should fluid therapy be instituted? (2) What kind(s) of solution(s) should be used? (3) How much fluid should be administered? (4) How fast should the solution be given? (5) What route of administration should be used? (6) How will the success of the therapy be evaluated? The answers to these questions are individual in character and are critically dependent on a knowledge and understanding of normal homeostatic mechanisms. They are also dependent on the history of the patient, a basic understanding of how a particular disease affects water and electrolyte balance, and a correct diagnosis.

The purpose of fluid and electrolyte therapy is to correct dehydration or overhydration and electrolyte imbalance and/or acid-base imbalance. It may also be indicated to correct a condition of acidosis or alkalosis, treat shock, give parenteral nourishment, or even stimulate organ function (i.e., the kidneys). Causes of fluid, electrolyte, and/or protein loss include situations wherein substances are not available because of lack of supply or condition of the animal; for example, an animal with a fractured mandible may be unable to take in food or liquid, or an animal with a CNS disturbance may be unable to eat or drink because of the primary disease state. Other causes of fluid, electrolyte, and/or protein imbalances may involve excessive elimination.

The following information must be provided by questioning the owner, observation of the patient, and/or clinical examination: duration and frequency of vomiting and/or diarrhea, consistency of stools, frequency of urination, color of urine, presence and character of thirst, fluid and dietary intake, dryness or elasticity (turgor) of the skin, nature and color of the mucous membranes and sclera, presence of excessive salivation or panting, odor of the breath, and weight loss or gain.

In combination with clinical signs, laboratory examination of the blood provides a rational basis for estimating patient fluid and electrolyte needs and monitoring treatment success. Measurements should include hematocrit, plasma protein, blood gases (PO_2, PCO_2, base excess, HCO_3^-, or total CO_2) and electrolytes (Na^+, K^+, Cl^-), blood urea nitrogen, and creatinine. Because red blood cells and plasma protein are largely limited to the vascular space, the concentration of both tends to increase with dehydration. It is best to assess both hematocrit and plasma protein since results of one or the other test alone can be misleading if preillness values are out of the normal range. For example, preexisting anemia, hypoproteinemia, or physiologic events such as splenic contraction can confound interpretation of either parameter if considered alone.

Collection, measurement, and analysis of urine are important for proper care of the critically ill patient. Urinalysis should include tests for specific gravity, glucose, acetone, pH, and albumin and microscopic sediment examination. During a state of dehydration, if the kidneys are functioning normally, specific gravity will increase and urine volume will decrease. If the specific gravity of urine is unchanged or lowered and the animal shows clinical signs of dehydration, the kidneys are probably not functioning properly, and more sophisticated renal function tests must be employed. Specific gravity of urine should be monitored during the treatment period. A decrease in this parameter indicates that hydration is taking place. If the animal has not yet received treatment with a solution containing glucose and it is found in the urine, diabetic acidosis is possibly the cause of dehydration. The urine glucose should also be monitored during treatment. If the animal is receiving glucose and the urine glucose reaches +3 or +4, the dosage must be lowered. Acetone in the urine is a frequent finding during dehydration and/or carbohydrate starvation. If the pH of the urine in species with normally acid urine tests alkaline, a diagnosis of alkalosis may be indicated if no kidney or urinary tract disease is present. The presence of urinary albumin and sediment may be an indication of renal disease. If the kidneys are functioning properly, they can adjust markedly to insult. However, in the presence of renal impairment, therapy must be specific or the treatment may be fatal.

Diligent assessment of clinical signs and laboratory parameters is essential to successful diagnosis and monitoring of fluid and electrolyte imbalances. Useful parameters are summarized in Table 25.16.

TABLE 25.16—Parameters to be monitored during fluid therapy

- Normal bronchovesicular lung sounds on auscultation
- Packed-cell volume
- Total protein
- Electrolytes: Na^+, Cl^-, Ca^{2+}, HCO_3^-
- Arterial pH
- Arterial PCO_2
- Urine output
- Hemodynamics
    - Central venous pressure
    - Pulmonary capillary wedge pressures
    - Mean arterial pressure
    - Mean pulmonary arterial pressure

Fluid Volume and Type. A standard approach to estimating fluid volume needs should be used. Replacement of adequate volume is often the single most important key to improved clinical status of animals with multiple fluid and electrolyte disturbances. Volume replacement should have three specific aims: correct existing deficits, satisfy maintenance needs, and replace continuing loss. Initial volume deficits are addressed by administration of replacement fluids. Calculation of the amount of fluid needed is based on clinical and laboratory assessment of percent of dehydration. See Table 25.5 for a summary of signs correlated to degree of dehydration. The volume needed to address the initial deficit is estimated according to the following equation:

$$\text{Replacement volume (L)} \\ = \text{body weight (kg)} \times \text{\% dehydration}$$

Clinicians working with both small and large animals should become comfortable with the large differences in volume that will be required to address deficits in different animals. For example, the replacement volume needed to address an 8% fluid deficit in a dehydrated mare weighing 500 kg is 100 times greater than that needed for a similarly dehydrated cat weighing 5 kg. Forty liters of fluid would initially be administered to the mare versus 400 mL to the cat. In general, the composition of replacement fluids should reflect the composition of the volume of fluid lost. For example, if the volume deficit is related to loss of electrolyte-rich gastrointestinal fluid, then a balanced replacement solution containing Na^+, K^+, Cl^-, and bicarbonate equivalents would likely be selected. Table 25.17 details the compositions of commonly utilized replacement fluids.

In addition to replacing existing deficits, maintenance fluid needs must be calculated. Maintenance fluids are needed when a patient does not voluntarily ingest sufficient food and water to replace normal losses occurring via urine, feces, respiratory tract, and skin. The average resting animal at standard conditions of humidity and temperature has a rather constant rate of water turnover. For practical purposes, 40–65 mL/kg/24 hr (30 mL/lb/day is often used as a rule of thumb) for mature animals and 130 mL/kg/24 hr for immature animals serve as average water turnovers for all mammalian species. Based on these assumptions, an average mature dog weighing 20 kg requires about 1.3 L for a daily maintenance supply of water, while a horse weighing 450 kg would require about 29 L/day. Maintenance needs may be modified under conditions of severe stress or fever, extreme environmental conditions, or in the presence of various disease processes. Older animals may need more or less maintenance volume depending upon the presence of polyuria or com-

Table 25.17—Composition of selected fluid therapy solutions

		Characteristics		Ion composition (mEq/L)						
Type	Solution	pH	Osmolarity (mOsm/L)	Na$^+$	K$^+$	Cl$^-$	Ca^{++}	Mg^{++}	Glucose (g/L)	Alkalinizing equivalents (mEq/L)
Replacement										
Acidifying BES	Ringer's	5.4	309	147	4	155	4	0	0	0
Acidifying BES	Normal saline (0.9%)	5.0	308	154	0	154	0	0	0	0

	14.9% KCl	—	4000	0	2000	2000	0	0	0	0

Note: BES = balanced electrolyte solution.

promised cardiovascular function, respectively. Administration of various drugs (e.g., glucocorticoids, diuretics) will also affect maintenance needs. The electrolyte composition of fluids used for maintenance differs from that of replacement fluids used to address initial deficits. Because of the composition of fluid lost daily in urine and as insensible loss from the skin and respiratory tract, maintenance fluids are typically lower in sodium (approximately 40 mEq/L) and higher in potassium (approximately 10–16 mEq/L) than replacement fluids. Table 25.17 details the composition of both commercial maintenance fluids and maintenance fluids that can be prepared using other commonly available fluid components.

If the animal being treated continues to lose water during the treatment period (e.g., due to continued vomiting, diarrhea, polyuria) this additional amount must be estimated and added to the replacement and maintenance volumes. The volume required to replace continued loss is based on clinical observation (e.g., frequency of defecation, character and volume of feces in the case of diarrhea). Like the volume used to address the initial deficit, the type of fluid selected to replace continuing loss should, in general, resemble the fluid lost. More often than not, balanced electrolyte solutions such as lactated Ringer's are chosen.

Application of the principles outlined above may be appreciated using the following case example. A 2-year-old, 20 kg mixed-breed dog presents with a chief complaint of diarrhea of two days' duration. A physical exam reveals a loss of skin elasticity and a definite delay in return of skin to normal position when tented. Both mucous membranes and tongue are dry and the eyeballs feel soft and slightly sunken. Capillary refill time is slightly prolonged. Based on these clinical signs, dehydration is assessed at 8%. The dog is continuing to pass semifluid stools every 2–3 hours, resulting in an estimated ongoing loss of 150 mL/day. The owner reports that the dog is not eating or drinking. Calculation of the volume of fluid to be administered to this dog over the next 24 hours would include:

Replacement of initial deficit:	20 kg × 0.08 =	1.6 L
Maintenance needs:	65 mL/kg/day × 20 kg =	1.3 L
Continued loss:		0.15 L
Total estimated fluid needs:		3.05 L

This volume is considered an estimate because it is based on clinical signs and average maintenance losses. Despite the importance of good data collection and appropriate application of fluid therapy principles, at some level adjusting volume is dependent upon a "guess and reassess" process driven by diligent and thorough patient observation (Roussel 1990).

Rates and Routes of Administration. The rate of fluid and/or electrolyte replacement should parallel the severity of dehydration and electrolyte or acid-base imbalance. Fluids should be administered rapidly at first and then at decreasing rates until the condition is corrected. Most investigators report that rates of about 15 mL/kg/hr are reasonable. Cornelius et al. (1978) have shown that rates of 90 mL/kg/hr are well tolerated in moderately dehydrated, unanesthetized normal dogs. No deaths occurred, but clinical signs of severe overhydration were evident in dogs given fluids at 360 mL/kg/hr. At 90 mL/kg/hr, pulmonary artery wedge pressures and central venous pressures were increased in dogs with normally functioning hearts. It can be presumed that a seriously ill dog, with compromised cardiac muscle contractility, could be injured by infusion rates that result in acute volume overload. If central venous pressures are being monitored, the infusion rate can be individually adjusted for each patient. This technique is simple and inexpensive. The attending veterinarian should monitor this parameter in the critically ill patient and adjust the rate of fluid administration according to individual needs.

Conservative and reasonable practice would dictate infusion rates of about 50 mL/kg/hr in severely dehydrated cases. Less severe cases should tolerate rates of 15–30 mL/kg/hr. In all cases the rate of infusion should be slowed after the first hour of administration and should be slowed considerably if no urine flow is established. After 4 or more hours of fluid administration without urine flow, the rate of administration should be 2 mL/kg/hr or less. Every attempt must be made to establish renal function if no urine flow is detected after 2 hours of fluid administration. To accurately monitor urine flow, all critically ill animals should have a urinary bladder catheter in place.

Common sense and clinical judgment must be exercised. If an animal is severely dehydrated and in shock, it is difficult to administer fluids too fast during the initial stages of treatment. If, however, an animal is almost normally hydrated and the aim is only to maintain hydration, the rate should be slowed considerably. The importance of renal function has been repeatedly emphasized. A commonly used method of determining if the kidneys are capable of functioning is to inject a small bolus (1–25 mL, depending on size of the animal) of 50% glucose. Urine from the catheterized bladder is then checked every 5 minutes for the presence of glucose, which indicates glomerular filtration is occurring.

The route of fluid administration depends on the type of illness being dealt with and the severity of the condition, degree of dehydration, condition of the patient, type of electrolyte imbalance, organic functions of the patient, and time and equipment available. Probably the easiest, most physiologic, and most overlooked route of administration of fluid and electrolytes is oral or nasogastric. The oral route is the least dangerous, since the solution can be administered without strict attention to tonicity, volume, and asepsis. Oral replacement of electrolytes by using combinations of electrolyte salts, glycine, and dextrose has been especially successful (Hamm and Hicks 1975). Proper technique for oral fluid administration should preclude complications associated with fluid aspiration or administration of excessive amounts of air.

A relatively unused route of administration that might be considered, especially in very young animals, is per rectum. Warm water, K^+, Na^+, and Cl^- are well absorbed via this route. It may be difficult, however, to get the animal to retain material given in this manner, especially in the presence of gastrointestinal disease. Rectal infusion of fluids in birds has been suggested as an effective alternative route to intravenous, intraosseous, oral, or subcutaneous (Ephrati and Lemeij 1997).

The most commonly used and perhaps most practical routes of fluid and electrolyte administration are the parenteral routes: intravenous (IV), subcutaneous (SC), or intraperitoneal (IP). The IV route is the most versatile. Severe disturbances of fluid and electrolyte balance demand it. Nearly all the toxicity of solutions administered in this manner is more related to rate than volume or composition. No indications for hypotonic solutions have been found, but indications for isotonic and hypertonic solutions exist, and some of these have been discussed previously. Some of the problems associated with IV administration include those associated with maintenance and asepsis of indwelling catheters, clotting, and hematomas, as well as the location of a vein on very small or very ill animals. Obviously, the fluids administered and equipment used must be sterile. Large volumes of fluid administered too rapidly may overload the circulatory system, causing pulmonary edema and even death, especially in severely ill or toxic cases. This is the preferred route for blood, blood plasma, and plasma volume expanders.

Subcutaneous administration of fluid is referred to as hypodermoclysis. This technique is convenient for correction of mild to moderate deficits in small animals. Fluids are absorbed more slowly than by the IV route, but if the animal is not in critical condition, this is of no real consequence. Only isotonic solutions should be used in this manner. Dextrose of any tonicity or any solutions lacking electrolytes in isotonic levels are contraindicated because they may produce an initial rapid diffusion of major extracellular electrolytes to the area. This can result in severe reactions, including death, especially if the animal is already in shock. Hypodermoclysis is extremely valuable in very young or very small animals. If the animal is difficult to restrain long enough for a prolonged IV infusion, this is a useful technique. When edema is present, absorption will not occur, and this route of administration is contraindicated. If the animal is chilled by a cold environment or a cold fluid is injected, absorption by this route will be delayed, and it is recommended that fluids be prewarmed to body temperature when feasible. Administration of fluids in one anatomical location should be limited to amounts that are readily absorbed (approximately 10–12 mL/kg) (Greco 1998). Fluid should be deposited dorsally along the area bordered by the scapulae anteriorly and the iliac crests posteriorly. Hypodermoclysis is not commonly used as a route of administration in large animals.

IP infusion of fluids has the same restrictions as those for hypodermoclysis. The technique may predispose to peritonitis, so aseptic procedures must be used. The fluids are mobilized faster than in SC administration, but this route is potentially more hazardous (puncture of abdominal organs). Nevertheless, this is a good route for electrolyte and water absorption. Plasma and a large percentage of red blood cells administered using this technique are rapidly absorbed. In large animals it can be a very practical method of treatment, since a large quantity of fluid can be administered rapidly with few adverse effects. Perhaps the greatest application of this technique is with peritoneal lavage.

PRODUCTS FOR FLUID THERAPY. Major categories of parenteral fluids include crystalloids, colloids, blood replacements, and nutritional solutions. Blood replacement products (whole blood, blood components, and red blood cell substitutes) and nutritional solutions (amino acids and fat emulsions) are considered elsewhere. The composition and characteristics of selected crystalloid solutions and additives used to spike parenteral solutions are listed in Table 25.17. Types and recommended dosages of synthetic colloids are listed in Table 25.18.

Crystalloids. As detailed in Table 25.17, crystalloid solutions are polyionic but differ in the amount of each ion and in tonicity. As discussed previously, the tonicity of parenteral fluids partially dictates distribution of volume into interstitial and intracellular spaces. Fluids that most closely resemble the ECF are isotonic, high in sodium, and low in potassium and may be acidifying or alkalinizing. These replacement fluids, also referred to as balanced electrolyte solutions (BES), may be given in large volumes at a rapid rate to patients in shock in an attempt to reestablish effective perfusion without severely altering electrolyte concentrations. Alkalinizing solutions depend upon metabolism of various substrates (e.g., lactate, acetate, gluconate) to alkalinizing equivalents in order to reduce acidemia. Lactate and acetate are metabolized in the liver and muscle, respectively, while gluconate is metabolized widely in the body. Perfusion and function of the liver are required for generation of alkalinizing equivalents from the most commonly used replacement fluid, lactated Ringer's solution. A large percentage of veterinary patients that require fluid therapy suffer from nonrespiratory acidosis and are treated with alkalinizing balanced electrolyte solutions. These fluids are generally indicated for animals suffering from diarrhea, vomiting (assuming vomitus contains bile), renal disease, trauma, and shock and those requiring pre- and postsurgical support. To avoid calcium precipitation, calcium-containing balanced electrolyte solutions, such as lactated Ringer's solution, should not be coadministered through the same port with whole blood or sodium bicarbonate.

Normal saline and Ringer's solution are considered acidifying solutions and are used to treat the relatively small percentage of small-animal patients that present with metabolic alkalosis. Both solutions are high in chloride and promote renal excretion of bicarbonate. Normal saline is also commonly used in treatment of patients with electrolyte disorders such as hyperkalemia or hypercalcemia in which absence of electrolytes in parenteral fluids is desirable. Assuming appropriate insulin therapy is instituted, normal saline is also considered the fluid of choice for treatment of diabetic ketoacidosis.

Colloids. The critical distribution of water between plasma and interstitial fluid is maintained in part by the colloid osmotic pressure (COP) of plasma protein. COP includes the osmotic pressure exerted by plasma proteins and their associated electrolyte molecules. This force draws water into capillaries and balances the hydrostatic pressure driving water out (see Starling relationships described earlier in this chapter). Although the basic concept of Starling relationships is straightforward, in vivo application of these concepts is complicated by the heterogeneity of Starling forces within different tissues and the complexity of transvascular fluid dynamics. Despite these caveats, it is practical to say that the balance between intravascular COP and capillary hydrostatic pressure drives net fluid extravasation and forms the basis for intravenous colloid therapy.

Therapeutic colloids may be of two types: natural and synthetic. Natural colloids include whole blood, plasma, and albumin. Synthetic colloids, the focus of this discussion, include dextran 40, dextran 70, hetastarch, pentastarch, and oxypolygelatin. Therapeutic colloid solutions contain large particles and are retained within the vascular space more readily than crystalloids. As a result, smaller volumes of colloids cause greater volume expansion than crystalloids do. Initial tissue perfusion has been found to be better after volume expansion with colloids or combinations of colloids and crystalloids than with crystalloids alone (Funk and Baldinger 1995). The duration of this effect varies and is dependent upon many variables, including the species of animal, dose, specific colloid formulation, preinfusion intravascular volume status, and microvascular permeability (Hughes 2000).

The osmotic effect of colloid solutions is related to the number of particles rather than the size of particles in a solution. However, heterogeneity of particle size causes considerable complexity in the pharmacokinetics of these solutions. Synthetic colloids contain

Table 25.18—Indications, dosages, administration, and side effects associated with use of selected colloids in dogs

Type of colloid	Indications	Dosage and administration	Side effects and contraindications
Plasma	Coagulopathies; disseminated intravascular coagulation; low antithrombin; acute hypoalbuminemia.	20–30 mL/kg/day administered: (a) continuously over 24 hr, (b) as a 2–4 hr infusion, (c) 6–10 mL/kg in 1 hr infusions every 8 hr, or (d) until plasma albumin is over 2.0 g/dL. Approximately 22.5 mL/kg of plasma needed to increase patient albumin by 5 g/L.	Rapid volume expansion may be detrimental to patients with oliguric or anuric renal failure or congestive heart failure.
Dextran 40	Rapid, short-term intravascular volume resuscitation from hypovolemic shock; rapid improvement of microcirculatory flow by lowering blood viscosity; prophylaxis of deep vein thrombosis and pulmonary emboli.	10–20 mL/kg/day IV bolus to effect; with distributive shock due to SIRS dextran can be followed by a CRI of hetastarch to maintain MAP of at least 80 mm Hg.	*See* plasma. Dilutional effect on serum coagulation factors in addition to possible direct effects on these factors. May be of limited clinical relevance except in patients with preexisting coagulopathies. Contraindicated in patients with severe coagulopathies. Sludging of RBCs in microcirculation in dehydrated patients may occur if sufficient crystalloids are not administered. Anaphylaxis reported in humans. ARF has been reported.
Dextran 70	Rapid, intravascular volume resuscitation from hypovolemic, traumatic, or hemorrhagic shock.	*See* dextran 40.	*See* dextran 40. Dextran 70 is thought to impair coagulation more than dextran 40. No ARF reported.
Hetastarch (hydroxyethyl starch or HES)	Rapid, intravascular volume resuscitation from all forms of shock; small-volume resuscitation; volume replacement and maintenance in SIRS patients.	10–40 mL/kg/day IV bolus to effect; with cardiogenic shock, pulmonary contusions, or head injury, 5 mL/kg boluses are administered to effect, using the smallest volume possible to maintain MAP of 80 mm Hg.	*See* dextran 40. Anaphylaxis has not been reported with hetastarch, but pruritus possibly associated with deposits of HES in cutaneous nerves has been reported in up to 33% of patients treated with long-term infusions. No ARF reported.
Pentastarch (PEN)	Rapid, intravascular volume resuscitation from hypovolemic, traumatic, or hemorrhagic shock.	10–25 mL/kg/day; terminal half-life shorter than HES.	*See* dextran 40. Anaphylaxis and ARF have not been reported with pentastarch.
Oxypolygelatin	Rapid, short-term intravascular volume resuscitation from hypovolemic shock.	5 mL/kg over 15 min; titrate to effect; do not exceed 15 mL/kg total dose. If more volume required, follow with another synthetic colloid.	*See* dextran 40. No ARF reported.

Source: Modified from Rudloff and Kirby1998. Other sources for information in table include Mathews 1998 and Hughes 2000.

Note: ARF = acute renal failure; CRI = constant-rate infusion; MAP = mean arterial pressure; SIRS = systemic inflammatory response syndrome.

molecules that vary in molecular weight more than the molecules in a solution of a natural colloid such as albumin. After synthetic colloids are administered, the smaller molecules pass rapidly into the urine and are eliminated or move to the interstitium, negating their ability to attract water into the vasculature. Larger molecules remain in the circulation to exert COP until they are hydrolyzed by amylase or removed by the monocyte phagocytic system. Because of differences in particle behavior and in pharmacokinetic study design (e.g., duration of study, volume status of study subjects, volumes and rates of colloid administration), specific half-lives reported for colloids may vary considerably (Mathews 1998). Such variation may pose therapeutic problems since actual duration of action of colloids may not coincide with manufacturer estimates of the same.

Indications for colloid use include perfusion deficits, hypooncotic states, deficiency of blood components, and diseases that lead to systemic inflammatory response syndrome (SIRS). SIRS is a generalized inflammatory process with evidence of decreased organ perfusion. Sepsis may be the source of SIRS but other conditions may also result in generalized systemic pathophysiology (e.g., heat stroke, acute pancreatitis, neoplasia). Hallmarks of SIRS include alterations in temperature, heart rate, respiratory rate, PCO_2, and white blood cell count. Peripheral vasculature dilates, capillary permeability increases, and plasma proteins leak from affected vessels. The resulting hypoalbuminemia leads to a reduction in COP, loss of vascular volume, and hypoperfusion of tissues. High molecular weight colloids administered to SIRS patients are retained more effectively in leaky vessels and force retention of volume. Approximately 20–25% of crystalloid remains within the vasculature 1 hour after infusion into normal animals compared with 100% of the volume of infused colloid. Hence, colloids may initially expand the volume of the intravascular space approximately fourfold more than crystalloids (Hughes 2000).

Colloids are often included in fluid regimens for small-volume resuscitation (e.g., during traumatic, hypovolemic, or cardiogenic shock), improvement of microcirculatory flow and capillary integrity (e.g., SIRS), and management of ongoing hemorrhage. While colloids are useful in reestablishing vascular integrity, replenishment of interstitial and intracellular fluid deficits depends upon appropriate use of colloids and crystalloids in combination. Colloid administration typically reduces the required amount of crystalloid fluid by as much as 40–60% (Rudloff 1998). Care must be taken to adjust amounts and rates of all fluids administered to prevent intravascular volume overload and subsequent interstitial edema. Monitoring of colloid therapy ideally includes direct measurement of COP with a membrane osmometer in addition to measurement of traditional indices of perfusion and hydration.

Problems associated with colloid therapy may include dilutional effects caused by expansion of the intravascular space. Packed-cell volume, albumin concentration, serum potassium concentration, and amount of circulating coagulation factors typically decline following administration of synthetic colloids. Rapid volume expansion may be of greatest concern in patients with oliguric or anuric renal failure or congestive heart failure. Precipitation of acute renal failure has been reported in humans with dextran 40 (Ferraboli et al. 1997). Impairment of coagulation as a result of dilution of coagulation factors is thought to be of limited clinical relevance in veterinary medicine except in patients with preexisting coagulopathies. Anaphylactic or anaphylactoid reactions associated with colloids have been reported in humans. Concern has also been raised over the effects of selected colloids on reticuloendothelial function (Hughes 2000). Because cats are more likely to show signs of allergic reactions, especially when synthetic colloids are administered quickly, only small volumes infused at slow rates (5 mL/kg increments given over 5–10 minutes, repeated to effect up to 20 mL/kg) are recommended for use in this species.

Table 25.18 lists indications, dosages, and administration details for colloids commonly used to treat dogs. Albumin (66,000–69,000 daltons) accounts for 80% of the COP of the only natural colloid listed, plasma. Each gram of albumin can retain as much as 18 mL of fluid in the intravascular space, assuming infused albumin does not leak from damaged vessels. The intravascular half-life of albumin in plasma is approximately 16 hours (Mathews 1998). The three major categories of synthetic colloids are dextrans, hydroxyethyl starches, and gelatins. Dextrans are prepared from a macromolecular polysaccharide produced by bacterial fermentation of sucrose. Because these products represent a range of molecules with different molecular weights, they are described by a weight average molecular weight (MWw). MWw is defined as the sum of the number of molecules at each molecular weight times their mass divided by the total weight of the molecules. Dextran 70 (MWw = 70,000 daltons) is more commonly used and is available as a 6% solution in either 0.9% saline or 5.0% dextrose. Hydroxyethyl starches are derived from plant amylopectin and are modified by hydroxyethylation to reduce hydrolysis by amylase. The most commonly used product in this category, hetastarch (Hespan®), has a MWw of 100,000–300,000 daltons and is available as a 6% (6 g/dL) solution in 0.9% saline. Pentastarch has a narrower range of molecular weights, a shorter duration of action than hetastarch, and is only approved in this country for leukapheresis. Only one gelatin product, oxypolygelatin (Vetaplasma®) derived from bovine bone gelatin, is approved in this country as a plasma substitute for fluid resuscitation.

Hypertonic Solutions. For several decades, resuscitation of experimental and clinical animals suffering from shock has been attempted using hypertonic saline (HSS). Throughout the 1900s, studies have generally supported the benefits of HSS for transient restoration of cardiovascular function. Although a full understanding of the mechanism of action has been elusive, there is agreement that the primary benefits of HSS infusion result from plasma volume expansion. High circulating concentrations of sodium attract water into the vasculature from the interstitial and intracellular spaces and help to restore capillary flow and tissue perfusion. Cardiac output has been reported to increase as a result of increased preload, decreased afterload related to systemic and pulmonary vasodilation (Constable et al. 1995), increased adrenergic activity through release of catecholamines, and improved oxygen delivery to the heart (Tobias et al. 1993). Positive inotropy has also been reported but this remains a controversial point (Cambier et al. 1997). In vitro studies have shown that, at least during the initial treatment period, negative inotropy may predominate (Constable et al. 1994). All of the above effects are short-lived (peak occurs within approximately 1 hour) but resuscitative benefits may be prolonged by combination of HSS with colloids such as dextran 70. Ideally, rapid recovery of cardiovascular parameters occurs with administration of smaller volumes of HSS or HSS plus dextran (HSD) compared to crystalloids, thus decreasing the risk of edema related to volume overload. In addition to primary volume expansion, HSS is thought to invoke a lung vagal reflex important to circulatory control during hypovolemia. How much this reflex contributes to the cardiovascular effects of HSS infusion remains controversial. HSS may also have immunomodulatory effects that protect organs from oxidative injury and enhance cell-mediated immunity (Coimbra et al. 1996).

HSS use is indicated in the treatment of shock associated with hemorrhage (Bauer et al. 1993), trauma (Schertel et al. 1996), gastric-dilatation volvulus (Schertel et al. 1997), acute pancreatitis (Horton et al. 1989), burns (Horton et al. 1990), and sepsis (Fantoni et al. 1999; Maciel et al. 1998). The evidence for use of HSS in the first three of these is most compelling, with fewer studies unequivocally demonstrating advantage under specific study conditions associated with the other disorders. HSS has also been utilized in treatment of head injury since, like mannitol, HSS draws interstitial and intracellular water away from edematous tissues and into the vasculature (Prough and Zornow 1998). Regardless of the indication, HSS effects are transient, necessitating combination with crystalloids or colloids to achieve long-term resuscitative goals. Effects of HSS should be monitored by improvement in cardiovascular parameters correlated with increased perfusion as well as by assessment of mean arterial blood pressure, electrocardiogram, and electrolytes. Monitoring is aimed at preventing volume overload and electrolyte imbalances that may occur as a result of therapy.

HSS use is contraindicated in hypernatremic patients or those with increased plasma osmolality. Use in dehydrated animals is controversial since these patients frequently suffer from increases in both parameters. Studies that support HSS use in the presence of dehydration include those in which resuscitation with HSD of hypovolemic, diarrheic calves found this method to be at least as effective as others (Constable et al. 1996; Walker et al. 1998). In animals suffering from shock related to trauma and hemorrhage, two additional problems, hypokalemia and increased risk of rehemorrhaging, may be of concern. Rehemorrhage—bleeding caused by breakdown of clots in areas where hemorrhage has previously occurred—may be related to the sudden increase in cardiac output and arterial blood pressure associated with HSS resuscitation (Schertel and Tobias 2000). HSS may also dilute circulating coagulation factors and affect platelet function. As with colloids, these concerns may only be of practical significance if the patient suffers from preexisting coagulopathies or thrombocytopenia. Using a swine model of hemorrhagic shock, Dubick et al. (1993) demonstrated that the combination of 7.5% NaCl/6% dextran 70 did not significantly affect various measures of coagulation and platelet aggregation in their model. Studies continue to address the pros and cons of HSS use in various animal models and in clinical patients (Krausz 1995). Variation across species lines, differences in physiological circumstances of each study, and different views of cost versus benefit ratios may account for differing conclusions on the overall value of HSS treatment.

HSS is administered most effectively in combination with colloids or crystalloids in order to optimize resuscitative effects. 5% HSS, at a dose of 6–10 mL/kg, and 7–7.5% HSS, at a dose of 4–8 mL/kg, are administered at a rate of 1 mL/kg/min. Similar dosages may be used for HSD. More rapid administration rates may invoke a vagal-mediated hypotension, decreased heart rate, bronchoconstriction, and rapid, shallow breathing. To prepare 7% saline in 6% dextran 70, 33.0 g of anhydrous sodium chloride is added to a 500 mL bag of 6% dextran 70 in 0.9% saline. Half of the sodium chloride crystals are placed into the barrel of a 35 mL syringe and an adequate volume of dextran 70 solution is drawn into the syringe to dissolve the crystals. This solution is filtered through a 0.22 μm filter and is injected back into the bag of dextran 70. The procedure is repeated a second time to dissolve the remaining half of the sodium chloride (Schertel and Tobias 2000). Although a reported advantage of HSS is presumed sterility due to hypertonicity, St. Jean et al. have demonstrated the ability of bacteria to adapt and survive in the hypertonic environment of HSS (St. Jean et al. 1997). Hence, aseptic technique consistent with handling of all intravenous fluids should be followed.

SPECIAL TOPICS

Horses. Horses present some special problems in acid-base management. In cases of severe diarrhea, shock, and intestinal obstruction, the horse seems predisposed to rather severe metabolic acidosis (Waterman 1977). Respiratory acidosis is a very common sequel to closed-circuit inhalation anesthesia in the horse. An abnormally low concentration of Na^+ is a common problem in dehydrated horses. Severe hypokalemia, with blood K^+ values less than 2.5–3 mEq/L, may require treatment with solutions high in K^+. Dangerous hyperkalemia, with blood levels greater than approximately 7 mEq/L, may be associated with acidosis in foals. Prompt correction of the acidosis will usually correct the hyperkalemia.

Cattle. Ruminants also present special fluid and electrolyte management problems. When a diagnosis of abomasal disease is coupled with an obvious fluid balance disorder, hypochloremia, hypokalemia, and alkalosis are usually present. These should be confirmed by appropriate laboratory tests. Grain overloading will result in severe dehydration and metabolic acidosis. Calf diarrhea also results in severe dehydration and metabolic acidosis, with dangerous hyperkalemia in some cases. If hyperkalemia exists, one must guard against administration of even more K^+. When dealing with herbivores, it is important to remember that normal feed contains high levels of K^+. When these animals are anorexic, they frequently become K^+ depleted.

The best way to replace K^+ deficits is by consumption of hay or grass, but K^+ must be added parenterally when the situation dictates. A wide variety of electrolyte mixtures containing K^+ are available for oral administration.

Anesthetic and Surgical Effects. General anesthesia may exert several effects on water, electrolyte, and acid-base balance. Almost all general anesthetics induce some degree of Ca^{++} channel blockade, resulting in some degree of vasodilation and myocardial depression. The end effect can be a reduction in cardiac output and/or alterations in organ blood flow. Arterial pressures are frequently lowered in a dose-dependent manner, and GFR may be affected. The commonly used inhalation anesthetic agents (halothane, enflurane, and isoflurane) all cause direct systemic vasodilation. Narcotics and some muscle relaxants also can cause vasodilation. As a result of the vasodilation, fluid requirements may be increased during the course of the surgical procedure to maintain adequate blood pressure and cardiac output. After recovery from the general anesthetic, when vascular tone is normalized, the patient may be volume overloaded and hypertensive. Fluid loss may also increase during general anesthesia as a result of tracheal intubation and/or artificial ventilation. Normal mechanisms for the humidification of inspired air are bypassed, and the cold, dry gases from the anesthesia machine can cause a considerable amount of fluid loss. Open body cavities allow for evaporative losses. Third spacing may occur with extravasation of fluid from the vascular to the extravascular, extracellular spaces. If extravasated fluid is replaced to maintain adequate circulatory volumes, the patient with inadequate cardiac reserve or poor renal function may suffer fluid overload and congestive heart failure when postoperative redistribution of the fluid back into the circulation occurs (Gold 1992).

Surgical injury can result in significant reductions in serum albumin, total proteins, and total lymphocyte counts. These decreases are typically greater following abdominal surgery. The decreases have been found to be primarily caused by the volume of IV fluids frequently required for resuscitation and to compensate for blood loss.

Chapter 25 presents the physiological basis for fluid and electrolyte balance, including discussion of selected renal mechanisms for regulation of water, sodium, chloride, potassium, hydrogen, and bicarbonate. In this chapter these concepts will be extended in order to understand the mechanism of action, therapeutic uses, and side effects of diuretic agents. The history of diuretics dates back to consumption by Paleolithic humans of caffeine-containing plants. Besides xanthine derivatives such as caffeine, osmotic diuretics were clinically important prior to the 20th century. The use of mercurial diuretics, now therapeutically obsolete, began in the early 1900s and was followed by introduction of the first modern diuretic, acetazolamide, in the mid-1950s. By the late 1950s and early 1960s the formulary of modern diuretics included chlorothiazide, furosemide, and potassium-sparing diuretics (Morrison 1997). These drugs and their relatives constitute the mainstays of diuretic treatment. Although not currently available for clinical veterinary use, a new class of diuretic agents, aquaretics, have recently emerged and will likely become clinically relevant.

RENAL PHYSIOLOGY

Nephron Function. Knowledge of renal anatomy and physiology is essential to understanding the mechanism of action of diuretic drugs. Although a thorough review of these topics is beyond the scope of this text, a brief overview of nephron function is provided. The basic functional unit of the kidney is the nephron, which consists of a filtering apparatus, the glomerulus, connected to an extended tubular structure that reabsorbs and conditions the glomerular ultrafiltrate to produce urine. Each kidney is composed of thousands of nephron units. Fig. 26.1 is a schematic drawing of a single nephron unit, indicating the broad subdivisions of nephron segments and the sites of action of diuretic

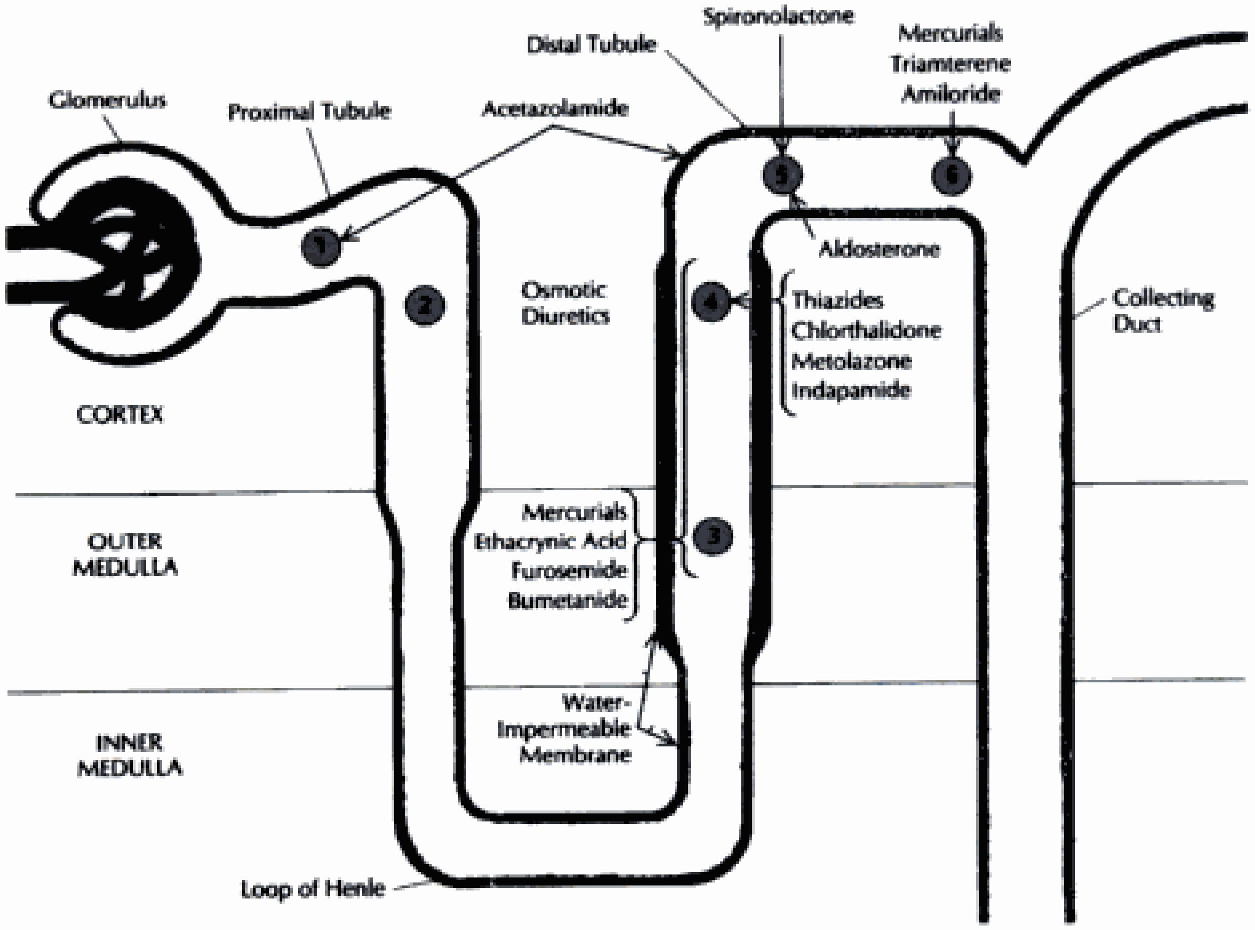

FIG. 26.1—Locations within the nephron where diuretic agents exert their effects.

agents. This diagram provides the simplest nomenclature for nephron segments. As knowledge of the function and epithelial morphology of each segment has increased, the tubular portion of the nephron has been subdivided into approximately 14 shorter segments referred to by a standardized nomenclature (Kriz and Kaissling 1992).

Formation of urine starts in the glomerulus, where a portion of plasma water is filtered through fenestrated glomerular capillary endothelial cells, a basement membrane, and, finally, filtration slit diaphragms formed by the visceral epithelial cells that cover the basement membrane on its urinary space side. The filtrate collects in Bowman's space, a double-walled invagination that forms a cup around the glomerular capillaries. From Bowman's capsule the filtered fluid passes into the proximal tubule and begins its passage through the renal tubular system. Small solutes are actively filtered with plasma water while larger elements, such as protein and macromolecules, are retained by the glomerular filter. The rate of filtration in each nephron (referred to as the single-nephron glomerular filtration rate, SNGFR) is a function of hydrostatic pressure in the glomerular capillaries (P_{GC}), hydrostatic pressure in Bowman's space or the proximal tubule (P_T), mean colloid osmotic pressure in the glomerular capillaries (Π_{GC}), colloid osmotic pressure in the proximal tubule (Π_T), and the ultrafiltration coefficient (K_f). The relationship between these forces is summarized by the following equation:

$$\text{SNGFR} = K_f[(P_{GC} - P_T) - (\Pi_{GC} - \Pi_T)]$$

This equation is usually simplified by defining $P_{GC} - P_T$ as the transcapillary hydraulic pressure difference (ΔP) and eliminating Π_T since little protein is filtered. Hence the equation below becomes the most useful expression:

$$\text{SNGFR} = K_f(\Delta P - \Pi_{GC})$$

Whereas K_f is determined by the properties of the filtering membrane, ΔP is primarily determined by the proportion of arterial pressure conveyed to the glomerular capillaries. As resistance changes in pre- and postglomerular vessels, ΔP varies. The pressure Π_{GC} depends upon the concentration of protein in arterial blood as well as the actual flow of blood to the nephron. SNGFR is an important parameter that may affect, or be affected by, the action of diuretic drugs.

Ultrafiltrate from the glomerulus enters the proximal tubule from Bowman's capsule. By the time urine exits the distal tubule and collecting duct, better than 99% of ultrafiltrate volume will be reabsorbed. Fig. 26.2 (left

FIG. 26.2—Reabsorption in the nephron. General characteristics of segmental tubular reabsorption (*left*) and details of transport mechanisms in each segment (*right*). Six of seven basic mechanisms for transport of solutes across renal epithelial membranes are shown. Channel-mediated diffusion (shown as an *interrupted cell membrane*) allows solutes to move passively through the membrane. Carrier-mediated, or facilitated, transport (*unfilled circle, single arrow*) (also referred to as a uniport) allows a single substance to move with, but not against, an electrochemical gradient. ATP-driven primary active transport (*filled circles*), usually in the form of Na^+,K^+-ATPase, mediates the bulk of renal transport and can move solutes against an electrochemical gradient. Secondary active transport utilizes the potential energy stored in electrochemical gradients to move solutes across membranes against their gradients. Two types of secondary active transport are shown. Cotransport of solutes (S), such as glucose, inorganic phosphate, and amino acids, with sodium in the same direction occurs through symports (*unfilled circles, two arrows, each pointing in the same direction across the cell membrane*). Countertransport of solutes in the opposite direction occurs through antiports (*unfilled circles, two arrows, each pointing in a different direction across the cell membrane*). Simple diffusion down a concentration gradient can occur through cell membranes if the solute is lipid soluble. Simple diffusion that occurs between cells (paracellular) is shown (*arrows directed between cells*). A final transport mechanism, solvent drag, can occur across membranes through aqueous pores or between cells (*not shown*). A^- = organic acid (anion).

TABLE 26.1—Approximate renal tubular reabsorption (%) of filtered substances

	Proximal tubule	Thick ascending limb of Henle's loop	Distal tubule	Total reabsorption (all segments)
H_2O	60	20	19	99

column) summarizes the characteristics of reabsorption in broad sections of the renal tubules. The thick ascending limb of the loop of Henle is of particular importance since this is the site of action of the most potent diuretic drugs. Approximately 25% of filtered solutes are reabsorbed in the loop of Henle, and most of this reabsorption occurs in the thick ascending limb. The thick ascending limb also makes a critical contact with the afferent arteriole through a cluster of specialized epithelial cells referred to as the macula densa. The macula densa monitors the NaCl concentration in filtrate leaving the loop of Henle. Together with extraglomerular mesangial cells and renin-producing cells of the glomerular arterioles, these components form the juxtaglomerular apparatus. A high concentration of salt in tubular fluid prompts a signal to the afferent arteriole causing constriction and decreased SNGFR. This, in combination with other responses, constitutes the tubuloglomerular feedback mechanism that protects the animal from salt and water wasting. Alternatively, excessive volume expansion causes the macula densa to inhibit renin release from the juxtaglomerular cells, leading to dilatation of the afferent arteriole. Because the ascending loop of Henle is poorly water permeable, tubular fluid at the end of this segment is dilute despite the presence of renal interstitial tissues with increasing osmolality toward the medulla. The renal interstitial concentration gradient, amplified by the countercurrent mechanism, provides the driving force for passive water reabsorption later in the nephron. The collecting duct system described in Fig. 26.2 includes the connecting tubule (also referred to as the late distal tubule), which is responsive to aldosterone. If extracellular fluid (ECF) sodium concentrations are too low, aldosterone is secreted, causing increased sodium reabsorption in the connecting tubule. Vasopressin, also referred to as arginine vasopressin (AVP) and antidiuretic hormone, is secreted when plasma osmolality is elevated or ECF volume contracts. Stimulation by vasopressin leads to receptor-mediated opening of water channels in the collecting ducts with subsequent retention of water and expansion of ECF volume. In general, modification of filtrate as it passes through the nephron is controlled at two different levels. Systemic regulatory mechanisms and effector hormones such as renin-angiotensin-aldosterone, natriuretic peptides, and vasopressin ensure the balance of salt and water metabolism. Cellular feedback loops and glomerulotubular balance modify tubular function and influence single-cell homeostasis. Diuretics may interfere at either or both levels to cause increases in salt and water excretion.

Renal Epithelial Transport and Secretion. Just as knowledge of functional renal anatomy has increased, so has understanding of cellular mechanisms for transport of solutes across renal epithelium. Since the early 1990s, many ion transporters and cotransporters that serve as targets for diuretic drugs have been cloned and characterized at the molecular level (Xu et al. 1994; Gamba et al. 1993, 1994). Fig. 26.2 (right column) summarizes the general mechanisms for renal epithelial transport in different segments of the renal tubules. Table 26.1 provides approximations of percent renal tubular reabsorption of selected substances by nephron segment.

In addition to ion transport mechanisms, the kidney also has highly effective and separate transport systems for movement of organic acids and bases. Energy from ATP-driven active transport is used to establish gradients for secondary active transport of both anions and cations. Families of proteins representing both anion and cation transporters move a wide variety of related substances. While these transporters have flexible stereospecificity, structural features of anions and cations that are efficiently transported have been identified (Jackson 1996). The presence of anion and cation transporters is essential for most highly protein-bound diuretic drugs to gain access to their site of action, the lumen of the renal tubule. Loop and thiazide diuretics and acetazolamide are secreted through the organic acid pathway, and amiloride and triamterene via an organic base transporter (Brater 1998). Renal insufficiency accompanied by reduced creatinine clearance decreases delivery of diuretic drugs to their secretory site and hence to their site of action. Accumulation of endogenous organic acids during chronic renal failure may result in competition with diuretics for transport at proximal tubule secretion sites (Brater 1993).

PRINCIPLES OF DIURETIC USE

Overview. The current therapeutic goal of diuretic use is increased excretion of sodium followed by water. The degree of sodium loss in the urine (referred to as natriuresis or, in combination with chloride, saluresis) varies with the mechanism of action of the drug. All except osmotic diuretics inhibit specific enzymes, transport proteins, hormone receptors, or ion channels that function, directly or indirectly, in renal tubular sodium reabsorption. Although saluresis is the primary clinical goal, diuretics also alter elimination of other ions to varying degrees (e.g., K$^+$, H$^+$, Ca^{2+}, Mg^{2+}, Cl$^-$, HCO$_3^-$, phosphates) and may affect renal hemodynamics. Diuretic-induced depletion of circulating blood volume may lead to adverse effects if therapy is not well monitored. For example, in patients with chronic hepatic disease hypoalbuminemia leads to a decrease in plasma colloidal osmotic pressure and shifts in fluid to other spaces. Even a small diuretic-induced decrease in arterial perfusion under these circumstances may lead to severe exacerbation of disease. Older animals and those with cardiac or renal disease are also at increased risk for adverse effects if diuretic-induced hypovolemia goes untreated. Because these groups are also the primary target groups for diuretic use, rational use of diuretic drugs is essential. Table 26.2 summarizes selected features of diuretic drugs most commonly used in veterinary medicine.

Edema Formation. The most common indication for diuretic use is mobilization of tissue edema. Understanding the physiological principles underlying edema formation depends upon an understanding of net capillary filtration (see Chap. 25 and the equation above for SNGFR). Net capillary filtration (NF), or fluid flux out of a capillary, is dependent upon Starling forces inside and outside the vessel. NF is determined by the difference between ΔP, which represents the hydrostatic pressure inside the capillary lumen minus the hydrostatic pressure in the interstitial fluid, and $\Delta\Pi$, representing the oncotic pressure inside the capillary minus the oncotic pressure in the interstitial fluid. This value multiplied by a filtration coefficient (K_f), representing the permeability of the capillary wall, predicts the movement of fluid into and out of the vascular compartment.

Normally the flux of fluid out of capillaries is equaled by the lymph flow away from the site. If flux exceeds flow, edema results. A simplistic explanation of edema formation starts with a decrease in plasma oncotic pressure that leads to loss of intravascular volume to the interstitial space. The loss of intravascular fluid leads to decreased plasma volume, which leads to renal salt and water retention. Eventually salt and water retention causes increased plasma volume, increased plasma hydrostatic pressure, and increased flux of fluid out of the capillary, resulting in accumulation of edema in the interstitium. In veterinary medicine the most

TABLE 26.2—Summary of diuretic drugs commonly used in veterinary medicine.

Drug	Indications, dosages, route of administration	Mechanism of action, route of elimination	Adverse effects
Mannitol	*Oliguric renal failure:* 0.25–0.5 gm/kg IV over 15–20 min. If diuresis occurs, may repeat every 4–6 hr up to a dose of 1.5 gm/kg in 12–24 hr. Monitor for urine production and dehydration. *Acute glaucoma:* 1–2 gm/kg IV over 15–20 min; withhold water for 30–60 min after dosing.	Osmotic diuretic Renal elimination	Hyper- or hypo-osmolality Hypokalemia Acute hypotension associated with hyponatremia
	Increased intracranial pressure:	1.5 gm/kg IV once.	
Furosemide	*Edema of cardiac, hepatic or renal origin:* SMALL ANIMALS: 1–3 mg/kg every 8–24 hr PO for chronic use; 2–5 mg/kg every 4–6 hr IV, IM, SC (dogs); 1–2 mg/kg every 12 hr up to 4 mg/kg every 8–12 hr IV, IM, SC, PO (cats). LARGE ANIMALS: 0.5–1.0 mg/kg twice daily or to effect. *Other uses:* Decrease bleeding in horses with EIPH (controversial). Establish diuresis in renal failure. Promote excretion of other substances (e.g.,other drugs, elevated electrolytes).	Inhibits Na+-K+-2Cl- symport. Referred to as loop or high ceiling diuretic. Primarily renal excretion of unchanged drug with remainder biotransformed by glucuronidation and renally excreted.	Hypokalemia Hypochloremic alkalosis Ototoxicity Hyperglycemia GI irritation Enhances aminoglycoside nephrotoxicity
Acetazolamide	Primarily ophthalmic use. Adjunctive therapy of glaucoma in dogs and cats: 10–30 mg/kg divided and administered 2–3 times daily orally. 50 mg/kg IV once.	Carbonic anhydrase inhibitor. Renal elimination.	Hypokalemia Acidosis Urinary tract calculi Hepatic encephalopathy

common causes of edema are cardiac (usually congestive heart failure; CHF), hepatic and renal disease.

CHF causes decreased cardiac output and decreased renal blood flow, leading to activation of the renin-angiotensin-aldosterone system followed by renal retention of salt and water. High baroreceptor activity causes increased peripheral vascular resistance and increased vasopressin, which lead to further salt and water retention by the kidneys. Increased central venous pressure caused by increased left ventricular end-diastolic pressures cause increased capillary hydrostatic pressure. All of these factors lead to greater fluid flux out of vessels, resulting in edema related to cardiac disease.

Diuretic Tolerance. This phenomenon has been best described in humans and can occur following short- or long-term administration of diuretics. Short-term tolerance, or diuretic braking, refers to a decrease in response to diuretics following administration of the first dose. Although the mechanism for braking is unclear, it may be mediated by sympathetic responsiveness and activation of the renin-angiotensin-aldosterone system, both of which act to restore circulating volume. Other mechanisms may include decreased arterial blood pressure, which reduces pressure-natriuresis, or alterations in atrial natriuretic peptide. Braking can be prevented by restoration of diuretic-induced volume loss. Long-term use of loop diuretics may cause hypertrophy of distal nephron segments that are continually flooded with higher-than-normal concentrations of sodium in tubular fluid. As distal segments hypertrophy and expression of renal epithelial transporters increases, more sodium is reabsorbed distally, blunting the initial saluretic effect achieved at the level of the loop of Henle. This form of tolerance can often be overcome by combinations of thiazides and loop diuretics that effectively block sodium reabsorption in both the loop of Henle and the distal nephron.

INHIBITORS OF CARBONIC ANHYDRASE

Chemistry/Formulations. This class of drugs was discovered as a result of the observation that sulfanilamide chemotherapeutic agents were capable of causing metabolic acidosis by inhibition of carbonic anhydrase (CA). Screening of sulfanilamides resulted in identification of compounds whose predominant mechanism of action was CA inhibition. These drugs have been used sparingly in veterinary medicine as diuretics and are more commonly used for ophthalmic purposes (see Chap. 55). The prototype drug in this class, acetazolamide (Diamox®, Dazamide®), is available in tablets (125 and 250 mg), extended-release capsules (500 mg), and injectable (500 mg per vial). Other CA inhibitors include preparations for oral use, dichlorphenamide (Daranide®) and methazolamide (Neptazane®), and a recently approved topical drug, dorzolamide (Trusopt®), for ophthalmic use.

Mechanisms and Sites of Action

RENAL MECHANISMS. Drugs in this class are active in the CA-rich segments of the nephron, in particular the proximal tubule. Noncompetitive, reversible inhibition of CA located in the luminal and basolateral membranes (type IV CA) as well as in the cytoplasm (type II CA) results in decreased formation of carbonic acid from CO_2 and H_2O (see Fig. 26.2 and equation below):

$$HCO_3^- + H^+ \leftrightarrow H_2CO_3 \leftrightarrow H_2O + CO_2$$

Reduction in the amount of carbonic acid yields fewer H^+ within proximal tubular cells. Because H^+ is normally exchanged for Na^+ from the tubular lumen, less Na^+ is reabsorbed and more is available to combine with urinary HCO_3^-. Diuresis is established when water is excreted with sodium bicarbonate. As sodium bicarbonate is trapped in the urine and eliminated, less HCO_3^- is returned to plasma, and a systemic acidosis eventually develops. As a result of the systemic acidosis, H^+ becomes available, Na^+ reabsorption is reestablished, and diuresis decreases. Continual use of CA inhibitors is therefore self-limiting in terms of diuretic action. Diuresis induced by CA inhibitors is mild due to incomplete inhibition of CA, redundancy of Na^+ transporting systems in the proximal tubule, and rescue of Na^+ by reabsorption later in the distal tubule. Because intracellular K^+ can, to some extent, substitute for H^+ in the Na^+ reabsorption step, CA inhibitors cause enhanced K^+ excretion. As more Na^+ is presented to the distal tubule, the potential for K^+ wasting increases. CA inhibitors also decrease secretion of titratable acids and ammonia in the collecting duct (Jackson 1996). For this reason, and due to the increased excretion of sodium bicarbonate, urine pH increases despite the decreasing systemic pH associated with CA-inhibitor-induced acidosis. This class of drugs has little, if any, effect on excretion of Ca^{2+} and Mg^{2+} but does enhance phosphate elimination.

EXTRARENAL ACTIONS. Other actions of CA inhibitors are related to the wide distribution of CA in body tissues including the eye, gastric mucosa, pancreas, central nervous system (CNS), and red blood cells. The most important therapeutic consequence is associated with CA inhibition in the eye. The ciliary processes of the eye mediate the formation of aqueous humor, which contains an abundance of HCO_3^-. This process is CA dependent and, when inhibited, leads to a decreased rate of formation of aqueous humor and subsequent reduction in intraocular pressure. Although not therapeutically relevant in veterinary medicine, CA inhibition in the CNS has been associated with anticonvulsant actions attributed to this class of drugs.

Absorption and Elimination. Limited information is available regarding pharmacokinetics of CA inhibitors in animals. Acetazolamide gains access to the renal tubules via the organic acid secretion pathway. A dose of 22 mg/kg is reported to have an onset of action of

30 minutes, maximal effects in 2–4 hours, and a duration of action of 4–6 hours in small animals (Roberts 1985). Oral absorption of drugs in this class is good. Acetazolamide is eliminated primarily through the kidneys.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions. Because CA inhibitors are sulfonamide derivatives, side effects commonly associated with sulfonamides can occur. CNS drowsiness and disorientation may occur as a result of inhibition of CA in the CNS. Because CA inhibitors decrease ammonia excretion, the severity of preexisting hepatic disease may be worsened and hepatic encephalopathy can be induced. Use is also contraindicated in patients with electrolyte disturbances (due to K^+ and Na^+ wasting) and those with metabolic or respiratory acidosis. Use in patients with severe pulmonary disease who cannot respond to drug-induced metabolic acidosis with respiratory compensation is also contraindicated. Because CA inhibitors alkalinize the urine, calcium phosphate calculi formation is enhanced, and excretion of weak organic bases is reduced. Rare blood dyscrasias associated with CA inhibitors have also been reported in the human, but not the veterinary, literature.

Therapeutic Uses. The primary indication for use of CA inhibitors is to inhibit production of aqueous humor and reduce intraocular pressure. In veterinary medicine, acetazolamide (10–30 mg/kg divided and given three times daily) and methazolamide (2–10 mg/kg given 2–3 times daily) are used in dogs for management of glaucoma. A one-time IV dose of acetazolamide (50 mg/kg) has been reported for management of acute glaucoma. Methazolamide is often preferred over acetazolamide for long-term glaucoma therapy due to fewer side effects. CA inhibitors are also used preoperatively to lower ocular pressure.

A recently approved topical CA inhibitor, dorzolamide (previously referred to as MK-507), offers several advantages for treatment of increased intraocular pressure (Mindel 1997). Although systemic CA inhibitors are effective at decreasing intraocular pressures, use of these drugs is often accompanied by undesirable side effects (see above). Compared to other CA inhibitors, one drop of a 2% ophthalmic solution of dorzolamide administered three times daily has limited systemic effects. Ocular side effects may include a stinging or burning sensation in the eye as reported in human medicine and development of an allergic response to the drug. Dorzolamide lacks the cardiovascular and pulmonary side effects that can occur with other treatments for increased intraocular pressure associated with glaucoma (e.g., beta blockers, cholinergic agonists). Dorzolamide has been used in the contralateral eye of dogs with primary glaucoma to prevent development of bilateral disease and has been used to treat secondary glaucoma in dogs and cats. Dorzolamide is probably not effective in acute closed-angle glaucoma. A frequent side effect reported in humans medicated with topical dorzolamide is the presence of a bitter or metal-like taste postmedication. This is apparently associated with drug-laden lacrimal fluid draining into the oropharynx and causing inhibition of CA and accumulation of bicarbonate (Mindel 1997).

In human medicine, CA inhibitors have been used as an adjunctive therapy for epilepsy and in management of acute mountain (high-altitude) sickness. In both human and veterinary medicine, the use of CA inhibitors as diuretics has limited effectiveness due to the rapid development of tolerance. Theoretically, acetazolamide could be used to manage metabolic alkalosis, but this is not a typical clinical practice in veterinary medicine.

OSMOTIC DIURETICS

Chemistry/Formulations. Solutions used as osmotic diuretics contain simple solutes of low molecular weight that have an increased osmolarity relative to plasma. These substances are typically freely filtered by the glomerulus, undergo limited tubular reabsorption, and are pharmacologically inert. The most common osmotic diuretic is mannitol, a six-carbon nonmetabolizable polyalcohol with a molecular weight of 182. Other agents include glycerin, isosorbide, urea, and hypertonic saline solutions. Because mannitol is the most commonly used osmotic diuretic in both human and veterinary medicine, subsequent discussion will focus primarily on this drug. Concentrated mannitol (15–25%) may crystallize at cooler temperatures, in which case the drug can often be resolubilized by warming the solution. Prior to administration, the solution should be cooled and any remaining crystals removed using an in-line intravenous (IV) filter. Veterinary-approved mannitol, USP, for IV use in dogs contains 180 mg/mL (990 mOsm/L); human products (Osmitrol®, Resectisol®) ranging from 5% (275 mOsm/L) to 25% (1375 mOsm/L) are available for IV administration.

Mechanisms and Sites of Action. Hyperosmolar solutions exert part of their effects by establishing an osmotic gradient between plasma and tissue water compartments. Acute effects of this gradient include decreases in hematocrit, blood viscosity, plasma sodium, plasma pH, and, to some degree, the volume of solid organs. Hence, parenchymal dehydration and acute hemodilution are theoretically related as long as the osmotically active particles are effectively separated by a relatively solute-impermeable barrier.

RENAL MECHANISMS. Initially osmotic diuretics were thought to act primarily at the level of the proximal tubule by limiting the movement of water from the lumen into the interstitial space. Water retained in the tubular lumen diluted concentrations of sodium and other ions, reduced ion reabsorption, and promoted diuresis. It is now held that osmotic diuretics, in particular mannitol, have effects throughout the length of the tubule, with the most prominent action occurring in the loop of Henle. Sodium reabsorption is markedly reduced in the descending and thin limbs of the loop of Henle, as determined by studies in dogs and rats. Sodium load to the thick ascending limb of the loop of Henle and to the distal tubule is consequently increased, but the nephron fails to recapture the increased loads of salt and water. As demonstrated in the dog, sodium reabsorption is also thought to be directly inhibited in medullary collecting ducts (Better et al. 1997).

Other reported renal effects of mannitol include increases in cortical and medullary blood flow due to a decrease in renal vascular resistance, impairment of urinary concentration, dilution by dissipation of medullary hypertonicity, an increase in GFR during renal hypoperfusion (may vary according to species), and an increase in urinary excretion of other electrolytes (e.g., K^+, Ca^{2+}, Mg^{2+}, phosphate, bicarbonate) (Better et al. 1997). Mannitol may also prompt the release of atrial natriuretic factor (ANF) and vasodilatory prostaglandins. Inhibition of renin release by mannitol has also been described.

EXTRARENAL MECHANISMS. The actions of mannitol extend beyond the renal effects and include changes in blood rheology, direct transient effects on vascular tone, and increases in cardiac output. In addition to decreasing the hematocrit by hemodilution, mannitol decreases the volume, rigidity, and cohesiveness of red blood cell membranes. The combination of reduced viscosity and reduced mechanical resistance presumably leads to enhanced blood flow. Mannitol-induced increases in cardiac output are thought to be related to reduced peripheral resistance and reduced afterload, a transient increase in preload, and mild positive inotropy. Mannitol may also exert a cytoprotective effect by acting as an oxygen-free radical scavenger (Paczynski 1997).

Absorption and Elimination. Mannitol is not metabolized and is handled as an inert substance by the body. Studies in dogs and humans indicate that mannitol distribution and elimination follow a two-compartment model (Cloyd et al. 1986; Rudehill et al. 1993). The distribution half-life of intravenously administered mannitol is measured in minutes. Elimination half-life is dose dependent and ranges from 0.5 to 1.5 hours for doses between 0.25 and 1.5 g/kg. Mannitol is eliminated rapidly by the kidneys unless renal function is impaired. As a result, penetration of mannitol into tissues is limited by rapidly falling plasma concentrations. Mannitol and urea are administered intravenously in a slow bolus over 15–30 minutes. Glycerin and isosorbide are administered orally. Of the available osmotic diuretics, only glycerin is eliminated by biotransformation.

Adverse Effects and Drug Interactions

ACUTE ADVERSE EFFECTS. Pulse pressure and mean arterial blood pressure usually increase transiently with mannitol administration. However, acute hypotensive, hyponatremic effects of mannitol administration have been reported, especially subsequent to rapid infusion in dehydrated individuals. The mechanism for this acute vasodilatory effect is not well understood, but the problem can largely be prevented by appropriate rates of administration (0.25–1.5 g/kg over 15–30 min). Acute hyponatremia may account for the nausea and vomiting that are sometimes observed with mannitol infusion. Rapid expansion of plasma volume related to attraction of fluid into the vascular compartment may precipitate CHF or pulmonary edema in certain patient populations. However, because the drug is cleared rapidly this problem is not common unless renal function is impaired.

DEHYDRATION AND ELECTROLYTE DISTURBANCES. Because the ratio of the volume of fluid eliminated in urine to the volume of mannitol administered is high, care should be taken to avoid hypertonic dehydration. Circulating plasma volume tends to be preserved as hypertonic dehydration develops, making it harder to clinically detect that a problem exists. The presence of dehydration and significant hypernatremia should be closely monitored using body weight, urine output, and other clinical parameters. In addition to hypertonic dehydration, loss of other electrolytes, including potassium, phosphate, and magnesium, can lead to clinically significant cardiac arrhythmias and neuromuscular complications.

HYPEROSMOLAR STATE AND OSMOTIC COMPENSATION. The phenomenon of osmotic compensation occurs when cells respond to prolonged treatment with a hyperosmolar agent by increasing the presence of intracellular, idiogenic osmoles. Compensation is thought to occur rapidly when the osmolality of plasma is increased by 25 mOsm/kg or more above normal. Newly generated, osmotically active intracellular particles counteract the dehydrating effect of hyperosmolar plasma. Osmotic compensation can limit therapeutic effectiveness by decreasing the osmotic gradient from tissue to plasma. Increased intracellular osmolarity may also promote conditions, especially in the brain, where iatrogenic edema may occur. The risk of edema formation is increased if a hyperosmolar state is reversed rapidly, leaving the intracellular osmoles as the most osmotically active site. To prevent this complication, the duration of return of plasma to normal osmolality should be approximately equal to the duration of the hyperosmolar state.

REBOUND PHENOMENON. Rebound intracranial hypertension has been defined as a significant increase in tension of cerebrospinal fluid following a period of reduction in cerebrospinal fluid tension caused by administration of hypertonic solutions. The rebound phenomenon is thought to be caused by penetration of osmotically active particles into brain tissue, thus creating an osmotic gradient favoring the inward movement of water and edema formation. In the case of the blood-brain barrier (BBB), tonicity, or osmotic effectiveness, can be expressed using an osmotic reflection coefficient for a given solute. The ideal osmotic agent has a value of 1, and a fully permeable agent exerts no osmotic force and has a value of 0. It is relevant to note that the BBB is much less permeable to sodium, chloride, and mannitol and relatively more permeable to glucose and urea (Paczynski 1997). Hence if urea penetrates brain tissue and the concentration of urea in the plasma subsequently decreases, tissue urea becomes the most attractive osmotic draw and a likely site for iatrogenic edema formation. The incidence of true rebound phenomena is unclear and, as with other adverse effects of osmotherapy, may often be prevented by cautious use of hyperosmolar agents in patients with renal impairment or fluid imbalances.

Contraindications. The use of mannitol in patients with ongoing intracranial hemorrhage, anuric renal failure, severe dehydration, or pulmonary congestion or edema is contraindicated.

Adequate fluid therapy should be administered to dehydrated animals prior to administration of mannitol. Mannitol should not be added to whole-blood products unless at least 20 mEq/L of sodium chloride is added to the solution; otherwise, pseudoagglutination may occur.

Therapeutic Uses. Mannitol is used in the prophylaxis and treatment of renal failure, for the reduction of intracranial and intraocular pressure, and with other diuretics to mobilize edema. For reasons already discussed, short-term use of mannitol is most effective to prevent adverse effects and decreased therapeutic efficacy.

PROPHYLAXIS OF ACUTE RENAL FAILURE. Anuric patients should not be routinely treated with mannitol, although a small (0.25–0.5 g/kg), single test dose may be used to try and induce diuresis. Administration of mannitol to patients with renal dysfunction must be done cautiously to prevent problems associated with decreased elimination and prolonged hyperosmolality. Acute renal failure (ARF) may be caused extrinsically (pre- and postrenal failure) or intrinsically, often associated with acute renal tubular necrosis (ATN). Mannitol has been found to be effective in limiting the decrease in GFR caused by ATN if administered before the ischemic insult or exposure to nephrotoxins. Protection of tubules from necrosis may be due to dilution of nephrotoxic substances, reduction of swelling of tubular elements, or removal of tubular casts that are obstructing urine flow. In human medicine, mannitol has been shown to be clearly beneficial in the preservation of kidneys for transplant and for decreasing the incidence of posttransplant ARF. Fewer data are available to support the general value of mannitol for treatment of ARF outside the area of transplantation (Better et al. 1997). In vascular and open-heart surgery, prophylactic mannitol maintains urine flow but not GFR. Some evidence suggests that mannitol administration in patients with established ATN may increase the conversion of oliguric to nonoliguric patients (Levinsky and Bernard 1988).

REDUCTION OF INTRACRANIAL PRESSURE. Osmotherapy has been used for decades to decrease intracranial pressure (ICP). Reduction in ICP is rapid and usually appears within minutes of completion of administration, with maximum effects within the hour. Several theories have been formulated to account for the effectiveness of mannitol in reducing ICP. The osmotic theory holds that brain shrinkage occurs as a result of osmotically driven movement of fluid from tissue and into the vascular compartment. Sensitive, high-resolution imaging methods seem to support the significance of osmotically induced changes in brain water content (Betz et al. 1989). The hemodynamic theory of ICP reduction states that cerebral blood volume is decreased as a result of decreased blood viscosity and increased cerebral perfusion pressure, both of which act to enhance oxygen delivery to the brain. Increased oxygen delivery to the brain is thought to trigger a compensatory reduction in vascular caliber and secondarily a reduction in cerebral blood volume. Detractors of this idea suggest that mannitol is just as likely to decrease blood viscosity as a result of hemoconcentration secondary to hypertonic dehydration. While attention to fluid replacement should prevent dehydration, it has recently been suggested that alternative agents, such as hypertonic saline, are safer and equally effective at reducing ICP. Hypertonic saline has been shown to establish a strong transendothelial osmotic gradient but without the tendency to reduce intravascular volume (Prough and Zornow 1998). Finally, the diuretic theory of ICP reduction suggests that mannitol-induced decreases in central venous pressure translate directly to decreases in ICP due to the valveless communication between the central venous system and the jugular drainage system. This effect may be more important in sustaining, rather than inducing, a decrease in ICP (Paczynski 1997). Regardless of the theory, mannitol has been used for temporary reduction of ICP in patients with a variety of intracranial lesions as well as those with spinal cord trauma and edema. Evidence of ongoing intracranial hemorrhage is considered a contraindication for mannitol administration.

OTHER USES. Osmotic diuretics have also been used successfully to control intraocular pressure during acute glaucoma attacks and to reduce intraocular pressure before or after ophthalmic surgery. Decreases in intraocular pressure occur by loss of intraocular water to hyperosmolar plasma. As the vitreous shrinks, the lens moves posteriorly and the iridocorneal angle opens, improving drainage from the eye. The duration of action depends upon the degree to which the osmotic diuretic is excluded from ocular fluids. Mannitol is reported to increase retinal oxygen tension and is used at a dose of 1–2 g/kg at a rate of 1 mL/kg/min to reduce intraocular pressure in dogs.

INHIBITORS OF NA^+-K^+-$2CL^-$ SYMPORT (LOOP, OR HIGH-CEILING, DIURETICS). Drugs belonging to this class are among the most potent and the most commonly prescribed diuretics, and all share a common mechanism of action. By blocking a key sodium transport mechanism in the thick ascending limb of the loop of Henle (hence the name loop diuretic), these drugs inhibit reabsorption of approximately 25% of the filtered sodium load. Nephron segments distal to the thick ascending limb (TAL) are incapable of reabsorbing the additional solute, leading to a marked (or high-ceiling) natriuresis and diuresis. Because furosemide (Lasix®) is by far the most commonly used diuretic in veterinary medicine, the remaining discussion will focus primarily on this drug (also referred to as frusemide). Other drugs in this class include ethacrynic acid (Edecrin®), bumetanide (Bumex®), and the most recent addition approved in the United States, torsemide (Demadex®).

Chemistry/Formulations. Except for ethacrynic acid, the structurally diverse drugs in this class are sulfonamide derivatives. Furosemide is light sensitive and stable under alkaline conditions; the veterinary injectable preparations (Lasix®, Diuride®, or generic; 50 mg/mL) have a light yellow color, whereas the human injectable (Lasix®; 10 mg/mL) should not be used if it appears yellow. A wide range of veterinary preparations of furosemide are available, including oral tablets approved for use in dogs and cats (12.5 mg, 50 mg), oral solution approved for use in dogs (10 mg/mL), large-animal boluses approved for use in cattle (2 g/bolus), and injectable (5%) approved for use in dogs, cats, horses not intended for food, and cattle. Milk and slaughter withdrawal time for both oral and injectable formulations for cattle is 48 hours.

Mechanisms and Sites of Action

RENAL EFFECTS. Drugs in this class block the Na^+-K^+-$2Cl^-$ symporter in the TAL by binding to the Cl^- binding site of the transporter protein. All of these drugs must be actively secreted into the tubular lumen by an organic acid pathway in order to reach and inhibit the luminal symporter. A high degree of protein binding (>95%) limits glomerular filtration of furosemide and other loop diuretics, making tubular secretion essential. The mechanism involved in Na^+ reabsorption in the TAL depends upon Na^+,K^+-ATPase activity in the basal membrane of tubular cells (see Table 26.1). The transmembrane Na^+ gradient generated by ATPase drives the Na^+-K^+-$2Cl^-$ symporter in the luminal membrane. Basolateral Cl^- conductance and luminal K^+ conductance determine membrane voltage. The polarity of K^+ and Cl^- conductances results in a lumen-positive transepithelial voltage. This voltage drives cations between tubular cells via the paracellular shunt pathway. When loop diuretics block the Na^+-K^+-$2Cl^-$ symporter, Cl^- concentrations in the cell fall, the cell becomes hyperpolarized, transepithelial voltage is disrupted, and paracellular cation reabsorption is blocked (Bleich and Gregor 1997). Because renin-producing cells in the area of the macula densa generate part of their membrane voltage via Cl^- channels, the new Cl^- equilibrium also depolarizes these cells and enhances the secretion of renin. Loop diuretics interfere with establishment of a hypertonic medullary interstitium and disrupt the countercurrent mechanism. Hence, these drugs block the kidney's ability to concentrate and dilute urine appropriately. Inhibitors of the Na^+-K^+-$2Cl^-$ symporter also inhibit Ca^{2+} and Mg^{2+} reabsorption in the TAL by disruption of the transepithelial potential difference. Some loop diuretics, notably furosemide, also have weak CA-inhibiting activity that leads to enhanced urinary excretion of HCO_3^- and phosphate. All Na^+-K^+-$2Cl^-$ symporter inhibitors increase the urinary excretion of K^+ and H^+ by presenting a greater load of Na^+ to the distal tubule. Sodium is reabsorbed while K^+ and H^+ are excreted.

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the diuretic, natriuretic, and chloruretic responses to furosemide. Furosemide enhances production of prostaglandin E_2 (PGE_2), which in turn inhibits chloride and sodium reabsorption in the TAL. In the presence of NSAIDs, PGE_2 production is blocked, and furosemide-induced diuresis is prevented (Kirchner 1987). In the absence of volume depletion, loop diuretics generally increase and redistribute total renal blood flow. The mechanism for this effect is thought to be related to prostaglandins, and the effect is diminished or blocked in the presence of NSAIDs (Data et al. 1978). Furosemide-induced hemodynamic changes correlate with an increase in urinary excretion of PGE_2.

EXTRARENAL EFFECTS. Furosemide causes extrarenal hemodynamic effects that include increased venous compliance and decreased right atrial pressure, pulmonary artery pressure, pulmonary artery wedge pressure, and pulmonary blood volume (Hinchcliff and Muir 1991). Prostaglandins are thought to account for the acute increase in systemic venous capacitance and subsequent decrease in left ventricular filling pressure. All of these effects are dependent upon the presence of a functional kidney and the uninhibited production of prostaglandins. In the isolated rabbit heart, furosemide has also been reported to exert a mild negative inotropic effect that is prostaglandin dependent (Feldman et al. 1987). Inhaled furosemide in humans has been shown to protect against the early response to inhaled allergens and to prevent exercise-induced bronchoconstriction (Bianco et al. 1988, 1989). Furosemide may prevent bronchoconstriction in part by inhibiting release of inflammatory mediators from lung cells (Anderson et al. 1991). Pulmonary gas exchange is reportedly improved by furosemide in experimental pulmonary edema. Furosemide also reduces the rate of pulmonary transvascular fluid filtration through a reduction in pulmonary vein pressure (Demling and Will 1978).

Absorption and Elimination. Furosemide is approximately 77% bioavailable in dogs and has an elimination half-life of about 1 hour following an IV dose of 5 mg/kg (Hirai et al. 1992). The absorption of orally administered furosemide takes place mainly in the upper parts of the canine alimentary tract, decreasing rapidly across the jejunum. Due to variable oral bioavailability and rapid elimination in the dog, a prolonged-release furosemide formulated in hydroxypropyl methylcellulose matrix tablets has been investigated (Smal et al. 1996). Peak effects of an IV dosage of furosemide in the dog are reported at approximately 30 minutes and following oral dosing at about 1–2 hours. The rate of urinary furosemide excretion, more so even than the concentration of plasma furosemide, has been found to closely correlate with diuretic response in dogs. As in humans, the relation between the natriuretic response and the concentration of diuretic in the urine (at the site of action) is represented by a sigmoidal curve (Fig. 26.3). The shape of the curve suggests that a threshold quantity of drug must be achieved at the site of action in order to elicit a response and that a maximal dose can be identified that yields a maximal response. Beyond that maximal dose, the curve plateaus, and limited additional benefits are derived from dose increases (Brater 1998; Hirai et al. 1992).

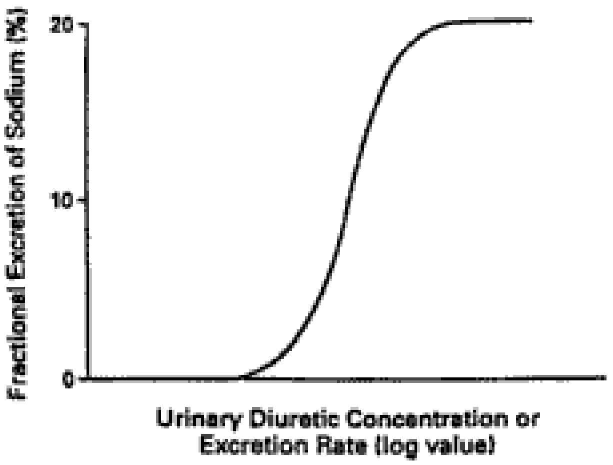

Figure 26.3—Pharmacodynamics of a loop diuretic. The relation between the natriuretic response and the amount of diuretic reaching the site of action is represented by a sigmoidal curve.

Elimination half-life of IV furosemide in the horse is similar to that in the dog and, in the absence of renal impairment, is slightly less than 1 hour. Preventing renal elimination of the drug in horses by bilateral ureteral ligation increases elimination half-life by approximately 3-fold to an average of 164 minutes. This result demonstrates that furosemide elimination in the horse is primarily, but not exclusively, renal (Dyke et al. 1998). The hemodynamic effects of furosemide in this model are prevented by ureteral ligation, suggesting that these effects are diuresis dependent (Hinchcliff et al. 1996).

In humans and other animals, including the dog and horse, approximately 50–60% of a furosemide dose is excreted unchanged in the urine, and the remaining drug is conjugated to glucuronic acid in either the kidney, the liver, or other extrahepatic site (Brater 1998; Dyke et al. 1998).

Plasma half-life in patients with renal insufficiency is prolonged, and dosage adjustments should be made. Binding of furosemide to excessive amounts of albumin (>4g/L) in the urine decreases the amount of unbound, active drug and diminishes the diuretic response. In human patients with nephrotic syndrome, doses of two to three times normal are recommended to provide sufficient amounts of active drug to block the Na^+-K^+-$2Cl^-$ symporter.

In humans bumetanide and torsemide are metabolized in large part by the liver, and so dosage generally does not need to be adjusted for renal disease. Oral bioavailability of these drugs is much more predictable than that of furosemide and in humans ranges from 80 to 100% (Brater 1998).

Toxicity, Adverse Effects, Contraindications, and Drug Interactions. Most adverse effects of furosemide administration are related to abnormalities of fluid and electrolyte balance. Extracellular volume depletion and hyponatremia may lead to reduced blood pressure and diminished organ perfusion. Most at risk for adverse effects related to volume depletion are patients with renal disease (may decrease GFR, increase prerenal azotemia, and, possibly, cause tubular necrosis), cardiac disease (stroke volume and cardiac output may decrease), and hepatic disease (precipitation of hepatic encephalopathy). As noted previously, Na^+-K^+-$2Cl^-$ symporter inhibitors deliver an increased load of Na^+ to the distal tubules, resulting in a renin-angiotensin-aldosterone-driven increase in excretion of K^+ and H^+ in exchange for Na^+. Hypochloremic alkalosis and hypokalemia may result. Risk factors for cardiac dysrhythmias related to diuretic-induced hypokalemia include inadequate dietary intake of K^+, concurrent administration of cardiac glycosides, and additional electrolyte imbalances. A common cause of anorexia in CHF patients is digitalis toxicity, and risk of arrhythmias is increased in these patients if hypokalemia is present. Deficiencies in Mg^{2+} and Ca^{2+} may also be caused by diuretic-enhanced excretion of these substances. Serum electrolyte levels should be monitored in patients receiving ongoing diuretic therapy, especially if risk factors exist related to appetite, diuretic dosage, or severity of disease.

Ototoxicity that is usually transient has been described primarily with ethacrynic acid and less often with all other loop diuretics. In veterinary medicine, ototoxicity may be of greatest concern in treatment of cats with high-dose IV regimens. Other adverse effects reported with use of loop diuretics include gastrointestinal disturbances, bone marrow depression, and hyperglycemia. Hyperglycemia may be related to impairment of proinsulin-to-insulin conversion associated with diuretic-induced decreases in K^+ levels. Patients hypersensitive to sulfonamides may also be hypersensitive to furosemide since this drug contains a sulfonamide moiety. Diuretic-induced depletion of water-soluble vitamins may occur, and supplementation of B-complex vitamins has been recommended for animals receiving continuous diuretic therapy (Keene and Rush 1995).

Loop diuretics are contraindicated in animals with severe fluid and electrolyte disturbances or anuria that does not respond to test doses of diuretics.

Drug interactions may occur when furosemide is administered with theophylline (enhanced effects), aminoglycosides or cisplatin (enhanced ototoxicity and, if volume depleted, nephrotoxicity), digitalis glycosides (diuretic-induced hypokalemia may increase risk of arrhythmias), aspirin or other anticoagulants (anticoagulant activity increased), neuromuscular blockers (alteration in extent of muscle relaxation), corticosteroids (enhanced potassium wasting), insulin (alteration of insulin requirements associated with hyperglycemic effects), lithium and propranolol (increased plasma levels), probenecid (competition for secretion of diuretic into tubular lumen leading to decreased diuretic effect), NSAIDs (as previously described, decreased diuretic effects), and thiazides (synergistic diuretic activity).

Therapeutic Uses. Furosemide is used in small animals for treatment of edema of cardiac, hepatic, or renal origin. In general, the dose of drug in dogs (1–3 mg/kg every 8–24 hours PO for chronic use; 2–5 mg/kg every 4–6 hours IV, IM, SC) is higher than that used in cats (1–2 mg/kg every 12 hours up to 4 mg/kg every 8–12 hours IV, IM, SC, PO) (Ware 1998). Furosemide is also used to establish diuresis in renal failure and to promote excretion of other substances, including elevated electrolytes such as Ca^{2+} and K^+. In large animals, furosemide has been used to treat edema in cattle and edema and exercise-induced pulmonary hemorrhage (EIPH) in horses. A general dose of 0.5–1 mg/kg twice daily or as needed to control edema has been recommended in large animals (Reef and McGuirk 1996). Benefits of furosemide use for treatment of EIPH remain controversial (see below). Specific state guidelines should be consulted for details of furosemide use (dose, frequency, allowable levels) in racing animals.

RENAL INSUFFICIENCY. Decreased GFR and decreased delivery of drug to the tubular site of action and site of elimination in renal insufficiency results in decreased efficacy and increased half-life of furosemide. A sufficiently high dose of drug must be administered to attain an effective amount of drug at the site of action. For the dog, furosemide doses starting at 2 mg/kg IV and increasing in 2 mg/kg increments every hour for 3 hours may be used to try and induce diuresis in severe renal insufficiency. Once a maximal dosage is reached (approximately 6–8 mg/kg), exceeding this amount is not advantageous based on the sigmoidal shape of the fractional sodium excretion curve (Fig. 26.3). In all cases, fluid deficits should be addressed prior to furosemide therapy.

CARDIOGENIC OR PULMONARY EDEMA. Furosemide has been widely used to reduce extracellular volume and minimize venous and pulmonary congestion in chronic and acute CHF. Human patients with CHF do not require large dosages since furosemide is adequately delivered to the tubular fluid. However, because renal responsiveness to loop diuretics appears to be decreased in these patients, increased frequency of administration has been recommended (Brater 1998). Diuretics have traditionally been considered front-line therapy for the treatment of chronic CHF in small animals, and furosemide is reported to be the most frequently used drug for this purpose (Goodwin and Hamlin 1993; Watson and Church 1995). Despite the popularity of furosemide, human studies have revealed that CHF patients controlled on loop diuretics alone deteriorate more quickly than those treated with either angiotensin-converting enzyme (ACE) inhibitors or digoxin. Use of furosemide alone is thought to enhance early activation of the renin-angiotensin-aldosterone system, with detrimental effects on long-term prognosis (Svedberg et al. 1990). Current recommendations include furosemide for treatment of more advanced stages of heart failure in patients already receiving ACE inhibitors, digoxin, or both. Furosemide remains a drug of choice for treatment of acute cardiogenic pulmonary edema. Within the context of severity and chronicity of disease, the lowest effective dosage and frequency of furosemide administration should be determined by observation of clinical signs and consideration of owner observations.

EXERCISE-INDUCED PULMONARY HEMORRHAGE (EIPH). EIPH, or bleeding from the lungs as a consequence of exercise, occurs in horses engaged in a variety of athletic activities. The problem has been best studied in racing horses, particularly Thoroughbreds. In general, EIPH is thought to occur because systemic arterial pressures during maximal exercise are higher than pulmonary arterial pressures. As a result, pulmonary capillaries are subjected to rapid increases in transmural pressures sufficient to cause vascular disruption. Transmural pressures are calculated by subtracting pulmonary capillary pressure from alveolar pressure. Pulmonary capillary pressure can be estimated as the mean between left atrial and pulmonary arterial pressure. Alveolar pressure is approximated indirectly using transpulmonary pressure. This value is estimated by measurement of changes in esophageal pressures. Another parameter relevant to assessment of EIPH is pulmonary wedge pressure, defined as the back-pressure opposing pulmonary perfusion. This parameter increases with exercise and is considered an index of pulmonary venous pressure. In addition to changes in pulmonary pressures, other factors implicated in the pathophysiology of EIPH include concurrent small airway disease, upper airway obstruction, exercise-induced hyperviscosity, and environmental effects (Lester et al. 1999).

In most studies, furosemide has been found to reduce right atrial, pulmonary arterial, and pulmonary wedge pressures in exercising horses. Some studies suggest that changes in pulmonary pressures caused by furosemide are due to reduction in plasma and blood volume and not to direct effects of the drug on the pulmonary vasculature. Furosemide produces a rapid reduction in blood and plasma volume, which has been shown in the horse to be essential for subsequent reduction in pulmonary pressures (Hinchcliff et al. 1996). Furthermore, administration of polyionic fluids in an amount equal to the volume lost in urine restores furosemide-induced decreases in right atrial pressure and blood volume in the horse (Rivas and Hinchcliff 1997).

Data from additional studies leave open the question of direct effects of furosemide on pulmonary pressures and mechanics in EIPH. In one study horses treated with NSAIDs (phenylbutazone and flunixin) prior to administration of furosemide followed by exercise did not show reductions in pulmonary and right atrial pressures (Olsen et al. 1992). In a subsequent study these effects could not be reproduced (Manohar 1994). Differences in the studies may be related to drug dosages, time of administration, amount of diuresis, and degree of cyclooxygenase inhibition. While it is accepted that NSAIDs decrease the diuretic response to furosemide, it is as yet unresolved whether these drugs mitigate furosemide-induced reductions in pulmonary and right atrial pressures. It is also not clear whether the magnitude of reduction of pulmonary capillary transmural pressure with furosemide is sufficient to prevent capillary rupture in exercising horses (Soma and Uboh 1998). This is consistent with clinical observations that furosemide reduces, but does not completely eliminate, pulmonary hemorrhage in exercising horses.

Administration of furosemide to racing animals is thought to enhance their performance, although this conclusion remains somewhat controversial. Use of furosemide in racing Thoroughbreds, Quarter Horses, and Standardbreds is estimated at 74.3, 19, and 22.5%, respectively (Hinchcliff 1999). A recent cross-sectional study concluded that Thoroughbreds receiving furosemide raced faster, earned more money, and were more likely to win or finish in the top three positions than unmedicated horses (Gross et al. 1999). Early studies showed increases in racing times when EIPH was diagnosed and a subsequent improvement of racing times upon administration of furosemide (Soma et al. 1985). Treadmill studies have not consistently shown furosemide-induced changes in maximal O_2 consumption, time to fatigue, or the speed at which fatigue occurred in exercising horses (Hinchcliff et al. 1993). However, in these and later studies, the loss of weight associated with furosemide administration did reduce carbon dioxide production, the respiratory exchange ratio, and plasma lactate. Furosemide-induced gains in performance were reversed by addition of a weight equal to the weight of the volume lost. These results suggest that performance benefits associated with furosemide administration to EIPH horses may be unrelated to reduction in hemorrhage and more related to changes in body weight (Soma and Uboh 1998). Based on human studies, this interpretation should not be extended to circumstances in which the race distance is long and exertion prolonged. In these cases, the detrimental effects of dehydration would rapidly offset the advantage of running under reduced weight.

A final issue related to use of furosemide in racing animals involves the regulation of administration of furosemide and other drugs to equine athletes. Doses of 250–500 mg furosemide per horse (0.5–1.0 mg/kg) administered IV no later than 4 hours prior to post time are permitted for medication of horses with EIPH in most jurisdictions in the United States. Specific regulations at a given track should be consulted. The regulation of furosemide administration according to track rules has been approached in a variety of ways. Some jurisdictions use a combination of urine specific gravity of 1.015 or 1.010 and a plasma concentration of greater than 60 or 100 ng/mL as an indication of a violation of the rules. The combination of these two parameters, low specific gravity and high plasma concentration, will suggest that an irregularity related to dose, time, or route of furosemide administration occurred (Soma and Uboh 1998).

Widespread use of furosemide in racing animals also presents problems related to screening of urine for presence of regulated substances. The urinary concentration of coadministered drugs may be diluted as a function of furosemide-enhanced diuresis. Urinary excretion rates of some drugs, especially those that are water-soluble acids, may be altered as a result of furosemide competition for the organic anion tubular secretion pathway. Furosemide has been shown to decrease the urinary concentration of phenylbutazone through both of these mechanisms. In comparison, the excretion rate of other agents, notably fentanyl, procaine, and methylphenidate, is increased by furosemide. Faster clearance of these substances may make it more difficult to detect illegal use prior to a race (Hinchcliff and Muir 1991).

OTHER USES. Furosemide has been shown to decrease pulmonary resistance and increase dynamic compliance in ponies with chronic obstructive pulmonary disease. In this case, the rapidity of the response and the finding that the response could be blocked by NSAIDs suggested a cyclooxygenase-mediated event rather than an effect dependent upon loss of body fluid (Broadstone et al. 1991). Immediate changes in pulmonary pressures in other species (e.g., dogs with pulmonary edema) are thought to be related to direct effects of furosemide on the pulmonary vasculature. Similar to use in small animals, furosemide is indicated for treatment of CHF and associated pulmonary edema by decreasing cardiac preload and plasma volume. Furosemide is also recommended to increase urine flow in acute renal failure in horses.

INHIBITORS OF NA$^+$-CL$^-$ SYMPORT (THIAZIDE AND THIAZIDE-LIKE DIURETICS)

Chemistry/Formulations. Thiazide diuretics are benzothiadiazines or analogs and are derivatives of CA-inhibiting sulfonamides. Compared to loop diuretics, thiazides promote renal excretion of chloride, rather than bicarbonate, with sodium, producing a true saluretic effect. Two of the first thiazides synthesized, and the two drugs most commonly used in veterinary medicine, are chlorothiazide (Diuril®, human-approved 250 and 500 mg tablets, 50 mg/mL suspension, and 500 mg/vial injectable available) and hydrochlorothiazide (Hydrozide®, veterinary-approved 25 mg/mL injectable; HydroDiuril®, human-approved 25, 50, and 100 mg tablets and 10 mg/mL oral suspension). Both drugs are derivatives of benzothiadiazine and are water soluble. Hydrozide® is the only veterinary-approved product for use in cattle and has a 72-hour milk withholding time for lactating dairy cattle; no meat withholding time has been reported. Newer generation, more lipid-soluble benzothiadiazine derivatives include cyclothiazide and methychlothiazide.

Nonbenzothiadiazine derivatives have thiazide-like effects, and these drugs also promote excretion of sodium with chloride. Quinazolinone derivatives are in this class and include metolazone and chlorthalidone. These drugs are not commonly used in veterinary medicine but are examples of thiazide-like diuretics.

Mechanisms and Sites of Action. The primary site of action of thiazides is the distal convoluted tubule, with some secondary activity, possibly CA-related, in the proximal tubule. In the distal tubule, NaCl reabsorption is mediated by an electroneutral cotransport (symport) system (see Fig. 26.2). The driving force for Cl$^-$ entry is the transmembrane Na$^+$ gradient established by the activity of basolateral Na$^+$,K$^+$-ATPase. The apical NaCl cotransporter is reversibly inhibited by thiazides. Basolateral movement of Cl$^-$ out of the cell is possibly mediated by a KCl cotransport system. The lumen-negative transepithelial potential generated by the polarity of K$^+$ and Cl$^-$ exit may drive anion reabsorption via a paracellular shunt pathway. Ca$^+$ reabsorption is enhanced by thiazides, perhaps by increasing distal tubule Ca^{2+}-binding proteins. Because 90% of filtered Na$^+$ is reabsorbed prior to the distal tubule, the peak diuresis caused by thiazides is moderate compared to loop diuretics. Like loop diuretics, thiazides enhance excretion of K$^+$ by increasing the delivery of Na$^+$ to the distal tubule.

Absorption and Elimination. Thiazide and thiazide-like diuretics are absorbed slowly and incompletely from the gastrointestinal tract. Most drugs in this class are highly protein bound and are excreted renally (chlorothiazide and hydrochlorothiazide) or by a combination of renal and biliary routes (thiazide-like drugs). Hydrochlorothiazide is less protein bound (40%) than others in the class and partitions and accumulates in red blood cells (Velazquez et al. 1995). All drugs in this class gain access to the lumen of the renal tubule via an organic acid secretory pathway. Hence effectiveness of these drugs is decreased if renal blood flow diminishes.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions. Similar to loop diuretics, most problems associated with administration of thiazides are related to fluid and electrolyte disturbances. Potassium wasting, especially with concurrent use of digitalis, increases the risk of cardiac arrhythmias. Low K$^+$ may secondarily affect conversion of proinsulin to insulin, leading to hyperglycemia. Enhanced calcium reabsorption can lead to hypercalcemia, and mild magnesuria may cause magnesium deficiency. Depletion of extracellular volume, hyponatremia, hypochloremia, and hypochloremic metabolic alkalosis may occur as adverse effects with prolonged or aggressive thiazide use. Because thiazides block solute reabsorption at nephron sites involved in dilution of urine, these agents increase the risk of hyponatremia under conditions of increased consumption of hypotonic fluids. CNS and gastrointestinal effects may occur but are not common.

Sensitivity to sulfonamides limits use of thiazide diuretics because of the structural similarity between these two classes of drugs. Patients with severe renal disease, hypovolemia, or electrolyte disturbances are poor candidates for thiazide therapy. Impaired hepatic function that may be worsened by volume contraction (leading to hepatic encephalopathy) is a contraindication for thiazide use. Diabetic patients are at risk for thiazide-induced derangements of glucose and insulin.

Drug interactions include decreased effects of anticoagulants and insulin and increased effects of some anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. Combination therapy using low-dose thiazides with front-line antihypertensives (e.g., ACE inhibitors) is currently considered to be an effective alternative strategy for management of human hypertension (Neutel et al. 1996). At low doses, side effects of thiazides are decreased, making their use in combination regimens particularly appealing.

Thiazides are reported to prolong the half-life of quinidine. In the face of thiazide-induced hypokalemia, an elevated plasma quinidine level increases the risk of polymorphic ventricular tachycardia (*torsades de pointes*), a condition that can deteriorate into ventricular fibrillation (Jackson 1996). NSAIDs may reduce the effectiveness of thiazides and loop diuretics by increasing solute reabsorption at the TAL of the loop of Henle (Brater 1998).

Therapeutic Uses. Thiazides may be used to treat edema of cardiac, hepatic, or renal origin. Typical oral dosages in the dog and cat are 20–40 mg/kg every 12 hours (chlorothiazide) and 2–4 mg/kg every 12 hours (hydrochlorothiazide). Effects of both chlorothiazide and hydrochlorothiazide peak at 4 hours and last up to 12 hours, with hydrochlorothiazide typically having a longer duration (12 hr) than chlorothiazide (6–12 hr). Cattle may be treated for udder edema with hydrochlorothiazide (125–250 mg IV or IM once or twice daily). Oral chlorothiazide (not a veterinary-approved product) at a dose of 4–8 mg/kg once or twice daily has been substituted for injectable hydrochlorothiazide following the first or second day of parenteral treatment.

Thiazides have previously been used in veterinary medicine in management of the early stages of CHF. As mentioned previously, early use of loop and thiazide diuretics in CHF activates aldosterone-mediated mechanisms that eventually lead to cardiac deterioration. For this and other reasons, the use of thiazides in treatment of CHF is not common in veterinary medicine. In general, furosemide is more commonly used in veterinary medicine to treat edema, whether it be cardiac, hepatic, or renal in origin. In human medicine, thiazides are commonly used in the management of hypertension. Because thiazides increase reabsorption of calcium, they may also be beneficial in treatment of calcium nephrolithiasis in humans and animals.

Thiazides are used effectively to reduce the volume of urine in patients with nephrogenic diabetes insipidus. Diuretic-induced volume contraction leads to increased proximal tubule reabsorption and a decrease in urine volume of 30–50%. Although dosages are individualized in these patients, starting ranges of 10–20 mg/kg twice daily (chlorothiazide) or 2.75–5.5 mg/kg (hydrochlorothiazide) twice daily have been suggested (Nichols and Thompson 1995).

INHIBITORS OF RENAL EPITHELIAL SODIUM CHANNELS (K^+-SPARING DIURETICS)

Chemistry/Formulations. The two relevant drugs in this class, triamterene (Dyrenium®) and amiloride (Midamor®), both belong to the class of cyclic amidine diuretics. Triamterene is a pteridine ring with amino groups at the 2, 4, and 7 positions. It was originally synthesized as a folic acid antagonist. Amiloride consists of a substituted pyrazine ring with a carbonylguanidinium side chain. A number of analogs of this basic structure have been synthesized and have been useful tools in elucidating mechanisms of sodium transport. Both triamterene and amiloride are organic bases and are secreted into the proximal tubule by an organic base transport system. Although neither of these drugs is used with frequency in veterinary medicine, triamterene is the more commonly used and hence will be the focus of these discussions. No parenteral forms of the drug are available; oral preparations are available in 50 and 100 mg capsules.

Mechanisms and Sites of Action. Triamterene and amiloride cause a mild increase in excretion of NaCl and a retention of K^+. Both drugs slightly augment diuresis and are used in combination with loop diuretics or thiazides to decrease K^+ excretion (hence the term *K^+-sparing*). Both drugs act at the late distal tubule (or connecting tubule) and collecting duct to block the electrogenic transport of Na^+ (see Fig. 26.2). As with other diuretics, the basolateral Na^+,K^+-ATPase creates an electrochemical gradient that drives events at the luminal surface of the tubular cell. In this case, the principal cells of the connecting tubule contain a Na^+ channel in their luminal membrane that provides a pathway for entry of Na^+ and sets up a lumen-negative transepithelial potential. The transepithelial voltage is the key force involved in driving K^+ out of the principal cell and into the tubular lumen. Blockade of Na^+ channels by triamterene or amiloride hyperpolarizes the luminal membrane, reduces the lumen–negative potential difference, and decreases the excretion of K^+, H^+, Ca^{2+}, and Mg^{2+}. It has been speculated that effects of both of these drugs may also be mediated by inhibition of a Na^+-H^+ antiport located in the late distal tubule and collecting duct. Additional, direct effects on Mg^{2+} excretion may also occur.

Triamterene has been shown to exert cardiac effects that are not secondary to alterations in renal function. Early studies documented a prolongation of the cardiac action potential duration and functional refractory period and an increase in myocardial contractile force. Triamterene has also been shown to decrease digitalis-induced K^+ loss from the heart and increase the dose of digitalis necessary to induce toxic effects in dogs (Palmer and Kleyman 1995; Netzer et al. 1995). Neither triamterene nor amiloride has been shown to affect renal hemodynamics, and neither acts as an aldosterone antagonist.

Absorption and Elimination. Both amiloride and triamterene are administered orally; triamterene is up to 70% bioavailable. Amiloride is renally excreted. The pharmacokinetics of triamterene are complex. The parent drug is converted in the liver to an active metabolite, 4-hydroxytriamterene sulfate, which is actively secreted into the renal tubules. Hence renal or hepatic disease could impair elimination of triamterene. The peak onset of action of triamterene is 6–8 hours, with effects persisting up to 12–16 hours.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions. The most important potential side effect of these drugs is hyperkalemia. The presence of diseases or circumstances that may increase the risk of hyperkalemia (e.g., renal failure, coadministration of other drugs with K^+-sparing properties, including ACE inhibitors and K^+ supplements) should be noted and these patients treated with other diuretic combinations.

Triamterene may decrease GFR and, in combination with NSAIDs, has been shown to increase the likelihood of hyperkalemia and renal dysfunction. Triamterene-induced renal casts may be responsible for increased risk of interstitial nephritis and renal stones. Both triamterene and amiloride may induce hypersensitivity reactions that include rash and photosensitivity in humans. CNS, gastrointestinal, and hematological side effects have also been reported. As with most other diuretics, use in patients with severe hepatic disease or renal disease is contraindicated. In human patients with hepatic disease, the mild folic acid antagonism inherent in triamterene may increase the risk of megaloblastosis.

Therapeutic Use. Because these drugs have relatively weak diuretic properties, they are clinically important primarily because of their K^+-sparing properties in combination with loop and thiazide diuretics. Both have been used in this capacity for treatment of edema associated with CHF, liver cirrhosis, nephrotic syndrome, steroid-induced edema, and idiopathic edema. Triamterene is administered at a dose of 2–4 mg/kg/day orally to dogs with food to avoid gastrointestinal side effects.

ANTAGONISTS OF MINERALOCORTICOID RECEPTORS (ALDOSTERONE ANTAGONISTS AND K^+-SPARING DIURETICS)

Chemistry/Formulations. Spironolactone is a 17-spirolactone and is the only aldosterone antagonist approved in the United States. Canrenone, an active metabolite of spironolactone, and potassium canrenoate are closely related structurally and are available in other countries. All of these drugs share a four-ring, steroid structure similar to the mineralocorticoid aldosterone. Spironolactone is available as a human-approved oral preparation (Aldactone®) in 25, 50, and 100 mg tablets.

Mechanisms and Sites of Action. Aldosterone is a steroid hormone that binds to mineralocorticoid receptors (MRs) located in the cytoplasm of target cells. The inactive MR complex is bound to heat shock protein 90 (HSP90), a protective chaperon protein, and is incapable of binding to target DNA sequences. Upon binding of aldosterone, HSP90 dissociates from the receptor-hormone complex, allowing movement of the activated receptor into the nucleus. The complex binds to target sequences of DNA referred to as mineralocorticoid-response elements (also termed hormone-responsive elements) that regulate transcription of downstream, mineralocorticoid-responsive genes. Protein products of these responsive genes, aldosterone-induced proteins (AIPs), cause Na^+ reabsorption and increase excretion of K^+ and H^+ in the late distal tubule and collecting duct. AIPs are thought to have multiple effects, including activation, redistribution, and de novo synthesis of Na^+ channels and Na^+,K^+-ATPase, changes in permeability of tight junctions, and increased mitochondrial production of ATP. These effects combine to cause an increase in Na^+ conductance of the luminal membrane and increased Na^+ pump activity in the basolateral membrane. As a result, NaCl transport is increased across tubular epithelial cells, and the lumen-negative transepithelial voltage is increased. Secretion of K^+ and H^+ into the tubular lumen increases with increasing voltages.

Aldosterone antagonists act by binding to the MR and facilitating the release of HSP90 from the steroid-binding subunit of the receptor. The unprotected MR complex is thought to be inactivated by proteases. In the absence of activated MRs, gene transcription is not induced, AIPs are not produced, and the physiological effects of aldosterone are blocked.

In addition to antagonism of aldosterone, spironolactone is thought to act in a manner similar to calcium channel blockers to cause direct vasodilation. By binding to plasma membrane sites, spironolactone may inhibit inward slow calcium channels and depress contractions dependent on release of calcium from the sarcoplasmic reticulum. Aldosterone antagonists have also been shown to increase circulating levels of atrial natriuretic peptide as evaluated in the dog. Hence direct and aldosterone-mediated effects of the drug may contribute to its usefulness in treatment of cardiac disease (Endou and Hosoyamada 1995).

Absorption and Elimination. In humans, spironolactone is absorbed moderately well (60–90%), is highly protein-bound, and is extensively biotransformed in the liver, exhibiting a first-pass effect. An active metabolite, canrenone, has a longer half-life than the parent drug and extends the biological effects of spironolactone to about 16 hours in humans. Peak diuresis occurs as late as 2–3 days after initiation of therapy. Aldosterone antagonists do not require secretion into the renal tubule to induce diuresis.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions. Hyperkalemia, dehydration, and hyponatremia are the most common side effects of aldosterone antagonists. When used alone, these drugs can also cause hyperchloremic metabolic acidosis. In humans, sexual side effects limit the use of spironolactone in some patients. The most likely explanation for these effects relates to the binding of drug not only to renal aldosterone receptors but also to progesterone and dihydrotestosterone receptors. This lack of receptor specificity drives continued efforts to identify a more MR-specific antagonist for use in human medicine.

As previously noted, combination of any K^+-sparing diuretic with ACE inhibitors must be accomplished cautiously to avoid hyperkalemia. This is a clinically significant scenario that merits patient monitoring of plasma K^+ concentrations. Because both spironolactone and digoxin have steroid-like structures, the former is thought to compete with digoxin for renal clearance, thus prolonging the half-life of digoxin (Hedman et al. 1992). The presence of spironolactone in plasma may also confound therapeutic drug monitoring of digoxin if a cross-reactive antidigoxin antibody is used in the assay. Aspirin apparently blocks spironolactone-induced natriuresis (Endou and Hosoyamada 1995).

Therapeutic Uses. The effectiveness of aldosterone antagonists in promoting diuresis is largely dependent upon elevated concentrations of endogenous aldosterone. Aldosterone secretion increases upon activation of the renin-angiotensin-aldosterone system, which, in turn, responds to reductions in serum sodium, effective blood volume, and cardiac output, and decreases in serum K^+. Secondary hyperaldosteronism and edema are associated with cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites. Spironolactone is used in veterinary medicine at a dose of 2–4 mg/kg/day orally in management of refractory edema associated with these conditions and is considered the diuretic of choice in management of hepatic cirrhosis. In both human and veterinary medicine, aldosterone antagonists are commonly administered with a thiazide or loop diuretic to increase peak diuresis and to spare K^+.

Elevated aldosterone levels have been shown to be a useful prognostic indicator in heart failure, with higher levels correlated with a poorer prognosis. Activation of the renin-angiotensin-aldosterone system in arterial hypertension is thought to lead to remodeling of the myocardial collagen network with progressive cardiac interstitial fibrosis. As fibrosis increases, diastolic function deteriorates and pathologic cardiac hypertrophy occurs. When aldosterone-mediated effects are blocked by spironolactone, progression of myocardial failure is presumably slowed. A clinical study recently supported this contention by showing significant delays in progression of CHF in human patients treated with spironolactone (Pitt et al. 1999). Despite the potential side effect of hyperkalemia associated with coadministration of spironolactone and ACE inhibitors, this combination with appropriate dosages has been deemed effective in management of CHF. Patient monitoring for K^+ derangements is critical to safe implementation of this approach. In veterinary medicine, spironolactone may be useful in patients with CHF secondary to chronic valvular heart disease or dilated cardiomyopathy that become unresponsive to therapy with ACE inhibitors, digoxin, and furosemide.

AQUARETICS. Vasopressin (or arginine vasopressin, AVP) regulates water and solute excretion in the kidney by binding to V_2 receptors in the principal cells of the renal collecting duct system. As one of three G-protein-coupled AVP receptor subtypes (V_{1a}, V_{1b}, V_2), V_2 receptors mediate the antidiuretic effects of AVP. V_2 receptor antagonists, so-called aquaretic agents, promote solute-free water excretion. These antagonists hold considerable promise for treatment of edematous states associated with heart failure, liver cirrhosis, nephrotic syndrome, and syndrome of inappropriate secretion of antidiuretic hormone. An orally active, nonpeptide, selective V_2 receptor antagonist, OPC-31260, has been shown to induce aquaresis in humans and is currently in clinical development in Japan. This drug has been shown to significantly increase urine volume and decrease urine osmolality and body weight without affecting urinary sodium excretion (Orita and Nakahama 1998). Another promising V_2 antagonist, SR 121463A, has been shown to be highly selective for V_2 receptors and effective at induction of aquaresis in several species. Like OPC-31260, urinary electrolytes are unaltered by drug administration (Serradeil-Le Gal 1998).

Although vasopressin antagonists represent the most promising area of drug development for induction of aquaresis, drugs that interfere with secretion of AVP from the neurohypophysis and drugs that directly inhibit water channels in the collecting ducts are also of interest. Aquaporin-CD, the water channel of the principal cell of the cortical and medullary collecting duct, has been cloned and provides an attractive site for drugs intended to inhibit diuresis.

Blood can be considered a bodily organ comprising several different cell types suspended in a fluid medium, or plasma. Blood volume is typically about 8% of body weight; approximately 40% of this consists of cellular elements (erythrocytes, leukocytes, and thrombocytes), and about 60% consists of plasma. More than 99% of the blood cells are erythrocytes, and their principal function is to transport hemoglobin, which in turn carries oxygen from the lungs to the tissues. Erythrocytes have other activities besides transport of hemoglobin-bound oxygen, including carbon dioxide transport from tissues to the lungs for excretion and buffering of acids produced in the normal course of cellular respiration. Although small in number relative to erythrocytes, leukocytes play an indispensable role in the processing of antigens, defense against microorganisms, reparation of wounds, and propagation of the inflammatory response. Likewise, thrombocytes are participants in many inflammatory and reparative processes and are absolutely essential for normal coagulation of blood. However, inadequate tissue oxygenation is the principal pathophysiologic event and is caused by the selective depletion of circulating erythrocyte numbers, i.e., anemia.

The clinical effects of anemia depend upon the severity of reduction in erythrocyte numbers, the time over which this depletion has occurred, and whether this loss is accompanied by a comparable loss of plasma, which affects circulating blood volume. Acute depletion of 25–40% of blood volume can lead to hypovolemic shock. The loss of large numbers of erythrocytes is better tolerated when the loss is of sufficient duration to allow compensatory physiologic adaptations. Thus, depletion of erythrocyte numbers can result in acute illness and death or chronic debilitating illness characterized by unthriftiness and poor performance. Antianemic agents, also referred to as hematinic or hematopoietic drugs, are potentially useful adjuncts to the therapeutic management of such patients if drug selection is based on timely identification of specific causative factors. Certain hematinic drugs may be used nonspecifically to support erythropoiesis irrespective of etiology, whereas other agents are specifically for particular causes of anemia. It is, therefore, important to understand the process of erythropoiesis and affiliated laboratory indices employed in the classification of erythrocyte disorders.

ERYTHROPOIESIS

Erythrocyte Kinetics. The total mass of circulating erythrocytes (the erythron) is regulated in the normal animal within very narrow limits so that sufficient amounts of hemoglobin are available to provide adequate oxygenation of tissues, but without erythrocytes becoming so concentrated in plasma that they impede the flow of blood through small vessels. A small percentage of the erythron is renewed on a continual basis, as senescent erythrocytes are removed from the circulation and new erythrocytes are released from hematopoietic organs as replacements (Jain 1986). The principal site for erythropoiesis in healthy, adult animals is the bone marrow, whereas "extramedullary hematopoiesis" may also occur in the spleen and liver in utero, in neonates, and in anemic adults when the bone marrow regenerative response is inadequate. The "preprogrammed" demise of older erythrocytes is determined largely by their inability to undergo self-repair, wherein certain cellular enzymes gradually lose activity, with subsequent deterioration of cellular metabolic properties (Table 27.1). In mammalian erythrocytes, new enzymes can no longer be produced, owing to lack of the nucleus and ribosomes required for protein synthesis. In avian and reptilian species, which have nucleated mature erythrocytes, the life span of red blood cells can reach 600–1400 days (Lee et al. 1999). Shortening of erythrocyte life span may occur when extracellular events accelerate oxidation of the cell membrane or denaturation of intracellular proteins, principally hemoglobin (Harvey 1997). Conversely, the activity of intracellular reparative pathways that normally defend against such damage may also be altered by specific nutrients or toxicants. The principal mechanisms of erythrocyte destruction include fragmentation, osmotic lysis, erythrophagocytosis, complement-induced cytolysis, and hemoglobin denaturation (Lee et al. 1999). The principal sites of erythrocyte destruction are extravascular and depend on the actions of the mononuclear phagocyte system (formerly called the reticuloendothelial system), which is located predominantly in the spleen and liver. No more than about 10% of the normal destruction of effete erythrocytes occurs intravascularly, but this can increase significantly in certain pathologic states.

TABLE 27.1—Erythrocyte life span in adults of various mammalian species

Species	Mean life span (days)
Human	117–127
Cattle	157–162
Dog	119–122
Cat	86–106
Goat	160–165
Horse	140–150
Pig	62–71
Sheep	70–153

Erythroid Bone Marrow. Erythropoiesis is a function of rapidly dividing precursor cells located in the hematopoietic tissues. It can be characterized by a model wherein pluripotent stem cells serially give rise to lineage-restricted stem cells, which in turn divide and change into morphologically recognizable erythroid precursor cells (Beutler et al. 2000; Weiser 1995) (Fig. 27.1). Characteristic changes in cell size, morphology, antigenic markers, humoral responsiveness, and function occur through predictable stages of cell proliferation and differentiation, until relatively mature erythrocytes are released into the circulation. The rate and integrity of erythropoiesis can be evaluated in most animals by the enumeration and morphologic evaluation of erythroid precursors in the bone marrow. Erythropoiesis is also reflected in the appearance of erythrocytes newly released into the circulation. These cells are characterized in most species (Equidae are notable exceptions) by cytosolic remnants of ribosomal ribonucleic acid and can be estimated by enumeration of specially stained peripheral blood "reticulocyte" counts (Jain 1986). Likewise, they are typically somewhat larger than more mature cells and may also be identified by various methods to determine their greater

(Modified from Beutler 2000 and Weiser 1995.)

cell volume or their effect on mean corpuscular volume of the total erythrocyte population (Radin et al. 1986).

Tissue Oxygenation as a Stimulus. The rate of erythrocyte production is typically increased by conditions that decrease the quantity of oxygen delivered to tissues (Lee et al. 1999). When an animal becomes anemic or hypoxemic, the bone marrow is stimulated to accelerate production of large numbers of erythrocytes for release into the circulation. Chronic pathologic states that result in diminished blood flow through peripheral tissues, and especially those conditions that interfere with oxygen uptake by the blood as it passes through the pulmonary circulation, also cause an acceleration of erythropoiesis. Heart failure and lung diseases, in particular, result in cellular hypoxia, which can trigger increased production of erythrocytes. These examples represent compensatory adjustments by the erythropoietic system to improve the capability of blood to provide adequate delivery of oxygen to the tissues. This increase in erythrocyte production is initiated quite rapidly in response to inadequate tissue oxygenation but only becomes apparent after approximately 48 hours (Weiser 1995). After 3–5 additional days, the rate of erythropoiesis is maximized and may become as much as 8–10 times normal. Erythrocytes continue to be released at an accelerated rate as long as the animal is subjected to the pathophysiologic condition that initially reduced oxygen delivery. Thus, the erythrocyte mass would have to increase to levels sufficient to compensate for a reduction in their numbers or hemoglobin content. Alternatively, the oxygen content of blood and its release in peripheral tissues would have to increase to levels sufficient to compensate for a reduction in inspired oxygen tension, a decrease in oxygen uptake by blood in the pulmonary circulation, or impairment of oxygen delivery by hemoglobin to the peripheral tissues. Upon resolution of the abnormality, transport of oxygen to the tissues will normalize, and the stimulus for increased erythrocyte production is thereby lost. Consequently, erythropoiesis decelerates, and control of the number of circulating erythrocytes is returned to the usual servomechanism for replacing senescent cells.

Erythropoietin. Inadequate oxygenation of the erythropoietic centers of the bone marrow is not a *direct* stimulus for increased erythrocyte production; i.e., the bone marrow does not detect or respond directly to hypoxia itself. Instead, hypoxia promotes release into the circulation of a humoral factor synthesized and secreted predominantly by the kidneys, and it is this factor (erythropoietin) that subsequently stimulates proliferation and differentiation of erythroid precursors in hematopoietic tissues (Erslev and Besarab 1997; Sawyer 1994). Hypoxia increases expression of erythropoietin (EPO) mRNA in interstitial cortical cells located near the base of the renal proximal tubular cells (Fig. 27.2). Hepatocytes, macrophages, and even some erythroid precursor cells may also be capable of

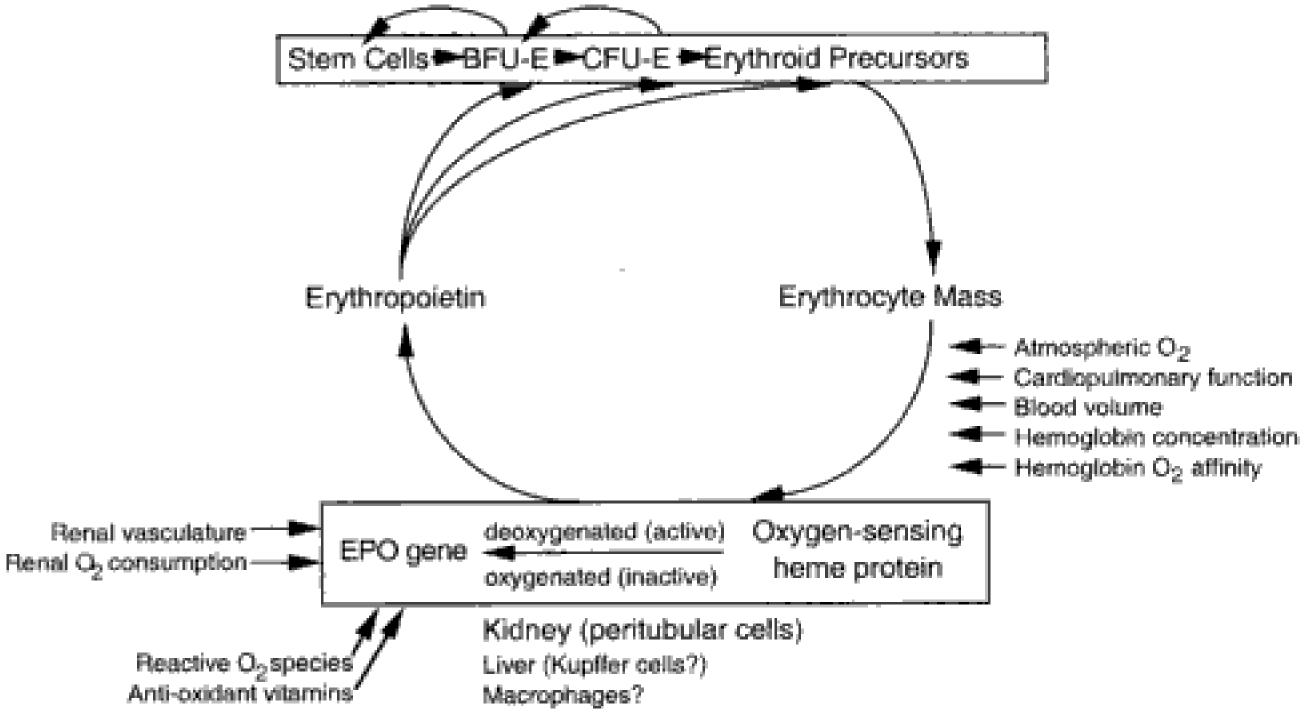

FIG. 27.2—Model of feedback loop controlling erythropoietin production. BFU-E = burst-forming units—erythroid), CFU-E = colony-forming units—erythroid, EPO = erythropoietin. (Modified from Beutler 2000.)

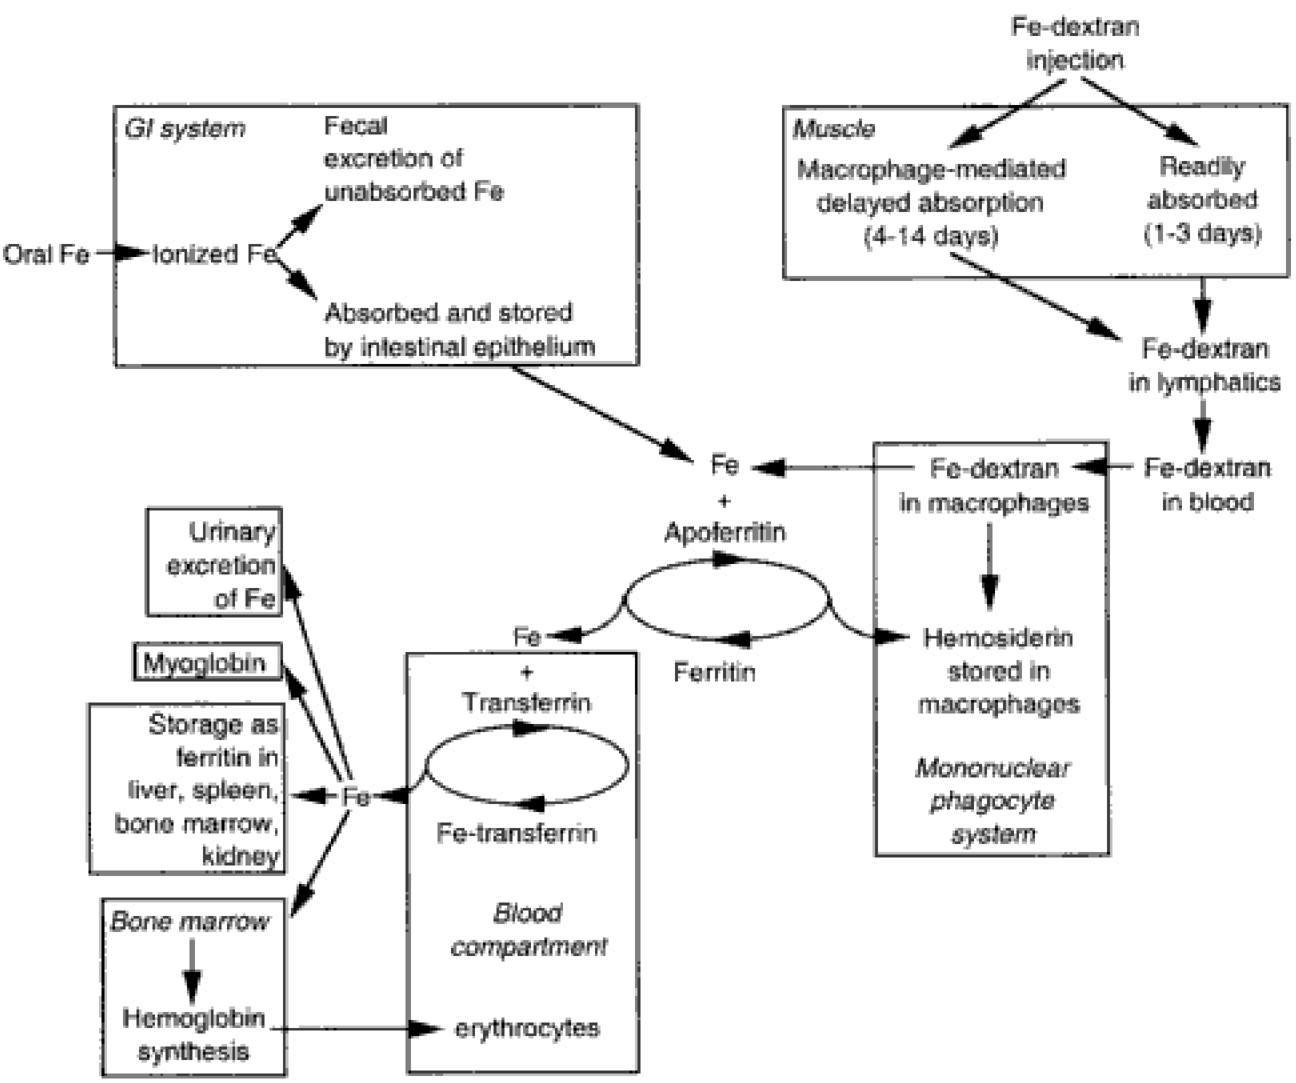
producing small amounts of EPO. Although oxygenation is the key effector in EPO synthesis, various agonists (such as androgens, interleukin-4, and insulin-derived growth factors) and antagonists (such as tumor necrosis factor-α, interleukin-1, and transforming growth factor-β) also influence its production (Erslev and Besarab 1997; Sawyer 1994; Jelkmann et al. 1994). Experimental findings, including the inhibition of EPO production at low partial pressures of oxygen by carbon monoxide, provide evidence that a heme protein is intimately involved in the oxygen-sensing mechanism (Goldberg et al. 1988). During hypoxia, this heme protein is in its active deoxy conformation, which through binding to specific ligands triggers expression of the EPO gene. When oxygen tension is sufficiently high, the heme protein sensor is converted to its inactive, oxygenated form and no longer stimulates EPO production. Potential therapeutic implications of this mechanism will be discussed later.

EPO appears to exert its trophic effects principally during the progenitor cell stages of erythropoiesis (Erslev and Besarab 1997; Sawyer 1994). Mitogenesis and differentiation of both the pluripotential and unipotential burst-forming units—erythroid and colony-forming units—erythroid cells are stimulated by EPO, in conjunction with other humoral factors, including granulocyte–macrophage–colony-stimulating factor, interleukin-3, interleukin-4, stem cell factor, insulin, and insulin-like growth factor-1 (DeMartino et al. 1994; Kelley et al. 1993; Kurtz et al. 1983). EPO may also play a supporting role in promoting the differentiation and viability of maturing erythroid cells, including induction of globin mRNA transcription and suppression of apoptosis in later erythroid precursors (DeMartino et al. 1994; Sawyer 1994; Silva et al. 1996). Heterogeneity in responsiveness to EPO among early erythroid progenitors and later erythroid precursor cells appears to be related to differences in target cell EPO receptor numbers, affinity for EPO, and/or structure-function interactions with second messengers (Kelley et al. 1994). A dose-response relationship between the concentration of EPO and the inhibition of apoptosis in erythroid precursors has been linked to selective expression of a full length or a truncated form of the EPO receptor in target cells (Nakamura et al. 1992).

Erythrocyte production may be inadequate despite maximal stimulation by EPO. This may occur if release of other erythropoietic humoral factors is insufficient to support normal erythropoiesis, as may be the case in diseases characterized by microenvironmental changes in the bone marrow due to inflammation or neoplasia (Fuchs et al. 1994). Likewise, a hormonal milieu conducive to erythropoiesis may result in ineffectual erythrocyte production when specific nutrients are lacking (e.g., iron, copper, pyridoxine, vitamin B_{12}, folic acid) or when erythroid precursor cells are prematurely destroyed prior to maturation and release of erythrocytes from the bone marrow (e.g., immune-mediated destruction). In addition to the production of decreased numbers of mature erythrocytes, ineffectual erythropoiesis may be characterized by the appearance of incomplete, immature, or morphologically and functionally abnormal cells in the circulation.



Fe-dextran injection
GI system
Fecal excretion of unabsorbed Fe
Oral Fe
Ionized Fe
Absorbed and stored by intestinal epithelium
Muscle
Macrophage-mediated delayed absorption (4-14 days)
Readily absorbed (1-3 days)
Fe-dextran in lymphatics
Fe + Apoferritin
Fe-dextran in macrophages
Fe-dextran in blood
Urinary excretion of Fe
Myoglobin
Storage as ferritin in liver, spleen, bone marrow, kidney
Fe
Fe + Transferrin
Ferritin
Hemosiderin stored in macrophages
Mononuclear phagocyte system
Fe-transferrin
Bone marrow
Blood compartment
Hemoglobin synthesis

MICRONUTRIENTS REQUIRED FOR ERYTHROPOIESIS

Hemoglobin Synthesis. Hemoglobin synthesis is initiated in the early stages of erythrocyte production, becomes microscopically visible in Wright's stained preparations during the rubricyte (or polychromatophilic normoblast) stage, and continues until the nucleus (in mammals) undergoes pyknotic degeneration in the metarubricyte (or orthochromatic normoblast) stage (Lee et al. 1999). Production of *d*-aminolevulinic acid (ALA) from glycine and succinyl-CoA in the mitochondria is the first, and rate-limiting, step of heme synthesis (Kaneko 1997). This reaction requires pyridoxal phosphate as a cofactor, and a dietary deficiency of vitamin B_6 can result in an anemia morphologically and functionally characteristic of decreased hemoglobin synthesis (see section on iron deficiency anemia below). ALA is transported to the cytosol, where through a series of reactions it is converted into coproporphyrinogen III, which is then transported back into the mitochondria for derivation of protoporphyrin IX. Insertion of ferrous iron into protoporphyrin IX is catalyzed by heme synthetase (ferrochelatase) to produce the heme molecule, which is transferred from the mitochondria to the cytosol for condensation with globin chains to produce hemoglobin. During this process, the iron moiety of heme becomes oxidized to the ferric state, and the ferriheme thus formed is inserted into an α- or β-globin chain. The ferriheme-containing globin chains spontaneously combine to form α-β dimers, two of which combine, in turn, to produce mature hemoglobin tetramers.

The Iron Cycle. Iron is required not only for the formation of hemoglobin but also for myoglobin and ferroenzymes such as the cytochromes, cytochrome oxidases, catalase, and others. Because of the essential participation of iron-containing substances in normal cellular functions throughout the body, it is not surprising that iron is conserved and recycled in a highly efficient manner (Fig. 27.3) (Smith 1997). Approximately two-thirds of total body iron is contained in hemoglobin, which is distributed throughout the erythron in circulating cells and in immature erythrocytes in the hematopoietic tissues. When aged erythrocytes are removed from the circulation, their hemoglobin is rapidly metabolized by cells of the mononuclear phagocyte system. Most of the iron released from this process is recirculated and made available to newly forming erythrocytes within the bone marrow. Thus, little iron is wasted, and only a small portion of dietary iron need normally be absorbed on a daily basis to maintain adequate body stores and normal synthesis of hemoglobin for erythropoiesis. The amount of iron assimilated daily by normal animals, usually only a few milligrams or less, balances the small amount of iron normally lost from the body in hair, nails, and desquamation of cells.

The small intestine proximal to the midjejunum is the principal absorptive and excretory organ for iron. Absorption of iron across the intestinal mucosa is the rate-limiting step in controlling body stores of this element. Iron is absorbed in the ferrous (reduced) state through the intestinal epithelial cells in a process regulated by enterocyte mitochondrial activity and cytosolic iron-chelating proteins such as transferrin and apoferritin. Small quantities of excess iron are stored in the intestinal epithelial cells after oxidation to the ferric form and combination with apoferritin to form ferritin. This iron may subsequently be excreted from the body when the ferritin-containing enterocytes are shed from their villous tips into the intestinal lumen. The circulating form of iron, bound to transferrin, is transported throughout the body and utilized by the bone marrow in the synthesis of hemoglobin. Iron can also be placed in storage as ferritin in most cells of the body, especially the hepatocytes. Excess iron may form intracellular aggregates with proteins and polysaccharides to form poorly soluble complexes of hemosiderin. When body iron stores are increased, circulating levels of ferritin are increased, blood transferrin becomes saturated, and, in turn, the transfer of iron from intestinal mucosal cells becomes limited. This "mucosal block" of iron absorption is thought to be an important limiting factor that prevents the body from accumulating excess iron under normal conditions. The capacity of the mucosal block mechanism can be exceeded if excessive amounts of iron are ingested, thereby leading to iron toxicosis.

Nutrient Deficiencies Affecting Hemoglobin Synthesis. Intestinal iron absorption can increase up to 15-fold in dogs with chronic blood loss anemia and maximally stimulated erythropoiesis. This no doubt occurs because of a reversal of the mucosal block as binding sites for iron become increasingly available in both the transferrin and apoferritin pools. Dietary iron deficiency is uncommon in adult animals (Fulton et al. 1988) but is routinely observed in neonates that are born with limited iron reserves and that principally consume milk or milk substitutes low in iron content (Fettman et al. 1987; Weiser and Kociba 1983). Iron deficiency in adults is most often associated with chronic blood loss, resulting in a deficit between the rate of iron loss and the rate of dietary iron intake (Weiser and O'Grady 1983). Iron deficiency is manifested initially as a normocytic, hypochromic anemia, owing to impaired hemoglobin synthesis. As iron stores are depleted and hemoglobin synthesis is further handicapped, the anemia typically becomes microcytic and hypochromic. Iron deficiency anemia may also be due to increased removal of erythrocytes from the circulation. Iron deficiency appears to increase erythrocyte fragility, thereby shortening their life span, perhaps due to decreased erythrocytic glutathione peroxidase activity and decreased capacity to prevent oxidative damage to the cell membrane and/or hemoglobin (Weiser and O'Grady 1983).

It is thought that the concentration of hemoglobin in maturing erythroid precursor cells determines the number of cell divisions prior to release from the bone marrow. Thus, impaired hemoglobin synthesis leads to both decreased cell hemoglobin content and additional cell divisions, resulting in smaller mature erythrocytes. Dietary vitamin B_6 deficiency likewise results in a microcytic, hypochromic anemia, owing to impaired hemoglobin synthesis. Ceruloplasmin, the principal copper-binding protein in the body, also functions as a ferrooxidase. In this role, it is responsible for the oxidation of ferrous iron from ferritin to ferric iron for transport in transferrin and subsequent incorporation into heme proteins. A deficiency of copper and of ferrooxidase activity will therefore effectively result in an iron deficiency and also produce a microcytic, hypochromic anemia.

Nutrient Deficiencies Affecting Division of Erythroid Precursor Cells

VITAMIN B_{12}. Cyanocobalamin (vitamin B_{12}) is a cobalt-containing vitamin required by cells throughout the body for conversion of ribose nucleotides into deoxyribose nucleotides, a major step in the formation of deoxyribonucleic acid (DNA). Thus, it is an essential nutrient for nuclear maturation and cell division, and deficiency of this vitamin results in generalized depression of cellular development and tissue growth. Because the erythropoietic centers of the bone marrow are among the most rapidly growing and proliferating tissues, inadequate amounts of cyanocobalamin are especially manifested by decreases in erythrocyte production.

Erythrocytic precursors fail to mature properly under conditions of vitamin B_{12} deficiency, and cell proliferation is inhibited (Lee et al. 1999). Instead of repeated divisions yielding numerous progressively smaller progeny, the more primitive cells of the erythroid series undergo fewer cell divisions, continue to synthesize hemoglobin, and remain larger than normal. The enlarged cells typically retain an immature nucleus and develop malformed and fragile cell membranes. The affected precursor cells are termed "megaloblasts," and the corresponding anucleate mature erythrocytes are termed "macrocytes." The latter contain normal concentrations of hemoglobin and are capable of transporting oxygen after entering the circulation. However, immaturity of both the megaloblasts and the macrocytes results in increased cellular fragility, causing the cells to have a shortened life span. Thus, both decreased rates of erythropoiesis and increased rates of erythrocyte senescence contribute to the development of the macrocytic, normochromic anemia characteristic of a vitamin B_{12} deficiency. This should not be confused with the normo- or hypochromic, macrocytic changes typical of many regenerative anemias, wherein larger and less mature anucleate erythrocytes are released into the circulation (Jain 1986).

A major cause of maturation failure of erythrocytes in humans is a defect in intestinal absorption of vitamin B_{12}, resulting in "pernicious anemia" (Lee et al. 1999). This condition is associated most commonly with failure of the gastric mucosa to produce "intrinsic factor," a glycoprotein substance that combines with dietary vitamin B_{12} to protect it from digestive enzymes and to promote its uptake by pinocytosis into intestinal epithelial cells. Absorbed vitamin is then released into the blood and stored in the liver. The large quantity and long biological half-life of B_{12} in the liver may result in a lag time of many months between insufficient intake of the vitamin and expression of deficiency as a maturation failure in circulating erythrocytes.

Naturally occurring anemia due to vitamin B_{12} deficiency is infrequently recognized in domestic animals. A hereditary defect in intestinal cobalamin absorption has been identified in dogs, but intestinal malabsorption associated with exocrine pancreatic insufficiency or small intestinal bacterial overgrowth is more common (see Chap. 36). Nevertheless, a vitamin B_{12}–responsive macrocytic anemia is rarely observed. Adult ruminants are not dependent on a dietary source of this vitamin because ruminal microflora synthesize all the required supplies of cyanocobalamin. However, a dietary source of cobalt is required by ruminal organisms to synthesize vitamin B_{12}, and cobalt shortage can result in an indirect deficiency of the vitamin. Enteric bacteria of many nonruminant species can also synthesize cyanocobalamin, thereby reducing the need for a dietary source. However, vitamin B_{12} deficiencies may still result from inadequate absorption of the vitamin from the digestive tract.

FOLIC ACID. Pteroylglutamic acid (folic acid), like cyanocobalamin, is an obligate participant in the synthesis of nucleoproteins involved in erythrocyte division and maturation (Lee et al. 1999). Anemias associated with a lack of folic acid are, therefore, also characterized as megaloblastic and macrocytic. Folic acid deficiency anemias are considered rare in most species; however, naturally occurring folate antagonists in moldy feeds can block intestinal microbial synthesis of folacin in herbivores. Folic acid–responsive anemias may occur in animals treated with synthetic folate antagonists for their antineoplastic (methotrexate) or antimicrobial (sulfonamides) activities. Likewise, the anticonvulsants phenytoin and primidone may also have folate-antagonistic activity.

PROTEIN. Protein in adequate amounts is important for a normal rate of hemoglobin synthesis and erythrocyte production. A primary deficiency of protein in the diet, or a secondary deficiency subsequent to intestinal or urinary protein loss, can contribute to the development of anemia. Nevertheless, protein deficiency, by itself, has not been demonstrated as an important cause of anemia in domestic animals, and treatment with protein alone will not correct anemia of any cause. As a supportive measure, protein supplementation may be of benefit to the patient convalescing from anemia, particularly if hypoproteinemia is a concurrent problem.

OTHER NUTRIENTS. Production of normal erythrocytes is influenced directly or indirectly by several nutrients that act as coenzymes or cofactors in the synthesis of hemoglobin, metabolic enzymes, or other important structural and functional proteins. These include riboflavin, niacin, pantothenic acid, thiamin, biotin, and ascorbic acid. Antioxidant vitamins A, E, and C play an important role in protecting erythrocytes against oxidative damage from free radicals, and their deficiency can contribute to shortened erythrocyte survival in the circulation. Recent studies have also shown that vitamin A exerts a specific effect to stimulate EPO production by quenching reactive oxygen species, thereby enhancing the production of a ligand termed "hypoxia-inducible factor-1," which activates an enhancer element in the EPO gene (Jelkmann et al. 1997). It is possible that supplementation with vitamin A or its carotenoid precursors may be useful as adjunctive therapy for the anemia of chronic renal disease, by increasing intrinsic EPO production. Primary deficiencies of most nutrient cofactors are rarely seen in domestic animals; exceptions will be noted in subsequent paragraphs when different types of anemias are considered. Details about vitamins and trace minerals are provided in Section 9.

ANEMIA. Inadequate erythrocyte mass is usually a secondary condition rather than a primary disorder. Anemia is best regarded as an important clinical sign indicative of an underlying pathophysiologic process that must be identified and corrected if hematopoietic therapy is to be successful; e.g., it would be irrational to administer iron to an animal with iron deficiency anemia due to gastrointestinal parasitism if the parasite burden is not also reduced. Knowledge about hematinic drugs should be integrated into a rational approach to management of anemia that depends upon identification and treatment of etiologic factors.

Classification of Anemia. Several classification systems have been used to describe different forms of

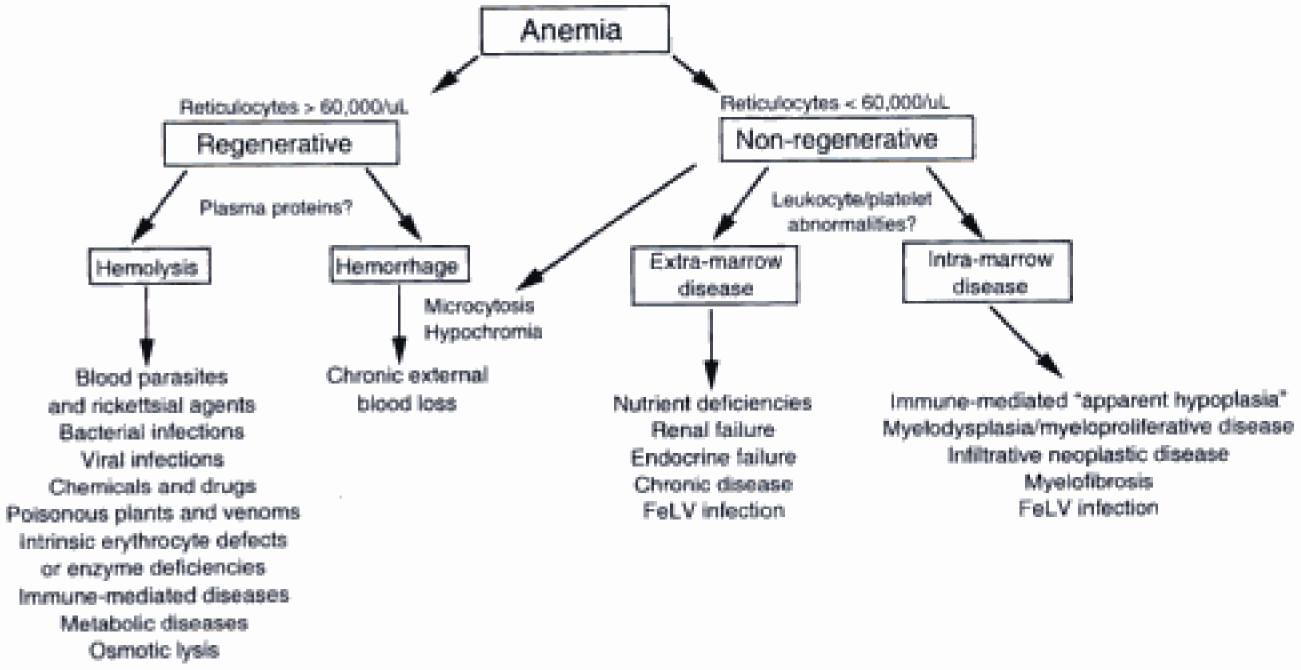

FIG. 27.4—Flowchart of approach to classification of anemia. FeLV = feline leukemia virus.(Modified from Weiser 1995.)

anemia (Fig. 27.4). These systems are based on several variables, including etiology, changes in erythrocyte morphology, and degree of bone marrow regenerative response (Beutler et al. 2000; Weiser 1995). The classification scheme involving the bone marrow regenerative response is necessary to determine the integrity of the erythropoietic response, and observation of changes in morphology is useful in refining the etiologic diagnosis (Table 27.2).

In a regenerative anemia, there is no problem intrinsic to erythrocyte production by hematopoietic tissues. The erythroid marrow responds to inadequate erythrocyte mass by accelerating erythropoiesis, which is reflected in peripheral blood by the appearance of polychromasia in Wright's stained blood films, reticulocytosis >60,000/mL in new methylene blue or brom cresol green stained blood films, and perhaps even the appearance of nucleated erythrocytes (Weiser 1995). Chronic blood loss from the body or increased rates of erythrocyte destruction are the principal causes of regenerative anemias (Fig. 27.4).

In a nonregenerative anemia, the erythropoietic response is insufficient relative to the required rate of replacement of senescent, damaged, or lost erythrocytes. Both extra- and intramarrow diseases can be responsible for the decreased production or maturation abnormalities characteristic of nonregenerative anemias (Fig. 27.4). Peripheral blood demonstrates none of the typical features of accelerated erythropoiesis expected in a regenerative anemia. There is an absence of sufficient polychromasia and a decrease, or negligible increase, in the reticulocyte count (<60,000/mL). Instead, there is a reduction in the circulating numbers of morphologically normal erythrocytes (normocytic, normochromic anemia) or the appearance of morphologically abnormal cells (macrocytic or microcytic anemias), which may have abnormal hemoglobin content (hypochromic anemia) (Table 27.2).

Blood Loss Anemia. Loss of blood from the vascular space, whether to the exterior of the body or to extravascular regions within the tissues, can be acute or chronic. The principal pathophysiologic effect of acute hemorrhage is hypovolemia rather than inadequate erythrocyte mass; e.g., the patient with acute, massive blood loss will more likely die of hemorrhagic shock before an anemia is manifested. If the animal survives acute hemorrhage, and especially if blood loss continues chronically, anemia may occur as erythropoietic capabilities are exceeded. Erythrocyte parameters such as packed-cell volume (PCV) and hemoglobin content can be normal for up to 18 hours after acute blood loss. In fact, the PCV and hemoglobin content may transiently increase following sympathetic activation, splenic contraction, and release of "residual" erythrocytes from the spleen. Hemodilution then occurs as a result of mobilization of extravascular fluids following changes in the balance of capillary hydrostatic pressure and interstitial oncotic pressure. The erythropoietic response is initiated shortly thereafter, owing to detection of hypoxia by the kidney, release of EPO, and stimulation of erythroid stem cell and precursor cell division and differentiation. A maximal erythropoietic response may require approximately 5 days after the hemorrhagic event, and restoration of normal erythrocyte mass can be complete within 7–10 days following a single hemorrhagic episode.

TABLE 27.2—Morphologic and etiologic classifications of anemia

Morphologic classification		
Erythrocyte size	Hemoglobin content	Etiologic classification
Macrocytic	Normochromic	Cobalt or vitamin B_{12} deficiency
		Folic acid deficiency
		FeLV-associated myelodysplasia
		Congenital erythropoietic porphyria
		Infrequent, asymptomatic characteristic of toy and miniature Poodles
Macrocytic	Hypochromic	Transient condition occurring during the active phase of erythroid regeneration following erythrocyte destruction or acute blood loss:
		Hemolysis
		blood parasites and rickettsial agents
		bacterial infections
		viral infections
		chemicals and drugs
		poisonous plants and venoms
		intrinsic erythrocyte defects/enzyme deficiencies
		immune-mediated
		metabolic diseases
		osmotic lysis
		Hemorrhage
		external
		internal
Normocytic	Normochromic	Acute blood loss prior to onset of regenerative response
		Anemia of chronic inflammatory disease
		Myelodysplasia/myeloproliferative disease
		Infiltrative neoplastic disease
		Myelofibrosis
		FeLV-associated myelodysplasia
		Immune-mediated destruction of erythroid progenitor cells resulting in "apparent erythroid hypoplasia"
		Anemia of chronic renal failure
		Anemia of certain endocrinopathies:
		hypoadrenocorticism
		hypothroidism
		panhypopituitarism
		hypoandrogenism
		hyperestrogenism
		Lead poisoning
		Cytotoxic marrow damage
		radiation
		chemicals
		bracken fern poisoning
Normocytic	Hypochromic	Early iron deficiency
Microcytic	Normochromic	Iron deficiency in progression
		Normal, asymptomatic characteristic of Japanese Akitas
Microcytic	Hypochromic	Iron deficiency
		congenital anemia of neonates
		chronic external blood loss
		chronic gastrointestinal blood loss
		infestation with hematophagous parasites
		Copper deficiency
		Pyridoxine deficiency
		Molybdenum toxicity

Source: Modified from Adams 1995 and Jain 1986.

Chronic Hemorrhage and Iron Deficiency Anemia. If blood loss continues, sufficient iron eventually will be lost from the body to produce an iron-depleted state even with continued ingestion of the usual quantities of dietary iron and increased efficiency of iron absorption. Under these conditions, the rate of hemoglobin loss exceeds that of iron absorption, so that the animal experiences a negative iron balance. The shortage of iron may severely impede erythropoiesis, and the typical microcytic, hypochromic anemia develops if blood loss continues. This is the type of iron deficiency anemia most commonly encountered in companion animals, and typically occurs with chronic gastrointestinal blood loss due to parasitism, bleeding ulcers, inflammatory bowel disease, or hemorrhaging tumors.

Hemolytic Anemia. Destruction of erythrocytes occurs in various disease states in domestic animals. Various blood parasites (*Anaplasma, Babesia, Hemobartonella, Eperythrozoon, Cytauxzoon*), rickettsia (*Ehrlichia*), bacteria (*Leptospira, Clostridium*), and viruses (feline leukemia virus, equine infectious anemia) have been associated with hemolytic anemias. A variety of chemical agents (saponins, snake venoms, phenothiazines), trace elements (lead, copper), and toxicants from poisonous plants (red maple, onion) are additional potential extrinsic causes of hemolysis (Harvey 1997). Immune-mediated hemolytic anemia following pharmaceutical administration, vaccination, or blood transfusion or of idiopathic origin has also been observed in all species. This is typically characterized by the observation of spherocytes in peripheral blood films. These cells have normal volume but appear to be smaller and without the usual biconcave disk appearance of healthy erythrocytes (Weiser 1995). Following opsonization by antibody and/or complement, it is thought that portions of the damaged cell membrane are removed by cells of the mononuclear phagocyte system, thereby reducing the ratio of cell surface area to cell volume. Cross-linking of erythrocytes by antibodies can result in microscopic or macroscopic autoagglutination, which may in some cases be temperature sensitive (cold vs. warm "hemagglutinins").

In cattle, hemolytic anemia has been associated with hypophosphatemic, postparturient hemoglobinuria (Harvey 1997). Congenital porphyria in cattle, pigs, cats, and humans resulting from genetically defective hemoglobin metabolism leads to accumulation of abnormal porphyrins in erythrocytic precursors, which results in hemolysis (Kaneko 1997). The human types of hereditary hemolytic anemias such as sickle cell disease and the thalassemias are not well documented in animals. Erythrocytic enzyme deficiencies, including glucose-6-phosphate dehydrogenase, phosphofructokinase, and pyruvate kinase, have been identified in animals with hereditary forms of hemolytic anemia (Harvey 1997).

Intact erythrocytes remaining in the blood may contain normal amounts of hemoglobin during hemolytic anemia. In the case of iron or copper deficiency, predisposition to oxidative hemolysis may be coupled with the traditional findings of hypochromic microcytosis. Erythroid centers of the bone marrow are usually hyperplastic, and iron from destroyed erythrocytes undergoes rapid recycling to support accelerated erythropoiesis. The appearance of immature erythrocytes in the peripheral blood is common, resulting in a regenerative hypo- or normochromic macrocytosis, polychromasia, and reticulocytosis.

Hemolytic anemia with Heinz body formation is characteristic of exposure of erythrocytes to agents that mediate oxidative damage and induce denaturation of hemoglobin (Harvey 1997). These include methylene blue (urinary antiseptic), phenothiazines (tranquilizers), doxorubicin (antineoplastic), propylene glycol (dietary humectant), benzyl alcohol (preservative), and allyl disulfides (phytochemicals). Because of low hepatic conjugative enzyme activities, cats have decreased capacity relative to other mammals to deactivate oxidative toxicants (Fettman 1991). In addition, feline hemoglobin is uniquely susceptible to oxidative damage, leading to a propensity for Heinz body formation in oxidatively damaged feline erythrocytes (Fettman 1991). Christopher (1989) studied the relationships between disease in 120 cats and the occurrence of Heinz bodies. Diabetes mellitus was most commonly associated with Heinz bodies (15.8% of the cases), followed by hyperthyroidism (12.5%), lymphoma (10.8%), and nonhemic cancer (10.8%).

Nonregenerative (Hypoplastic) Anemia. Anemia associated with bone marrow dysfunction may or may not be accompanied by defective production of other cell lines when granulocyte and thrombocyte production is also affected. Hypoplastic anemia occurs rarely as an idiopathic disorder. Potential extramarrow causes include exposure to bone marrow–suppressive chemicals (pesticides, insecticides, antineoplastic agents), endocrine failure affecting cell division and erythropoiesis (EPO, insulin, thyroid hormones), chronic inflammation/infection, feline leukemia virus infection, and nutrient deficiencies as described earlier (Fig. 27.4). Potential intramarrow causes include primary myelodysplastic and myeloproliferative diseases, infiltrative neoplastic diseases, and feline leukemia virus infection. A particular form of "apparent erythroid hypoplasia" has been associated with immune-mediated destruction of erythroid precursor cells (Jonas et al. 1987; Holloway et al. 1990). There may appear to be hyperplasia of early nucleated erythrocytes, but a "maturation arrest" of the erythroid line occurs, owing to phagocytosis and destruction of antibody/complement-fixated precursors. The peripheral blood is devoid of polychromatophilic erythrocytes or reticulocytes, and so the anemia appears to be hypoplastic.

Primary Dietary Iron Deficiency Anemia. Iron-responsive, microcytic, hypochromic anemia is relatively common in neonates of all species (Weiser and Kociba 1983) but is especially important in the swine industry (Hubbard et al. 1952). Pigs are born with limited body stores of iron (and copper), and sow's milk provides only one-seventh the daily requirement of iron for growth (Smith 1997). The incidence and susceptibility of suckling pigs to iron deficiency anemia have increased in parallel with an increase in intensification of modern husbandry techniques aimed at increasing weaning weight. Rapidly growing pigs are the most susceptible. In the past, pigs raised on natural dirt surfaces had free access to considerable amounts of iron in the soil. Pigs ingest only a limited amount of iron from their environment when kept on clean concrete floors. Clinical signs of anemia can develop by 3 weeks of age if preventive therapy with iron is omitted. Approximately 300 mg of iron must be absorbed by the baby pig during the first 3 weeks of life, but only ~21 mg (1 mg/day) is acquired by ingestion of sow's milk, and perhaps only 100 mg may be obtained from the environment during this time period. Thus, pigs raised in this manner are apt to be lacking nearly 200 mg of iron in their first 3 weeks. Supplementation is needed for approximately the first 5 weeks of life, until baby pigs can consume creep feed to provide the required iron.

Anemia of baby pigs is hypochromic and microcytic, typical of iron deficiency. Some pigs may seem fairly well nourished, but problems develop, exhibited in poor growth, listlessness, rough hair coat, wrinkled skin, and drooping ears and tails. The pigs may exhibit dyspnea, fatigue, pale skin, pale mucous membranes, and increased susceptibility to disease. Sudden death is not uncommon, and the mortality rate may be high.

POLYCYTHEMIA. A relative or absolute increase in the concentration of circulating erythrocytes is termed "polycythemia" (Campbell 1990). An increase in erythrocyte numbers is usually associated with a corresponding increase in the hemoglobin concentration of the blood as well. Relative polycythemia, or "erythrocytosis," results from loss of the fluid component of blood, or "hemoconcentration." This is often a transient state secondary to dehydration as a result of prolonged vomiting, persistent diarrhea, polyuria, excessive sweating, or loss by exudation and evaporation from burns and large wounds. Because this loss of fluid may be superimposed upon a deficiency of erythrocytes, it is possible that hemoconcentration may obscure the detection of anemia. If fluid loss is accompanied by protein loss as well, it may not be possible to use hyperproteinemia as an index of hemoconcentration. Thus, evaluation of physical signs of hypovolemia (skin resiliency, capillary refill time, enophthalmos, etc.) is essential in identifying concurrent hemoconcentration and anemia.

Absolute polycythemia is characterized by an increase in the total erythron. It may be transient, due to release of stored cells following sympathetically mediated splenic contraction but is usually associated with hyperplasia of erythropoietic elements of the bone marrow. It can be idiopathic as a primary disorder termed "polycythemia vera," wherein no other diseases may be found, and EPO levels are normal or decreased (Cook and Lothrop 1994; Hasler and Giger 1996). Absolute polycythemia can also result from a physiologically inappropriate increase in erythrogenesis, stimulated by excessive release of erythropoietic humoral factors such as EPO. Tumor-associated polycythemia has been observed with many types of neoplasia in humans, including renal cell carcinoma, hepatoma, pheochromocytoma, and adrenocortical tumors. It has been reported in dogs with carcinoma, fibrosarcoma, or lymphosarcoma of the kidneys (Gorse 1988; Nelson and Hager 1983; Peterson and Zanjani 1981). Physiologically appropriate absolute polycythemia can also develop secondary to diseases associated with chronic hypoxia that stimulate EPO release from the kidneys. Examples include "right-to-left" circulatory shunts, chronic pulmonary disease, or residence at high altitude, causing decreased partial pressure of inspired oxygen.

Clinical signs of polycythemia include plethora (ruddy mucous membranes), central nervous system disorders (seizures, ataxia, lethargy, dementia, blindness), and episodes of bleeding (epistaxis, hematemesis, hematochezia, and hematuria) (Campbell 1990). Many of these signs stem from increased blood viscosity that impedes blood flow, distends small capillaries, and predisposes to thrombosis and rupture of small vessels.

Treatment of secondary polycythemia should be directed at the primary disease and improvement of oxygen delivery to tissues. Likewise, paraneoplastic syndromes of absolute polycythemia may respond to removal of the tumor. Phlebotomy may be indicated for patients whose absolute polycythemia is responsible for clinical signs, before treatment can be directed at the tumor or myeloproliferative disorder responsible for excessive erythropoiesis. Various myelosuppressive drugs have been used to decrease erythropoiesis in patients with idiopathic polycythemia. These include chlorambucil, busulfan, melphalan, hydroxyurea, and radiophosphorus (^{32}P) (Campbell 1990; Peterson and Randolph 1982; Smith and Turrel 1989).

TREATMENT OF ANEMIA

Blood Loss Anemia

ACUTE HEMORRHAGE. The life-threatening problem in animals experiencing a single, acute episode of blood loss is hypovolemia leading to the onset of hemorrhagic shock. Blood volume repletion is the main therapeutic goal in these patients, usually on an emergency basis accompanied by other cardiopulmonary resuscitative procedures. Transfusion of whole blood is not always necessary under these conditions because the remaining endogenous erythrocyte mass generally is sufficient for hemoglobin-oxygen transport if volume repletion is sufficient. A balanced crystalloid solution, comparable in composition to normal extracellular fluid, may be adequate. When the source of hemorrhage has been controlled, additional use of a hypertonic crystalloid solution, such as 7.2% sodium chloride, may be indicated to promote fluid redistribution from extravascular tissues to the vascular compartment, as well as for its positive inotropic effects on the heart (Fettman 1985). If there is significant hypoproteinemia, vascular fluid loss to the extravascular tissues, or insufficient restoration of blood pressure following crystalloid fluid administration, synthetic colloid-containing solutions may be indicated (Rudloff and Kirby 1997). These include 0.9% saline solutions with 6–10% Dextran-40, Dextran-70, pentastarch, or hetastarch, but caution is urged for patients with preexisting dehydration, underlying renal disease, or coagulation abnormalities. Plasma transfusions may also be effective, but they do carry some risk of adverse immunologic reactions or occult infectious disease transmission.

If an acute bleeding episode continues for a lengthy interval (e.g., in a major surgical procedure), erythrocyte mass may become inadequate for oxygen transport despite blood volume maintenance with crystalloid or colloid solutions. At this point, hemoglobin replacement therapy is indicated through whole-blood transfusion, packed red blood cell transfusion, or administration of a cell-free, chemically modified hemoglobin solution. Whole-blood or packed-cell transfusions require ready accessibility to blood type–matched donors and/or the means for processing, storing, and replenishing supplies of fresh blood products (Callan et al. 1996; Harrell et al. 1997a,b; Kerl and Hohenhaus 1993; Wardrop et al. 1997). Transfusion reactions are a significant concern even when cross-match tests have been performed, because antibodies to other blood components or small amounts of antibodies to erythrocytes may not be detected. Because of the complexity and cost of maintaining an acceptable blood transfusion program, cell-free polymerized hemoglobin solutions have recently received increased attention in the human and veterinary medical communities. Only one polymerized, ultrapurified bovine hemoglobin preparation has received FDA approval for veterinary use, but chemically modified hemoglobin solutions that have been studied include polymerized, pyridoxylated, stroma-free human hemoglobin, fumaryl-ββ-cross-linked bovine hemoglobin, and polyethylene glycol-polymerized bovine hemoglobin (Gilroy and Odling-Smee 1990; Migita et al. 1997; Sprung et al. 1995; Ulatowski et al. 1996). These solutions have a colloid osmotic pressure similar to that of whole blood, a *P*50 for oxygen lower than that of whole blood but adequate for efficient oxygen delivery in clinical situations, and an extended shelf life compared to fresh blood products. They have been shown to be more effective than colloid solutions in restoring blood volume, oxygen transport, and cardiovascular performance in experimental models of hemorrhagic shock in rats, cats, dogs, and sheep. There are indications that some cell-free, polymerized hemoglobin solutions may also exert erythropoietic effects on the bone marrow, though the mechanism remains vague.

Chronic Hemorrhage. Successful therapy for chronic blood loss anemia requires the diagnosis and treatment of the inciting ailment as the principal objective. Severe anemia may require transfusion of whole blood or blood products. In addition to general supportive care and adequate nutrition, prolonged therapy with iron or other erythropoietic nutrients may be indicated. Because patients with chronic anemia are principally deficient in erythrocytes, plasma components may not be necessary. However, it is not unusual for anemic animals to be dehydrated as well; this may lead to circulatory shock and seems to be associated with packed-cell volumes of less than 15% in dogs and less than 12% in cats. Blood volume expansion is indicated under these circumstances, for which whole blood or cell-free, polymerized hemoglobin, crystalloid, and/or colloid solutions may be beneficial.

Baby Pig Anemia. Anemia of newborn pigs can be prevented by a variety of methods. Because of the labor involved in repeated oral administrations, a single intramuscular injection of an iron compound (e.g., 100–150 mg elemental iron as iron dextran) on the second or third day of life is often the preferred method of treatment. Within 3 days of iron administration, blood hemoglobin concentrations increase markedly (Fig. 27.5), and recipients respond by ingesting more milk and growing more rapidly than untreated pigs. Because copper deficiency may also participate in the pathogenesis of baby pig anemia, application of iron-copper preparations to the sow's udder has also proven effective in preventing this form of anemia.

Iron dextrans are frequently used iron supplements in newborn pigs; these compounds are absorbed into the lymphatic system within 3 days following intramuscular injection. The process of absorbing and transferring this iron from the injection site into the lymphatic system is achieved predominantly by macrophages. A variable portion of the iron dextran remains in the connective tissue at the injection site as a continuing, but less available, depot of iron. Iron dextran passes rapidly from the lymphatics into the blood and readily enters cells of the mononuclear phagocyte system throughout the body. Separation of the free iron from the polysaccharide occurs in these cells, and the dextran is largely excreted in the urine or metabolized

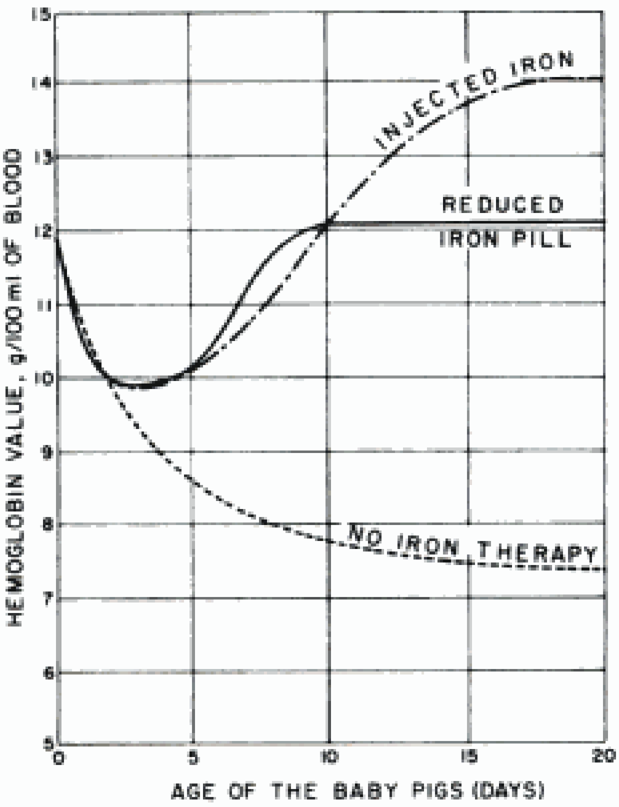

FIG. 27.5—Influence of iron therapy upon the hemoglobin value of newborn pigs. (From Hubbard et al. 1952.)

to glucose. The free iron enters the blood and combines with transferrin for transport throughout the body.

There is no established indication for iron therapy in pigs weighing 20 kg or more. Should anemia occur in older swine, it is more likely associated with an infectious agent or chronic blood loss than with a simple dietary deficiency of iron. Administration of iron preparations to prevent tail biting and other social vices induced by confinement is not indicated and has been associated with discoloration and condemnation of meat at slaughter.

Hemolytic Anemia. This condition is often a direct result of specific chemical, infectious, or antigenic agents that elicit oxidative or immunological damage to erythrocytes. Supportive therapy includes transfusion of whole blood or blood products if tissue oxygenation is sufficiently compromised. Specific treatment should focus on identification and elimination of the etiologic agents (Table 27.2), as discussed in detail elsewhere in this book. Existing oxidative damage to erythrocytes is difficult to reverse, but continued injury may be ameliorated by antioxidants or substances that promote endogenous free-radical-scavenging mechanisms. Intravenous *N*-acetylcysteine has been employed as a glutathione precursor in subduing the actions of oxidative drugs, including acetaminophen, propofol, and doxorubicin (Fettman 1991). Dietary cysteine supplementation has also been used to promote glutathione synthesis, as a preventative against oxidative damage by mycotoxins and plant alkaloids (Fettman 1991). Vitamins with antioxidant properties (A, E, and C) may also be beneficial. Infectious agents should be eliminated by treatment with appropriate antimicrobial agents. Immunologically mediated erythrocyte damage is also difficult to reverse, but continued injury may be prevented by administration of immunosuppressive drugs (corticosteroids, cyclophosphamide, azathioprine). Intravenous administration of human immune globulin has been useful for short-term stabilization of some dogs with immune-mediated hemolytic anemia but does not appear to have affected long-term survival (Scott-Montcrieff et al. 1997).

Nonregenerative (Hypoplastic) Anemia. The nonregenerative form of immune-mediated anemia, characterized by erythroid precursor phagocytosis within the bone marrow and subsequent abrogation of the erythropoietic response, may respond to immunosuppressive drugs or human γ globulin (Scott-Montcrieff et al. 1995). These cases usually are more refractory to treatment and may require immunosuppression of greater intensity and duration than do those with only immune-mediated destruction of mature erythrocytes. Systemic endocrinopathies such as hypothyroidism or hyperestrogenism that result in hypoplastic anemia must be treated by addressing the primary disorder. However, treatment with lithium carbonate (11 mg/kg per os, twice daily) has been associated with improved hematopoiesis in dogs with estrogen-induced bone marrow suppression (Hall 1992).

Anemia of Chronic Renal Disease

GENERAL APPROACH. Loss of endogenous EPO resulting from chronic renal disease culminates in a nonregenerative anemia (Cowgill 1992). In addition, uremia can be associated with reduced erythrocyte survival, platelet dysfunction, gastrointestinal bleeding, uremic inhibitors of erythropoiesis, myelofibrosis, and nutritional deficiencies that contribute to anemia. Therapy directed at slowing the progression of chronic renal failure or ameliorating the adverse consequences of uremia not only improve clinical performance but also promote erythropoiesis. Reducing circulating levels of uremic toxins removes inhibitory influences on bone marrow responsiveness to EPO and other erythropoietic hormones. Modification of the dietary intake of water, protein, essential fatty acids, phosphorus, sodium, water-soluble vitamins, antioxidants, trace minerals (including iron), alkalinizing agents, and other nutrients limits future renal damage and maintains or restores glomerular filtration.

SECONDARY HYPERPARATHYROIDISM. Secondary hyperparathyroidism is a fundamental component of chronic renal failure, and its management is associated with amelioration of further renal damage and improved mineral homeostasis (Polzin and Osborne 1995; Cowgill 1995). In addition, it has been proposed that increased parathyroid hormone (PTH) concentrations mediate several uremic changes, including suppression of EPO release and bone marrow responsiveness. Although serum PTH levels correlate poorly with the degree of uremia in dogs with chronic renal failure, most anemic patients have significantly higher PTH values than do nonanemic animals (King et al. 1992). Dietary phosphorus restriction and/or calcitriol supplementation have both been demonstrated to alleviate renal secondary hyperparathyroidism, and calcitriol has been shown to improve anemia and reduce the need for erythropoietin in human dialysis patients (Goicoechea et al. 1998).

IRON DEFICIENCY. Because gastrointestinal hemorrhage is a frequent complication of uremia, histamine H_2-receptor antagonists (cimetidine, ranitidine) and mucosal protectants (sucralfate) should be considered for the prevention and treatment of gastric ulceration associated with blood loss (Polzin and Osborne 1995; Cowgill 1995). Because this can result in iron deficiency, it is essential that renal disease patients be evaluated for iron status prior to institution of other pharmacotherapies for anemia. Treatment with iron supplements is the same as described for other causes of iron deficiency anemia below.

ANABOLIC STEROIDS. Treatment with exogenous erythropoietic hormones such as androgenic steroids is used to support the erythron in chronic renal disease patients (Shahidi 1973). However, evidence supporting the use of anabolic steroids to treat the anemia of chronic renal disease in veterinary patients has been equivocal. Following experimental nephrectomy in one study, dogs treated for 6 weeks with 3-oxo-D1,4-androstadiene-17β-ol-undecylenate experienced no significant improvement in food intake, lean body mass, nitrogen balance, or PCV (Finco et al. 1984). In another study of surgically-induced chronic renal failure, dogs who received 2 mg stanozolol orally, twice each day for six weeks experienced a significant increase in lean body mass and nitrogen balance, but effects on the erythron were not reported (Cowan et al. 1997). Longer duration therapy has been necessary to demonstrate beneficial effects in studies of human patients, who also have received maintenance hemodialysis. Based upon the definitive success of anabolic steroids in experimental animal models and in human patients, androgens have become a common, although not wholly proven, adjunct to the therapy for anemia of chronic renal disease in veterinary medicine (Cowgill 1995). Three classes of androgens have been used in uremic humans, including testosterone esters (propionate, enanthate, or cypionate), nortestosterone esters (nandrolone phenylpropionate, decanoate), and 17α-alkylated androgens. Androgens may improve erythropoiesis by directly stimulating erythroid precursors in the bone marrow and by stimulating EPO production by the remnant kidneys. Potential adverse effects of androgenic steroids include masculinization of females, fluid retention, hepatic toxicity, and, in males, prostatic hyperplasia or neoplasia.

ERYTHROPOIETIN. The clinical efficacy of endogenous EPO replacement with a recombinant human erythropoietin (rhEPO) has been documented in human patients (Erslev and Besarab 1997). Because the structure of EPO molecules has been relatively well conserved across many species, rhEPO can also be quite effective in restoring erythropoiesis to normal levels in uremic veterinary patients (Cowgill 1995; Cowgill et al. 1998). Patients with mild anemia of chronic renal disease may not require rhEPO treatment, but for those with moderate to marked anemia (PCV <30% in dogs and PCV <25% in cats), the benefits of rhEPO treatment often outweigh potential adverse effects. Therapy is initiated at 100 units/kg body weight by subcutaneous injection three times per week. This will initiate a regenerative response characterized by the appearance of reticulocytes in the peripheral blood (up to ~4.5% of total erythrocyte numbers in dogs and ~3.0% in cats) within a few days. PCV typically increases rapidly (up to ~1% per day during the first month) and returns to normal values within 2–3 weeks. When target erythrocyte numbers are attained, the dosage interval is reduced to twice, or even once, weekly, to avoid induction of erythrocytosis. If target values are not attained within 8–12 weeks, the dose is increased by 25–50 units/kg of body weight. Failure to respond to rhEPO can be attributed to many factors. It is essential that the patient's uremia is controlled, nutrient intake and body weight are stabilized, potential gastrointestinal bleeding is prevented, and iron status is normalized. Refractoriness to rhEPO has been observed in a significant number of treated animals and can be attributed to the development of anti-rhEPO antibodies in 20–50% of patients (Cowgill 1995). Recombinant canine EPO (rcEPO) has recently become available. Because rcEPO does not seem to cause erythroid hypoplasia in dogs, it may represent an improved alternative to rhEPO treatment in canine renal failure (Randolph et al. 1999). Potential adverse effects of rhEPO include polycythemia, systemic hypertension, vomiting, seizures, injection site discomfort, allergic mucocutaneous reactions, and, rarely, acute anaphylactic reactions. Severe, life-threatening anemia due to development of anti-rhEPO antibodies has been reported in horses and may resolve following cessation of rhEPO administration (Piercy et al. 1998).

NUTRIENTS AS HEMATINIC DRUGS

Iron. Therapeutic use of iron is indicated only in treatment and, in specific situations, prevention of iron deficiency anemia. Administration of iron in an attempt to correct anemia associated with other ailments is strictly empirical and has no proven clinical value. This limitation should be recognized by the clinician despite the fact that iron is included in a large number of commercial supplements intended to improve appetite, increase breeding efficiency, promote growth, and more. It should also be recognized that indiscriminate administration of iron preparations is accompanied by the danger of iron toxicosis or iron storage disease in healthy, as well as in unhealthy, animals.

Absorption, distribution, metabolism, and excretion of iron was summarized earlier (also see Fig. 27.3). Iron is distributed in several pools throughout the body: the hemoglobin pool in erythrocytes (60–70%), intracellular deposits of ferritin and hemosiderin (25%), the myoglobin pool in muscle (3–7%), the circulating pool of plasma transferrin (0.1%), and the respiratory enzyme pool (0.1%).

When administered orally, organic iron sources are better absorbed than inorganic sources, and ferrous salts are absorbed more efficiently than ferric salts. Many dietary components influence iron absorption from the intestine. Intraluminal factors that enhance absorption by increasing iron solubility include sugars (fructose and sorbitol), some amino acids, and a number of other organic acids, including ascorbic, succinic, lactic, and citric. Factors that depress iron absorption include calcium, phosphates, oxalate, bicarbonate, and phytic acid. Iron salts are chemically incompatible with many drugs, and mixing preparations is not advised; e.g., chelation of iron from ferrous sulfate by tetracycline limits the absorption of both compounds.

Extraluminal factors that affect iron absorption include the level of erythropoietic activity, body iron stores, and anemia. Hypoxic stimuli that promote erythropoiesis also increase iron absorption. Iron absorption is also increased when body stores of this element are low, even when hemoglobin content and oxygen transport are normal. Iron-deficient dogs will absorb up to 60% of orally administered iron, whereas less than 10% of dietary iron is absorbed under normal circumstances. Erythrocytosis following multiple transfusions, a return to normal oxygen tension after episodes of reduced oxygen availability, or large doses of antiproliferative chemotherapeutic agents or radiation will diminish erythropoiesis and iron absorption.

Severe iron deficiency paradoxically causes intestinal malabsorption of iron in dogs and humans (Kimber and Weintraub 1968). Thus, iron deficiency of sufficient intensity or duration may result in refractoriness to oral iron therapy for anemia. Thus, it is recommended that iron deficiency be treated first by administration of a parenteral preparation, followed by continued oral iron supplementation for approximately 1 month or for as long as the cause of iron imbalance might otherwise continue. In dogs, iron dextran should be administered intramuscularly at a dose of 10–20 mg/kg (Weiser and Kociba 1983). For neonatal cats, a single injection of 50 mg iron dextran is administered intramuscularly at approximately 18 days of age to prevent congenital iron deficiency anemia (Weiser and O'Grady 1983). The daily dose for ferrous sulfate is 100–300 mg/kg for adult dogs and 50–100 mg/kg for adult cats. Although little is known regarding an efficacious dose for iron dextran in adult large animals, doses for ferrous sulfate have been derived. They include 8–15 g per os per day for 2 weeks or more in cattle, 2–8 g per os per day for 2 weeks or more in horses, and 0.5–2 g per os per day for 2 weeks or more in swine and sheep.

ADVERSE EFFECTS. Mucosal block of iron absorption can be superseded by excessive doses of the element, especially if administered for prolonged periods of time. Iron overload and toxicosis can result. The usual concentration of iron in plasma is about 100 mg/dL, which is approximately one-third the binding capacity of the circulating transferrin pool. Transferrin can become completely saturated during iron overload. Accumulation of iron in the body may be expressed by two known conditions: hemosiderosis and hemochromatosis. Hemosiderosis refers to a localized process of abnormal iron pigmentation caused by increased amounts of hemosiderin in the tissues. This usually occurs after hemorrhage into tissues or a body cavity. Hemochromatosis is a systemic disease characterized by widespread hemosiderosis and micronodular hepatic cirrhosis. The former is due to systemic iron accumulation by tissue macrophages, and the latter is due to iron accumulation and toxicity of hepatocytes and Kupffer cells. Hemochromatosis can be found in association with intravascular hemolysis following exceptionally abundant destruction of erythrocytes due to immune-mediated hemolytic anemia or transfusion reactions, and after prolonged ingestion or large doses of iron. In addition, hemochromatosis is an inherited disease in humans and Salers cattle that is characterized by idiopathically increased gastrointestinal iron absorption and abnormal deposition of iron in parenchymal tissues (House et al. 1994).

All iron preparations probably have equal potential toxicity per unit of elemental iron. Orally administered iron is known to be relatively safe for humans and animals, provided excessive amounts are not administered acutely. Clinical signs of iron toxicosis in baby pigs include erosion, ulceration, and hemorrhage of the gastrointestinal mucosa, followed by melena and/or hematochezia and signs of acute blood loss, including pale skin, tachycardia, hypotension, dyspnea, lethargy, and circulatory shock. Animals treated with commercial parenteral iron preparations intended for other species are particularly prone to toxicosis. Twenty of 36 Simmental heifers treated with a large dose of a commercial iron preparation intended for horses died within 72 hours following treatment. Iron toxicity was evidenced by petechial hemorrhages in multiple organs, severe centrolobular necrosis of the liver, and >500 mg/dL elemental iron in the serum. Caution must be exercised when administering parenteral iron supplements, because the body does not have an efficient extraintestinal mechanism for iron excretion.

Treatment of oral iron poisoning is directed at preventing absorption by intestinal mucosal cells and is facilitated by use of a gastrointestinal adsorbent or an emetic agent as long as hemorrhagic vomiting is not occurring. Sodium bicarbonate (6% solution) can be used as a lavage, followed by oral administration of deferoxamine mesylate, a specific iron-chelating drug (Pitt et al. 1979; Klaassen 1996). For systemic treatment, the most effective means of removing iron is by chelation. Deferoxamine is administered intramuscularly (20 mg/kg every 4 hours). If circulatory shock is evident, the preparation can be administered intravenously (40 mg/kg over a 4-hour period, followed by 20 mg/kg every 12 hours). Deferoxamine promotes the urinary excretion of chelated iron so that several days of therapy are required to eliminate the entire toxic dose. Continued appearance of a reddish discoloration of the urine indicates that iron is still undergoing excretion and that deferoxamine chelation treatment should continue.

Vitamin and Mineral Preparations. The general indications and limitations of therapeutic use of vitamins and minerals are discussed in Section 9. The only established clinical use of these substances as hematinic agents is in the treatment of anemias caused by specific vitamin or mineral deficiencies. Successful therapy with these substances depends upon a clear understanding of their normal participation in the erythropoietic process and identification of the specific cause of anemia. Indiscriminate administration of vitamins or minerals can complicate the anemic state and be harmful in certain situations; e.g., in humans, therapy with folic acid can temporarily correct the hematologic manifestations of vitamin B_{12} deficiency while

TABLE 27.3—Representative iron preparations for veterinary use

Oral preparations	
Ferrous sulfate*	*E-Kwine*® vitamin B complex, cobalt
	Feosol® elixir, tablets, or sustained release capsules
	Fer-In-Sol® drops or exissicated capsules
	Fer-Iron® drops
	Fero-Gradumet Filmtabs® timed release tablets
	Ferospace® timed release capsules
	Ferralyn Lanacaps® timed release capsules
	Ferra-TD® timed release capsules
	Ferratin® arsenic, strychnine, copper, cobalt
	Ferro-Folic-500® folic acid, controlled release
	Ironate® vitamin B complex, vitamin C, copper
	Mol-Iron® tablets
	Livibron® vitamin B complex, manganese
	Vi-Natura® vitamin B complex
Ferrous lactate	*Ferro drops*® 25 mg/ml; for small animals
Ferrous gluconate	*Triple A & N Tab*® strychnine, arsenic, nucleic acids
	V-L-I-B® desiccated liver, vitamin B complex; for small animals
	Livolex® vitamin B complex
Ferrous fumarate	*V-Sorbits*® vitamin B complex, vitamins A, D, E
	Livitamin® vitamin B complex, vitamin C, desiccated liver
Ferrous sulfate	*Lib*® copper, cobalt, desiccated liver
Ferric pyrophosphate	*Vi-Sorbin*® vitamin B complex, sorbitol
Ferric ammonium citrate:	*Ferrisol, Iron-Plus Mineral Supplement*® vit. B complex, copper, cobalt
	Allane® vitamin B complex
Ferric chloride	*Caco-Copper*® arsenic, copper
Ferric citrochloride	*Ferrogen*® strychnine, cobalt, copper
Ferric hydroxide	*Purina Oral Pigemia*® dextran complex
Ferric methionine	*Ferrodex*® vegetable oil paste
Ferric proteinate	*Lixotinic*® vitamin B complex, copper, beef liver
	Duriron® copper proteinate, dried yeast
Parenteral preparations	
Iron dextran	*Ferrextran*®, *Ferrodex*®, *Nonemic*®, *Dexiron*®
Iron hydrogenate dextran	*Iron-Gard*®
Ferric hydroxide	*Iro-Jex*®, *Iron-Gard*®

*Dose (as ferrous sulfate septahydrate, providing 200 mg elemental iron per gram), daily for 2 weeks or more: horse, 2–8 g; cattle, 8–15 g; sheep and swine, 0.5–2 g; dog, 100–300 mg; cat, 50–100 mg.

allowing the serious neurological damage associated with the latter to progress.

A large number of multivitamin-multimineral "shotgun" admixtures are available for use in animals. Many of these preparations are advocated as hematinics; some examples are listed in Table 27.3. The antianemic efficacy of these remedies has not been established by carefully controlled studies. Clinicians should be aware of unsubstantiated claims in regard to vitamin-mineral mixtures. Typical effects that have been claimed for some preparations include strengthening of convalescing animals, increasing food intake, improving feed efficiency, and enhancing growth and production. If a deficiency is diagnosed, the clinician is best advised to administer only the deficient substance rather than rely on a multicomponent preparation that contains unnecessary and potentially toxic ingredients.

Several drugs and animal tissue extracts exert pronounced effects on hemostatic and blood coagulative mechanisms. Some of these substances promote hemostasis and have clinical value in control of blood oozing from small vessels. Hemostatic agents include thrombin, thromboplastin, fibrin, and fibrinogen. In contrast, drugs such as heparin and sodium citrate retard hemostasis by impeding clot formation. These anticoagulant agents are employed in the laboratory to prevent clotting of blood used in diagnostic tests or stored for transfusion. Heparin also is used in vivo, as are the coumarin-derivative anticoagulants, in treatment and prevention of thromboembolic disorders. Additional approaches involve the enzymes streptokinase and urokinase, which activate fibrinolytic breakdown of formed clots and clotting factors. Thrombus formation also is reduced by inhibitors of platelet aggregation such as aspirin and ticlopidine.

An overview of local factors involved in control of bleeding will first be presented as an aid to understanding how hemostatic and anticoagulant drugs affect hemostasis-related mechanisms.

HEMOSTASIS. The term hemostasis refers to prevention or control of hemorrhage. Physiologic control systems operate to ensure fluidity of blood under normal conditions, yet opposing systems promote coagulation when the circulatory system is invaded. Hemostasis is achieved through a series of interdependent mechanisms, including vascular spasm of the injured artery or vein, local aggregation of platelets into a plug, coagulation of the blood into a clot, and dissolution of the formed clot by fibrinolysis. The basic process of hemostasis can be separated into the vascular, platelet, coagulation, and fibrinolysis phases. The phases overlap considerably, and events in one step promote and even cause development of subsequent phases (Chart and Sanderson 1979).

Vascular and Platelet Phases. The vascular and platelet phases are closely allied. Until recently the central role of vascular endothelium in hemostasis was not appreciated. The endothelium has a multitude of anticoagulant and procoagulant functions (Nawroth et al. 1986). The inability to reproduce the effects of the endothelium on hemostasis helps explain why in vitro coagulation assays sometimes fail to properly reflect in vivo pathophysiologic events.

Immediately after a blood vessel is cut or otherwise traumatized, the vascular wall contracts and platelets start adhering to the injured site. The local vasoconstrictor response, or vascular spasm, mechanically retards the flow of blood escaping from the vessel. Vascular spasm may be partly a local reflex or myogenic response and partly humoral owing to vasoactive agents released from platelets and nearby cells. Local vasoconstriction lasts as long as 20-30 minutes, during which the ensuing phases of platelet aggregation and blood coagulation take place (Weiss 1978; Moncada and Vane 1979).

Damage to a blood vessel results in exposed subendothelial collagen. Collagen and other proteins localized to the subendothelium are strong stimuli for platelet adherence. For platelets to properly attach to a traumatized area, von Willebrand factor (vWf) must be present because the platelets express a vWf receptor that facilitates adherence. Once adhesion has occurred, the platelets undergo a change in shape and release diverse substances that recruit further platelets to the clot and promote the coagulation cascade. This process is termed aggregation. The substances released include adenosine diphosphate (ADP), adenosine triphosphate (ATP), serotonin, platelet factor 3 and 4, thromboxane A_2, and platelet-derived growth factor. This aggregation yields a rather loosely formed plug or platelet thrombus at the injury site.

INVOLVEMENT OF PROSTAGLANDINS. Adenosine diphosphate is a potent chemical activator of platelet aggregation, which in turn activates a phospholipase that acts on membrane phospholipid to yield arachidonic acid. The latter is transformed by a platelet cyclooxygenase into short-lived but potent aggregating compounds called cyclic endoperoxides (prostaglandins [PGs] G_2 and H_2). These endoperoxides are converted by platelet thromboxane synthase to a potent aggregating compound called thromboxane A_2. Thus platelet clumping initiates formation of chemical agents that promote further platelet aggregation. In contrast, prostacyclin (PGI_2) is a PG that inhibits platelet aggregation and may act as a counterbalance to thromboxane. PGI_2 is formed from arachidonic acid and intermediate cyclic endoperoxides. Prostacyclin synthase, the enzyme responsible for transformation of PGI_2 from the cyclic endoperoxides, is localized in the vascular wall rather than in platelets. The platelet activation sequence is shown in Fig. 28.1.

Vascular spasm and platelet adhesion, aggregation, and release of chemical agents are initiated within seconds after vascular trauma. During subsequent events, the platelet plug becomes more tightly bound and organized by incorporation of fibrin strands formed during coagulation.

Coagulation Phase. Blood clotting results from a complex series of interdependent events. Clotting ingredients normally exist as inactive factors in blood vessels, perivascular tissue, and the blood itself. Upon injury to the circulatory system, the inactive or procoagulant substances are transformed to active clotting factors. Activation of all factors does not occur simultaneously. Rather, the activated form of one factor activates a subsequent factor in a sequential series of reactions, yielding a cascade or "waterfall" effect. Biochemically, the activation process is accomplished for most of the clotting factors by the proteolytic splitting off of a small moiety of the inactive procoagulant factor.

Blood clotting factors generally are designated by Roman numerals I-V and VII-XIII, as listed in Table 28.1. Nomenclature of the factors has undergone considerable revision over the years. The terminologies used by Guyton (1976), Erslev and Gabuzda (1979), and Platt (1979) are basically followed in this discussion. Factors V and VII-XIII usually are designated by

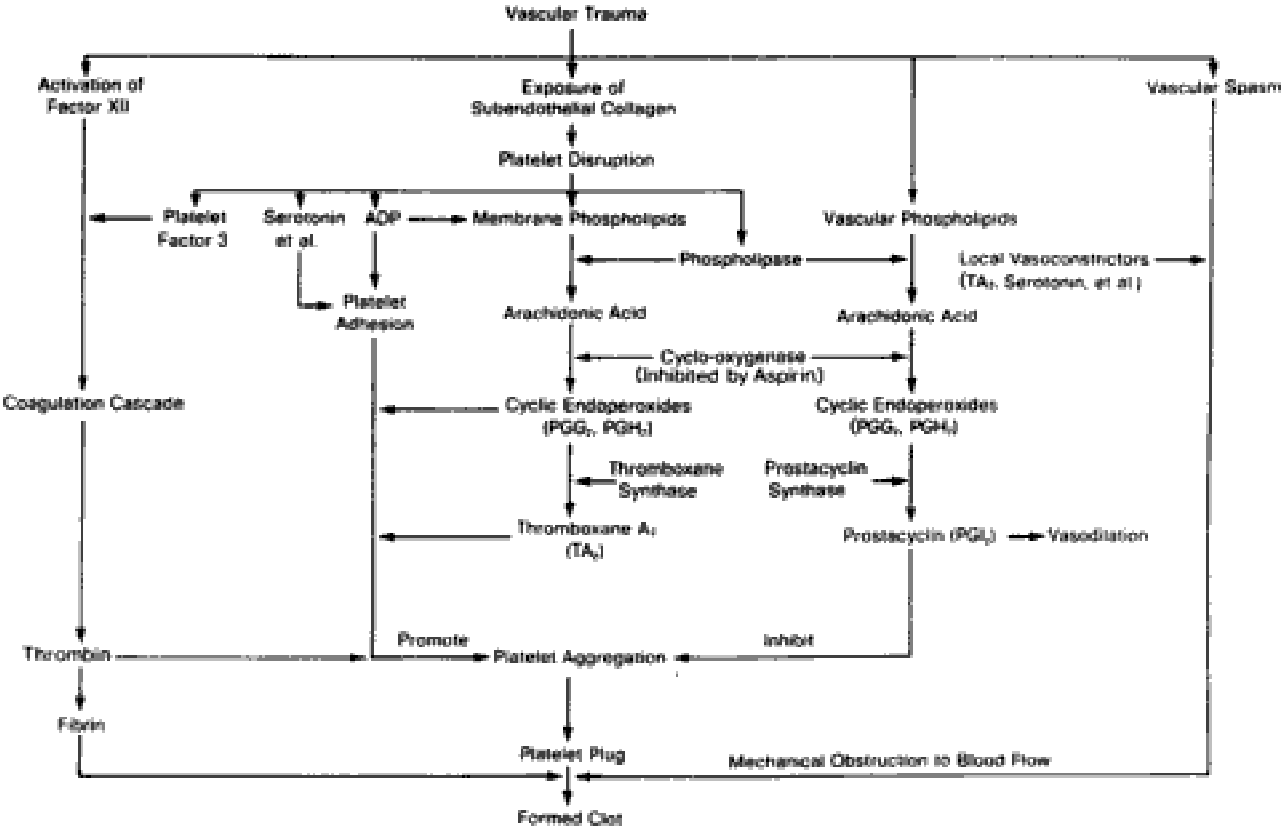

FIG. 28.1—Vascular and platelet phases of hemostasis. PG = prostaglandin; ADP = adenosine diphosphate.

TABLE 28.1—Blood coagulation factors and their synonyms

Factor	Synonym
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Tissue thromboplastin
Factor IV	Calcium
Factor V	Proaccelerin
Factor VII	Proconvertin; serum prothrombin conversion accelerator
Factor VIII	Antihemophilic factor
Factor IX	Plasma thromboplastin component; Christmas factor
Factor X	Stuart-Prower factor
Factor XI	Plasma thromboplastin antecedent
Factor XII	Hageman factor
Factor XIII	Fibrin stabilizing factor

their numbers, whereas factors I and II are referred to more commonly as fibrinogen and prothrombin respectively. Tissue thromboplastin is factor III and should not be confused with platelet factor 3. There is no factor VI. Important synonyms for the major clotting factors are included in Table 28.1.

Although clotting factors participate in coagulation through different pathways, the overall coagulation process can be divided into three major events: (1) a substance called prothrombin activator or complete thromboplastin is formed in response to trauma to blood vessels, extravascular tissues, or the blood itself; (2) prothrombin activator catalyzes the transformation of prothrombin to thrombin; and (3) thrombin rapidly catalyzes conversion of fibrinogen into threads of fibrin, which in turn enmesh platelets, plasma, and erythrocytes to form a clot.

The initial step, formation of prothrombin activator, is the most complex and least understood. This substance can be produced by two basic routes: the intrinsic pathway instigated by trauma to the blood itself and the extrinsic pathway that begins with damage to the vessel wall and extravascular tissues. In vivo the coagulation factors involved in the intrinsic and extrinsic coagulation pathways interact with each other. The strict separation of the intrinsic and extrinsic coagulation pathways is based upon the in vitro coagulation assays.

INTRINSIC PATHWAY. Blood taken by venipuncture and placed in a glass container clots normally within 5-10 minutes because all factors required for coagulation are present within the blood (Fig. 28.2). This pathway is initiated because trauma to the blood directly affects two important coagulation factors within the blood itself, the platelets and factor XII. Platelets damaged by contact with a wettable surface like glass (or collagen in vivo) release the phospholipid commonly referred to as platelet factor 3. In addition, factor XII is transformed into activated factor XII when disturbed by trauma to the blood. The activated form of factor XII in turn activates factor XI and forms kallikrein. Factor XI converts factor IX to an activated form. The activated factor IX interacts with factor VIII in conjunction with the platelet phospholipid to convert factor X to activated factor X. Finally, activated factor X interacts with factor V and platelet phospholipids to yield the complex called prothrombin activator (intrinsic thromboplastin system). Prothrombin activator immediately catalyzes the cleavage of prothrombin to thrombin, which converts fibrinogen into fibrin (Fig. 28.2).

EXTRINSIC PATHWAY. When tissue extract is added to whole blood, clotting occurs rapidly in about 10-15 seconds. The extrinsic factor that sets the coagulation cascade into motion is released from traumatized tissues (Fig. 28.2). Referred to as tissue thromboplastin, the extrinsic factor includes a combination of a proteolytic enzyme simply called tissue factor and tissue phospholipids that are probably derived from cell membrane components. First, the tissue factor interacts with clotting factor VII; this complex converts factor X to activated factor X in the presence of the tissue phospholipids. In addition, factor IX is activated, which can also lead to further factor X activation. The subsequent step is essentially the same as the last step in the intrinsic pathway; i.e., activated factor X interacts with factor V and tissue phospholipid to form prothrombin activator (extrinsic thromboplastin system). The difference is that tissue phospholipids are used in the extrinsic system while platelet phospholipids are used in the intrinsic system (Fig. 28.2).

FIBRIN FORMATION. Prothrombin activator, whether derived from the intrinsic or extrinsic pathway, converts the α_2-globulin prothrombin into thrombin. Thrombin in turn acts as a proteolytic enzyme and cleaves two low molecular weight peptides from each molecule of fibrinogen, forming a molecule of fibrin monomer. Thrombin also promotes platelet aggregation and activates factors XIII, XII, VIII, and V. Fibrin monomers immediately polymerize with each other, forming long fibrin threads that act as the reticulum network for the clot. The fibrin chains initially are somewhat loosely bound. However, clotting factor XIII (fibrin-stabilizing factor) quickly acts as an enzyme to cause covalent bonding between fibrin monomers and between adjacent fibrin threads. This process stabilizes and strengthens the meshwork of the clot. The clot comprises the interlocking fibrin chains and the entrapped blood cells, platelets, and plasma. Final clot retraction and serum extrusion are caused by a contractile protein thrombosthenin that is released from platelets (Fig. 28.2).

INVOLVEMENT OF CALCIUM. Calcium ions (Ca^{++}), referred to as clotting factor IV (Table 28.1), are required for all coagulation reactions except the first two steps in the intrinsic pathway. This dependency is exploited in the laboratory; Ca^{++}-complexing agents such as citrate are used as in vitro anticoagulants.

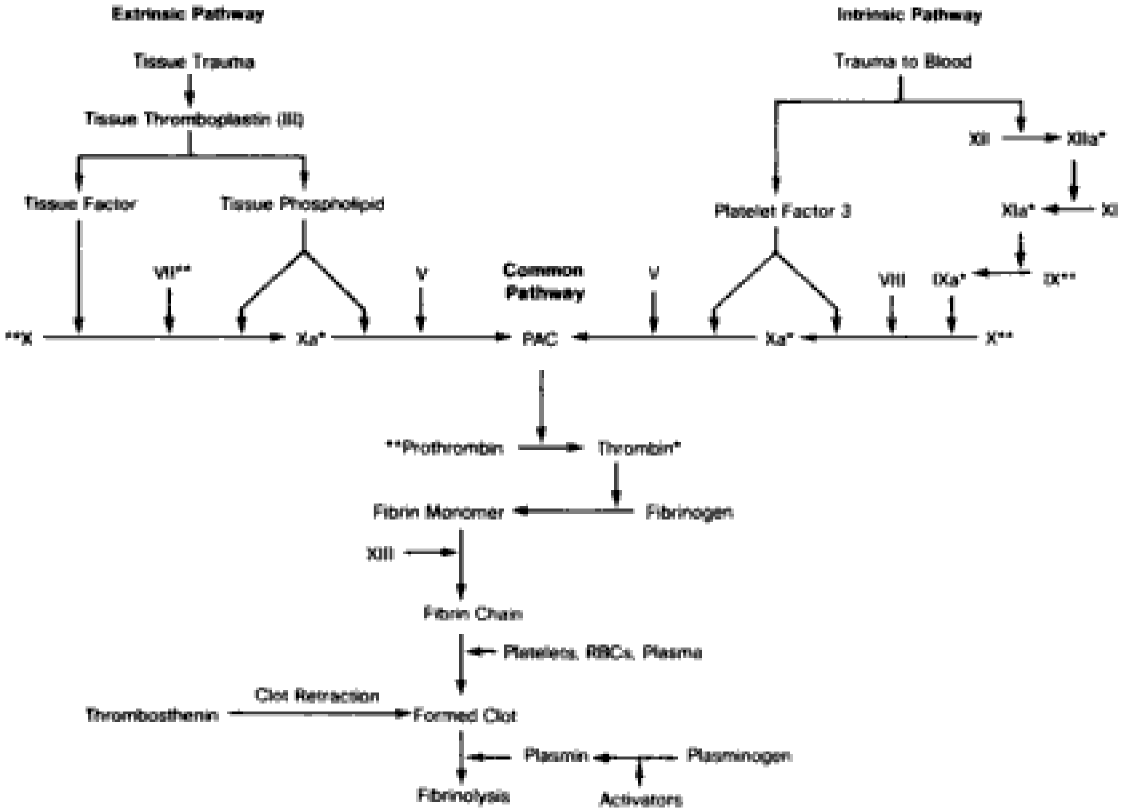

FIG. 28.2—Blood coagulation, clot formation, and fibrinolysis. PAC = prothrombin activator complex (also referred to as complete thromboplastin, prothrombinase, prothrombinase complex, and intrinsic or extrinsic thromboplastin); a = activated forms of clotting factors; * = factors inhibited by heparin; ** = factors inhibited by coumarin derivatives. Calcium is required in most reactions.

Availability of calcium generally is not a limiting factor in the body except rarely after massive transfusion of citrated blood. Usually, death from tetany and respiratory failure would result from hypocalcemia before the calcium concentration was low enough to significantly affect coagulation.

INVOLVEMENT OF KALLIKREIN-KININ SYSTEM. A deficiency of prekallikrein or high molecular weight kininogen prolongs the partial thromboplastin time of blood in vitro and thus slows the intrinsic clotting pathway. Kallikrein amplifies activation of factor XII, which in turn further increases conversion of prekallikrein to kallikrein (Donaldson et al. 1976).

Fibrinolysis Phase. A plasma β globulin called plasminogen is bound to fibrin and incorporated into the clot along with other plasma constituents. Fibrinolysis is initiated when plasminogen is activated by local agents to plasmin. Tissue-type plasminogen activator is produced by endothelial cells and fibroblasts and utilizes fibrin as a cofactor in the conversion of plasminogen to plasmin. Plasmin is a proteolytic enzyme that digests the fibrin chains into soluble polypeptides, thereby preventing further fibrin polymerization. Plasmin also digests other substances in the clot and surrounding blood, e.g., prothrombin; fibrinogen; and clotting factors V, VIII, and XII. Formation of plasmin results in dissolution of the clot and also in hypocoagulability of the blood because of loss of clotting factors. Thus fibrinolysis represents the physiologic converse of the coagulation process. It serves as a defense mechanism against overactivity of the coagulation mechanism. The long-term patency of the vascular tree no doubt depends on a balanced equilibrium between coagulation and fibrinolysis (Fig. 28.2).

Natural Anticoagulants. The sensitivity of the coagulation cascade to hematologic disruptions necessitates equally sensitive control systems to prevent indiscriminate clotting. As stated so colorfully by Erslev and Gabuzda (1979), the clotting factors "stand poised as the parts of a loaded gun with trigger cocked, aimed at fibrinogen." Physiologic systems are available that either "clean up" the clotted target after the thrombin bullet is shot or act as "safeties" to prevent the gun from discharging needlessly.

First, the vascular endothelium is exceptionally smooth surfaced, thereby preventing contact activation of platelets and factor XII. Prompt removal of activated factors from the circulation is attained physically by rapid blood flow that washes local concentrations away from the site of thrombus formation. The liver rapidly clears the activated factors with a half-life of only a few

TABLE 28.2—Selected hemostatic diseases in animals

I. Vascular defects (vasculitis)
II. Platelet defects
  A. Thrombocytopenia
    1. Idiopathic immune-mediated destruction
    2. Immune-mediated destruction secondary to drug administration, vaccination, and various diseases
    3. Bone marrow suppression (chemotherapeutics, estrogens)
    4. Increased consumption (disseminated intravascular coagulation, microangiopathy associated with neoplasia)
  B. Thrombocytopathy
    1. Inherited (Otterhounds, Basset Hounds, cattle)
    2. Acquired (drug administration [e.g., aspirin, antibiotics, lidocaine] gammopathy associated, uremia)
III. Von Willebrand disease (inherited deficiency of von Willebrand factor leading to defective platelet adhesion; found in humans, swine, dogs, and rabbits)
IV. Coagulation defects
  A. Inherited
    1. Hemophilia A (lack of functional factor VIII; found in humans, horses, cats, and dogs)
    2. Hemophilia B (lack of factor IX; found in humans, dogs, and cats)
    3. Hagemann factor deficiency (lack of factor XII; will produce significant prolongation of APTT and ACT results but is rarely related to a clinical bleeding disorder)
  B. Acquired
    1. Deficiency of vitamin K activity (vitamin K-antagonist rodenticide poisoning, malabsorption)
    2. Decreased hepatic synthesis (neoplasia, cirrhosis, infection)
    3. Increased consumption (disseminated intravascular coagulation)
V. Thrombotic diseases
  A. Disseminated intravascular coagulation (neoplasia, severe generalized inflammation, pancreatitis, hemolysis)
  B. Deficiency of AT III (nephrotic syndrome, heartworm adulticide treatment)
  C. Circulatory abnormalities (cardiomyopathy in cats)

minutes. Fibrinolytic dissolution of formed clots has been discussed.

Humoral inhibitors of intermediate products of coagulation play a vital role in limiting coagulatory processes. Substances with inhibitory effects include heparin, plasmin, antithrombin III, and tissue factor inhibitor (extrinsic pathway inhibitor, lipoprotein-associated coagulation inhibitor). Antithrombin III (AT III) is the most vital of these factors. It is a globulin with a molecular weight of 65,000 and has the ability to inactivate factors Xa, IXa, XIa, and XIIa and thrombin. Binding to heparin markedly increases the rate of inactivation of factor Xa and thrombin. In addition, the surface of the vascular endothelium serves as the site of the thrombomodulin/protein C/protein S anticoagulant system. Thrombomodulin is an integral membrane protein, and protein C and protein S are circulating vitamin K-dependent proteins. Thrombomodulin has a receptor site for thrombin. Once thrombin has been bound, its ability to form fibrin and aggregate platelets is nullified. Additionally, it becomes a powerful activator of protein C. Protein C has anticoagulation effects through inactivation of factors Va and VIIIa (Marlar et al. 1982) and promotes fibrinolysis (Roemisch et al. 1991). Protein S increases the rate of inactivation of factor V.

Humoral inhibitors of intermediate products of coagulation include heparin, antithromboplastin, plasmin, and antithrombin III (not to be confused with clotting factor III or platelet factor 3). Antithrombin III also is called the heparin cofactor. This enzyme is a thrombin antagonist, but it additionally inhibits activated forms of factors IX, X, XI, and XII. Antithrombin III combines in a stable manner with the enzymatically active binding sites of these factors, thereby preventing their accessibility to subsequent substrates in the clotting cascade. The combination of heparin with antithrombin III increases approximately 100-fold the affinity of the latter for the activated clotting factors. The anticoagulant activity of heparin is due to its interaction with antithrombin III; without the latter, heparin does not prevent clot formation (see discussion of heparin later in this chapter).

Fibrin itself is an effective antithrombin factor, because it removes from the circulation approximately 90% of the thrombin formed during the clotting process. This action assists in localizing the clot to the target site and retarding its spread to other regions of the vasculature.

Coagulopathies and Drugs. Clinically, a large number of pathophysiologic states influence hemostatic events in animals. Abnormalities of one or more of the vascular, platelet, coagulation, and fibrinolytic phases are not uncommon; some of these disorders are summarized in Table 28.2. Drugs can be helpful in managing certain types of coagulopathies, but identification of etiologic factors is important. Some of the more commonly used hemostatic, anticoagulant, fibrinolytic, and antiplatelet drugs are discussed below. Commonly used tests of hemostatic function are listed in Table 28.3.

HEMOSTATIC DRUGS

Topical Hemostatics. Several locally applied substances can provide assistance in control of persistent capillary bleeding if blood coagulation mechanisms are otherwise intact. The ideal topical hemostatic substance should provide good hemostasis, have minimal

TABLE 28.3—Hemostatic assays and their clinical relevance

1. **One-step prothrombin time (OSPT):** Screening test of the extrinsic and common pathway. It is most sensitive to factor VII deficiency. First assay to be prolonged with vitamin K deficiency.
2. **Activated partial thromboplastin time (APTT):** Screening test of the intrinsic and common pathway. Will be prolonged with hemophilia and with prolonged vitamin K deficiency.
3. **Activated coagulation test (ACT):** Screening test for the intrinsic pathway, with less sensitivity than APTT.
4. **Buccal mucosal bleeding time:** Screening test for primary hemostasis. Will be prolonged with platelet dysfunction, thrombocytopenia, vWf deficiency, or vasculitis.

tissue reactivity, and be easy to sterilize and handle. If hemostatic or fibrinolytic defects are present, however, topical agents are of little or no value; replacement therapy is indicated (Chap. 29). Although lyophilized concentrates of several clotting factors are available for investigational use, most clinically useful topical hemostatic preparations contain thrombin or collagen. These compounds control bleeding by providing artificial clotting material or forming a structural matrix for coagulation events and clot formation. Because most topical hemostatics are absorbed gradually over varying intervals, they commonly are referred to as the absorbable hemostatics.

The clinician must recognize that locally applied hemostatics are indicated only in the combat of capillary oozing from minute vessels of denuded or superficially bleeding surfaces. These compounds will not effectively prevent loss of blood from arteries or veins where there is appreciable pressure.

THROMBOPLASTIN. Thromboplastin (thrombokinase) is produced naturally by platelets and tissues in response to trauma. The commercial preparation is a powder extracted from bovine brains or from acetone-extracted lung and/or brain of rabbits. *Thromboplastin*, USP, aids hemostasis by promoting conversion of prothrombin to thrombin, thereby accelerating the coagulation process. It is employed as a local hemostatic in surgery when applied by spray or direct application in a sponge. Thromboplastin is used in measurement of prothrombin time and activity of blood in vitro, an important guide in anticoagulant drug therapy.

THROMBIN. *Thrombin*, USP, is a white sterile powder prepared by interaction of thromboplastin and calcium with prothrombin of bovine origin. It is standardized on the basis of National Institutes of Health (NIH) units; one NIH unit is the amount of thrombin required to clot 1 mL standard fibrinogen solution in 15 seconds. In control of bleeding, thrombin converts endogenous fibrinogen to fibrin for clot formation. It is useful where there is bleeding from parenchymatous tissues, cancellous bone, dental sockets, laryngeal and nasal surgery, and reconstructive surgery. Thrombin is particularly valuable as an adhesive agent for fixation of skin grafts. It can be applied topically as a powder or as a solution in sterile distilled water or isotonic saline (approximately 1000 units/mL); it can also be used in conjunction with absorbable gelatin sponge or fibrin foam. After neutralization of stomach acid, thrombin may be of some value in bleeding of the upper gastrointestinal (GI) tract.

Thrombin must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. Local ischemia can result from subcutaneous or intramuscular (IM) injection. Thrombin is antigenic, but allergic reactions are encountered rarely when it is applied topically.

FIBRINOGEN. *Human Fibrinogen*, USP (Fibrogen, Parenogen), is a concentrated fraction of normal human plasma and is available as sterile white powder. It is readily soluble in normal saline and is used principally on denuded mucous membranes and as an adhesive in skin grafts (as a 2% solution). Fibrinogen also is used for restoring normal plasma fibrinogen concentrations in the treatment of hemorrhagic complications arising from massive blood loss or acute hypofibrinogenemia. Adequate amounts of endogenous thrombin are required for conversion of fibrinogen into fibrin.

FIBRIN FOAM. Fibrin foam is a spongelike material prepared by action of thrombin on human fibrinogen. It is an insoluble substance marketed as strips of fine white sponge. Fibrin foam may be applied directly, with pressure, to the hemorrhagic area or after presoaking it in thrombin solution. This preparation acts as a preformed network to trap blood oozing from the surface area.

ABSORBABLE GELATIN SPONGE. *Absorbable Gelatin Sponge*, USP (Gelfoam), is a sterile, water-insoluble, gelatin-base sponge. It is nonantigenic and will absorb several times its weight of whole blood. This denaturized gelatin usually is soaked in bovine thrombin and left in the bleeding area following closure of operative wounds. When applied to the surface of the body or mucosal membranes, it liquefies within 3-5 days. Gelatin sponge is completely absorbed in 4-6 weeks, usually without inducing a reaction or excessive scar tissue formation. It is used primarily for capillary or venous bleeding.

OXIDIZED CELLULOSE. *Oxidized Cellulose*, USP (Surgicel, Oxycel, Hemo-Pak), is a specially treated form of surgical gauze or sponge that aids coagulation by reaction between hemoglobin and cellulosic acid. Upon interaction with blood and tissue fluids, oxidized cellulose facilitates formation of a gummy matrix for clot formation. It should be used only as temporary packing because its permanent implantation in tissues and fractures interferes with bone regeneration and may result in cyst formation. Oxidized cellulose also interferes with epithelialization and hence should not be used as a topical dressing except for short-term control of bleeding. Complete absorption of large amounts may require weeks. Also, oxidized cellulose should not be used in conjunction with thrombin since the latter is inactivated by the former's acidity. Oxidized cellulose is available as sterile cotton pledgets and gauze pads and strips.

MICROCRYSTALLINE COLLAGEN. Microcrystalline collagen is a surface hemostatic agent. A valuable property of this substance is its affinity for wet surfaces, to which it quickly adheres. Microcrystalline collagen is absorbed in about 6 weeks with minimal tissue reaction. It may be effective in the presence of clotting factor deficiencies but is less effective in thrombocytopenia. It has also been shown to be effective in systemically heparinized patients (Abbott 1974). Surface hemostasis obtained with this agent appears to be most effective and reliable in such cases as venoarterial anastomoses or surgery of the spleen and liver.

EPINEPHRINE AND NOREPINEPHRINE. Topically applied, *Epinephrine*, USP, and *Norepinephrine Bitartrate*, USP, produce an immediate but transitory vasoconstriction, which may be of some value in local control of bleeding from small vessels. See Chap. 6 for indications and limitations.

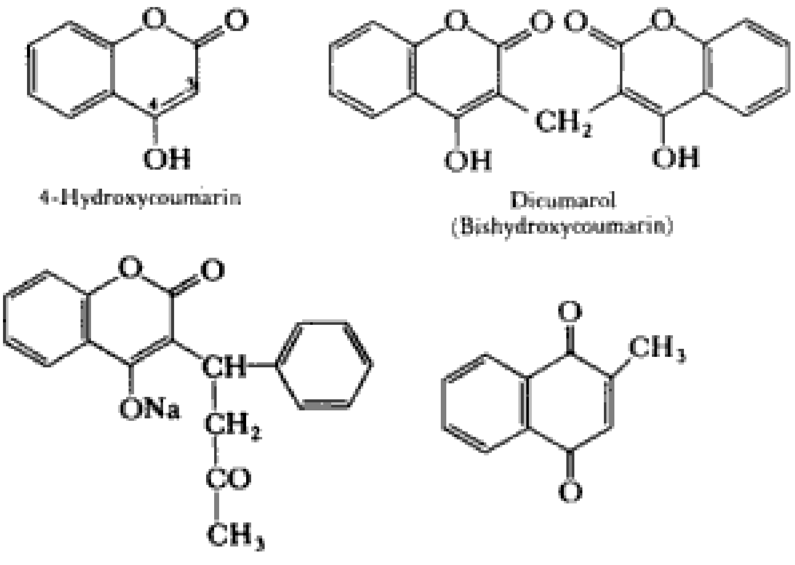
MISCELLANEOUS TOPICAL HEMOSTATICS. The locally acting hemostatics known as styptics are the oldest blood-clotting drugs. Styptics include such agents as ferric chloride, ferric sulfate, ferric subsulfate, alum, tannic acid, chromium trioxide, silver nitrate, zinc chloride, cotarnine chloride, and a variety of other astringent substances. Some of these drugs are used locally in full strength as powders dusted onto a bleeding area; in solution they are used in concentrations from 1 to 20%. Action of these drugs depends upon precipitation of the protein of blood and soft tissue, and they supposedly seal off the ruptured vessel. However, many of these agents, especially if used in high concentration, may damage tissues, resulting in sloughing and even recurrence of hemorrhage. Thus they should be used carefully and only on superficial lesions.

Systemic Hemostatics

BLOOD. Fresh whole blood or blood components are indicated for emergency treatment of acute hemorrhagic syndromes associated with deficiency of clotting factors or platelets (see Chap. 29).

VITAMIN K. Vitamin K is a fat-soluble vitamin that is found in a variety of plants and is produced by microorganisms. It occurs as a viscous clear liquid that is very sensitive to light. Its main therapeutic usage is in the treatment of vitamin K antagonist rodenticide intoxication.

CHEMISTRY AND MECHANISM OF ACTION. Vitamin K exists in three main forms. Vitamin K-1 (phytonadione) is present in plants, vitamin K-2 (menaquinone) is produced by microorganisms, and vitamin K-3 (menadione) is a synthetic derivative (Fig. 28.3). All of these compounds are naphthoquinone derivatives. Vitamin K aids in the production of functional clotting factors II, VII, IX, and X by postribosomal carboxylation of glutamyl residues. It also is vital for the production of active protein C and protein S, both of which have anticoagulatory effects.



4-Hydroxycoumarin

Dicumarol (Bishydroxycoumarin)

Warfarin Sodium

Menadione

FIG. 28.3—Structures of 4-hydroxycoumarin, dicumarol (bishydroxycoumarin), warfarin, and synthetic vitamin K (menadione).

Vitamin K-1 is actively absorbed in the small intestine. Vitamins K-2 and K-3 are passively absorbed in the ileum and colon. Solubilization by bile acids is required for absorption of vitamins K-1 and K-2. Biotransformation in the organism is required for vitamin K-3 to become active (Mount 1982).

CLINICAL USE. Deficiency of vitamin K activity will lead to a hypocoagulable state. The major cause of this syndrome in veterinary medicine is the ingestion of vitamin K antagonists. Antagonists can occur naturally (dicumarol, sweet clover poisoning) or as commercial rodenticides (coumarin, warfarin, indandiones, brodifacoum). Occasionally disorders in fat absorption can lead to decreased vitamin K absorption. Coagulopathies have been documented with lymphocytic-plasmacytic enteritis, exocrine pancreatic insufficiency, and bile duct obstruction (Perry et al. 1991; Edwards and Russell 1987; Neer and Hedlund 1987). In birds prolonged administration of sulfonamides for the treatment of coccidiosis can lead to vitamin K deficiency by destroying the intestinal microorganisms. In swine porcine hemorrhagic syndrome in weaned pigs is believed to be related to low vitamin K levels in feed (Liggett 1989). A heritable multifactor vitamin K-dependent coagulopathy has been documented in Devon Rex cats (Soute et al. 1992).

Hypocoagulability is documented clinically by prolongation of the coagulation times (activated coagulation test [ACT], prothrombine time [PT], activated partial thromboplastin time [APTT]). Factor VII is the vitamin K-dependent clotting factor with the shortest half-life and is also the factor predominantly measured by PT. As a result, PT values will change before APTT or ACT values will. This makes PT a good test to detect and monitor the therapy of a vitamin K-deficient state.

The therapeutic agent of choice is vitamin K-1. Vitamin K-3 has demonstrated poor efficacy in veterinary patients as well as toxic side effects (Alstad et al. 1985; Fernandez et al. 1984). Subcutaneous injection or oral administration are the preferred modes of administration. Intramuscular injections have been recommended; however, such an injection in an animal with a coagulopathy may lead to extensive life-threatening hemorrhage. Intravenous administration has been associated with anaphylactoid reactions. Most protocols recommend giving the initial dose of vitamin K by subcutaneous injection to ensure that therapeutic levels are reached. Thereafter, the drug can be given orally. A fatty meal will enhance oral absorption. Duration of treatment and dosage used will vary depending upon the clinical indication. Poisoning from first-generation vitamin K-antagonist rodenticides (coumarin, warfarin) should be treated for 4-6 days with 0.25-2.5 mg/kg divided BID in small animals, 300-500 mg TID in horses (Byars et al. 1986), and 1.1-3.3 mg/kg in cattle (Alstad et al. 1985). For second-generation vitamin K-antagonist rodenticides (diphacinone, brodifacoum), the treatment period should be extended to 14 days and a loading dose of 5 mg/kg should be given initially, followed by 2.5 mg/kg daily (Woody et al. 1992). Determination of PT 48 hours after cessation of therapy is recommended to detect residual toxicity. Substitution of vitamin K will begin to normalize PT values in 12-24 hours.

DESMOPRESSIN ACETATE (DDAVP). Desmopressin is a synthetic analog of vasopressin, and is used in the treatment of central diabetes insipidus and to transiently elevate levels of vWf. The elevation in vWf allows surgical procedures to be performed and aids in the control of capillary bleeding from wounds in animals with von Willebrand disease. In comparison to vasopressin, DDAVP has minimal pressor effects. Administration of this drug leads to the release of stored vWf from endothelial cells and macrophages. When DDAVP is given, a rapid rise in vWf levels occurs, with larger, more-active multimeres predominating (Kraus et al. 1987; Johnstone and Crane 1986). This effect is reduced if the drug is given repeatedly, since the storage pools will be depleted. The duration of elevation is approximately 2 hours (Mansell and Parry 1991). Though the elevation in vWf levels found in dogs is considerably lower than in humans, clinically a decrease in buccal mucosal bleeding time was seen (Kraus et al. 1989). In some dogs only a minimal response was noted. The recommended dosages for dogs is 0.4 μg/kg given subcutaneously.

PROTAMINE SULFATE. *Protamine Sulfate,* USP, is a low molecular weight protein found in the sperm of certain fish. It is strongly basic and combines with acidic heparin to form a stable salt that prevents any further anticoagulant activity of heparin. Protamine is used as an antagonist only to heparin-evoked hemorrhages. It also arrests action of heparin in vitro. Protamine itself has anticoagulant properties probably caused by interference with the reaction of thrombin and fibrinogen. This would imply that the clinician must take care not to overneutralize the action of heparin.

Protamine is available as a 1-2% solution. It is administered slowly by the IV route at a rate no greater than 50 mg over a 10-minute period. The average dose is 1-1.5 mg to antagonize each 1 mg heparin. The dose is related to the lapse of time from administration; e.g., 30 minutes after heparin injection only 0.5 mg protamine may be required to antagonize each 1 mg heparin.

ANTICOAGULANTS. The principal uses of anticoagulant agents are in vitro to prevent clotting of blood for transfusion or diagnostic use and in vivo to prevent development and enlargement of thrombi.

In Vitro Anticoagulants. A variety of chemicals have been used to prevent coagulation of shed blood. Essentially two categories of chemicals are used: those employed as anticoagulants in samples of blood intended for physical or chemical examination and those employed to preserve blood for transfusion. Certain of these agents can be used to prevent clotting both in vitro and in vivo (heparin), while others may be good for use in vitro but are not practical in vivo because of their toxicity (oxalates).

Anticoagulant agents used in laboratory examination of blood include (1) sodium oxalate in a concentration of 20% at the level of 0.01 mL/mL (2 mg/mL) blood; (2) *Sodium Citrate*, USP, in a concentration of 25% at the rate of 0.01 mL/mL (2.5 mg/mL) blood; (3) *Edetate Disodium*, USP (Endrate, Sodium Versenate), to prevent coagulation when used in a concentration of 1 mg/5 mL blood, the anticoagulant property being related to its ability to chelate calcium; and (4) heparin sodium to prevent coagulation (75 units to each 10 mL whole blood).

Any of these anticoagulants may be added to sample tubes in the desired amounts and evaporated to dryness. Sterile vacuum tubes that contain appropriate anticoagulants and double needles for ease in blood collection are available.

Anticoagulants used for blood and blood component transfusions ideally should maintain the function of the individual components and have preservative effects. Anticoagulant agents used for blood and blood plasma transfusion include (1) *Acid Citrate Dextrose*, USP (ACD solution), consisting of sodium citrate 25 g, citric acid 8 g, dextrose 24.5 g, and distilled water to make a total volume of 1000 mL, given at the level of 15 mL/100 mL blood. Several commercial firms prepare vacuum bottles containing these or comparable ingredients. The toxicity of citrated blood injected intravenously varies with rate of injection and total dose. The lethal dose of sodium citrate for the dog is estimated to be about 132 mg/kg after extensive hemorrhage; in the normal intact dog the lethal dose is about 286 mg/kg. (2) Citrate-phosphate-dextrose-adenine (CPDA-1) is now the most commonly used anticoagulant in human and veterinary transfusion medicine. It can maintain a high level of erythrocyte posttransfusion viability for up to 20 days in dogs (Price et al. 1988).

Other means also may prevent or retard coagulation. These are cold, at 2-5° C, and collection of blood into a receptacle having smooth and unwettable walls, e.g., paraffin or silicone coated. Silicone coating is the most effective method for many types of mechanical devices used for implantation, transfusion, and dialysis.

Systemic Anticoagulants. Two types of anticoagulants are used therapeutically for preventing enlargement of thrombi. Heparin used parenterally has a direct and almost instantaneous action on the coagulation process, whereas the coumarin derivatives (for oral administration) have an indirect anticoagulant effect by acting as vitamin K antagonists in the hepatic synthesis of certain coagulation factors. Therefore, action by the coumarin derivatives is delayed for several hours. For emergency treatment, heparin is used first and then may be followed by the coumarin derivatives.

Other anticoagulants include edetate sodium, sodium oxalate, and sodium citrate, which hinder coagulation by combining with calcium. However, these agents are not effective in vivo because lowering ionized calcium to the anticoagulant level is incompatible with life. Dextran sulfate has anticoagulant properties but its activity is variable; its use is limited to a plasma expander.

Both categories of the systemic anticoagulants act by inhibition of the action of formation of one or more clotting factors (see Fig. 28.2). This implies that these drugs exert their action by evoking a clotting defect similar to that of clinical diseases. Consequently, there is a relatively narrow therapeutic ratio, since hemorrhage can occur as a result of individual susceptibility or an interaction with other drugs used simultaneously (Szabuniewicz and McCrady 1977).

HEPARIN. Heparin (Heparin sodium, USP; Heparin calcium, Calciparine) is the only parenteral anticoagulant available and is also the most commonly used anticoagulant in veterinary medicine. It can be used in vivo and in vitro. Heparin has both antithrombotic and anticoagulatory effects, which are not necessarily dependent on each other. Heparin is prepared from bovine lung tissue or porcine intestinal mucosa. Both calcium and sodium salts of heparin are available for therapeutic use and occur as a white hygroscopic powder that is easily soluble in water. In human medicine recent research has focused on synthetic heparinoids and the clinical applicability of heparin fractions of various molecular weights.

CHEMISTRY AND MECHANISM OF ACTION. Pharmaceutical-grade heparin is a heterogeneous mixture of anionic sulfated mucopolysaccharides with molecular weights ranging from 1200 to 40,000 daltons. Relative antithrombotic and anticoagulatory activity is related to molecular size. The variability in both molecular composition and biologic activity necessitates standardization of drug concentration by bioassay of anticoagulant activity (expressed as units).

The reversible binding of heparin to antithrombin III (AT III), a protease inhibitor, is responsible for most of the anticoagulatory effect of heparin. Affinity for AT III is dependent upon molecular size (Fareed et al. 1985). Binding to AT III causes a conformational change in the AT III molecule that significantly enhances its inhibitory effect on various activated coagulation factors, especially thrombin and activated factor X (Xa). The rate of inactivation can increase 2000- to 10,000-fold. After inactivation has occurred, the heparin molecule dissociates from the complex and is available for further interactions. In a pharmaceutical heparin preparation, only 30-50% of the heparin molecules present will bind to AT III. Heparin acts as a template to which thrombin and AT III can bind and thereby interact to form an inactive compound. Simultaneous binding of factor Xa to AT III and heparin is not required for inactivation. Low-molecular-weight (LMW) fractions of heparin inactivate only factor Xa because they are not large enough to bind thrombin and AT III concurrently. The additional inactivation of thrombin by high-molecular-weight (HMW) fractions of heparin increases their anticoagulatory ability. At higher dosages heparin can also bind to heparin cofactor II, which inhibits only thrombin. Heparin also binds to endothelial cell walls, imparting a negative charge, affects platelet aggregation and adhesion, and increases levels of plasminogen activator (Hirsh et al. 1992a). In addition, it recently has been found that heparin administration leads to an increase in the levels of tissue factor inhibitor (Ostergaard et al. 1993). These effects all contribute to the anticoagulatory and antithrombotic action of heparin and vary with the individual heparin fractions. An additional effect of heparin that does not seem to be related to hemostasis is the ability to liberate lipoprotein lipase, which lowers serum triglyceride levels. This characteristic can be used to detect lipoprotein lipase deficiency.

The pharmacokinetics and pharmacodynamics of heparin are very complex. Most of an administered dose of heparin is bound extensively to endothelial cells, macrophages, and plasma proteins, which act as storage pools. Once these pools have been saturated, free heparin appears in the plasma and is excreted slowly by the kidney. Heparin is metabolized by the liver and also by the reticuloendothelial system (RES). Clearance of LMW fractions is slower than that of HMW fractions, which leads to their cumulation in the organism. All of these factors cause the kinetics of heparin to be highly variable between individuals and within the individual. A fixed dose cannot be expected to produce a uniform level of anticoagulation or antithrombotic effect. In addition, since most of heparin efficacy is dependent on AT III, low levels of this protein will result in reduced anticoagulant activity. Biologic half-life is variable and depends upon the dosage administered and the route of administration. Subcutaneous administration leads to slow release of heparin and has been found to have an effect equivalent to intravenous heparin for the prophylaxis of thrombosis. Intravenous administration leads to high initial levels with a short half-life.

CLINICAL USE. Heparin has a variety of uses in veterinary medicine. In humans it is used widely, especially in the prevention of venous thrombosis. Its use in the treatment of established thrombi is also advocated. The predominant use of heparin in veterinary medicine has been in the management of disseminated intravascular coagulation (DIC) and other potentially hypercoagulable states (Cushing's disease, nephrotic syndrome, cardiomyopathy). Low-dose heparin has been reported to decrease the complications associated with heartworm adulticide treatment (Vezzoni and Genchi 1989). It may also be of benefit in the treatment of severe pancreatitis (Wright and Goodhead 1970).

The major adverse side effect in animals is excessive anticoagulation leading to hemorrhage. Intramuscular administration is contraindicated, as it may lead to extensive hematoma formation. In horses, treatment for several days with doses of heparin that were believed to produce therapeutically desired levels of anticoagulation led to a significant (50%) drop in red blood cell (RBC) mass. This may have been associated with increased RBC removal by the RES (Duncan et al. 1983). Erythrocyte agglutination has also been associated with heparin therapy in horses (Mahaffey and Moore 1986).

Guidelines for heparin dosage vary widely. Both high-dose and low-dose regimens have been developed, their applicability will depend upon the clinical indication. High-dose heparin therapy aims to increase APTT 1.5-2.5 times baseline or ACT 1.2-1.4 times baseline. Its main clinical indication is the treatment of established thromboemboli. The amount of heparin required to achieve this goal will vary with each individual and, since the pharmacokinetics are nonlinear, will vary with each dose administered. In dogs 150-250 U/kg TID and in cats 250-375 U/kg TID will usually suffice to achieve this goal. A higher loading dose may be of benefit. Regular and frequent monitoring of clotting times is essential. Severe anemia was detected in horses administered dosages that led to the desired prolongation of clotting times after several days of treatment. Low-dose regimens are generally 75 U/kg TID in small animals and 25-100 U/kg TID in horses. This regimen is especially useful in the management of DIC. The effect on APTT should be minimal with low-dose heparin therapy, yet antithrombotic efficacy should be maintained. Bleeding tendencies also are reduced.

Vitamin K Antagonists

COUMARIN DERIVATIVES. Vitamin K antagonists are administered orally; the most important group of the oral anticoagulants are the coumarin derivatives. Coumarin, normally present in some species of sweet clover, has no anticoagulant action. However, bishydroxycoumarin, a derivative of moldy or spoiled sweet clover, is responsible for a hemorrhagic disease in cattle. This compound was synthesized by Link (1943-44). Other drugs have been synthesized with the 4-hydroxycoumarin structure. Of the several coumarin derivatives, bishydroxycoumarin (*Dicumarol*, USP) was the first oral anticoagulant and 3-(α-acetonylbenzyl)-4-hydroxycoumarin (*Warfarin Sodium*, USP; Panwarfin, Coumodin) was the second compound used.

CHEMISTRY. Dicumarol is a colorless, crystalline solid; it is relatively insoluble in water but forms soluble salts with strong alkalies. The chemical structures of coumarin, dicumarol, warfarin, and menadione are shown in Fig. 28.3. The structure of vitamin K suggests the competitive relation between the vitamin and these inhibitors. Bioavailability of warfarin is much greater than dicumarol because it is approximately 75,000 times more soluble in aqueous media. Warfarin is extensively used as a rodenticide because it produces fatal internal bleeding. Domestic animals also may be poisoned accidentally.

ACTION. Coumarin derivatives share one major pharmacologic action: in vivo inhibition of blood coagulative mechanisms. This activity is achieved not by direct depression of preformed components of the coagulation cascade but by inhibition of hepatic synthesis of vitamin K-dependent clotting factors, i.e., prothrombin and factors VII, IX, and X (Fig. 28.2). Unlike heparin, therefore, coumarin compounds are inactive in vitro. Their in vivo anticoagulant activity is apparent only after a latent period of at least 8-12 hours, which accounts for the time required for natural breakdown of circulating factors already present in the blood. After cessation of administration, anticoagulant effects can last for several days. This reflects the time necessary for reappearance of newly synthesized clotting factors.

The formation of functional clotting factors II, VII, IX, and X is dependent upon the presence of vitamin K. After the precursor proteins of these clotting factors have been synthesized in the liver, they must undergo carboxylation of terminal glutamic acid residues. The carboxylation results in the oxidative inactivation of vitamin K. The resulting vitamin K epoxide is then recycled by epoxide reductase so that it can again participate in the conversion of precursor proteins to functional clotting factors. Vitamin K antagonists exert their effect by inhibiting epoxide reductase. This results in a rapid depletion of vitamin K stores. The coagulation factors are still produced but are not functional.

Experimental evidence indicates that vitamin K and dicumarol are mutually antagonistic (O'Reilly 1972). Administration of vitamin K can reverse hypoprothrombinemia produced by coumarin compounds. This action is clinically important where there is an unusual response to dicumarol, as in overdosage or accidental ingestion. The antidotal effect of vitamin K and its clinical use have been discussed. The characteristics of coumarin derivatives and those of heparin are shown in Table 28.4.

ABSORPTION AND METABOLISM. Dicumarol, as other coumarin derivatives, is absorbed from the GI tract; over 90% is bound to plasma protein and some is stored in the liver. This binding is reversible and is in part responsible for the long plasma half-life of these drugs. Despite this property, the drug displays great variability in action. This may be due to variable metabolic transformation, GI absorption, a possible influence of diet (amount of vitamin K), and interaction with other drugs. Dicumarol is hydroxylated by hepatic enzymes to inactive compounds that are excreted in urine; the metabolites have no anticoagulant effect. Variations in rate of metabolism are due in part to genetic factors. A small quantity, if any, appears unchanged in urine. However, coumarins cross the placenta and are probably secreted in milk (Szabuniewicz and McCrady 1977).

LABORATORY CONTROL. Because of variability in individual and species response to dicumarol, laboratory monitoring of prothrombin activity is essential in its clinical use. The most widely used method for regulating dosage of the drug is the Quick test, or the one-stage prothrombin time. The prothrombin time for a patient on oral anticoagulant therapy should be two to two and one-half times the control value for that individual.

CLINICAL USE. Clinical use of dicumarol in humans has been rated as effective for prophylaxis and treatment of venous thrombosis. All coumarin derivatives can cause one principal side reaction, hemorrhage. However, bleeding rarely occurs if the dose is regulated in relation to prothrombin test results. Contraindications include bleeding from any cause, purpura of any type, or a severe state of malnutrition. The coumarin drugs have received little clinical use in animals.

DRUG INTERACTION. Drug interactions may be associated with the process of absorption, distribution, binding, metabolism, and excretion. A large number of interactions may potentiate or inhibit the anticoagulant action of the coumarin group of drugs. The most important prescribed drugs that may increase the response are phenylbutazone, heparin, salicylates, quinine, broad-spectrum antibiotics, and anabolic steroids. Among those that may decrease response are barbiturates (by induction of liver microsomal enzymes), chloral hydrate, and griseofulvin. Experimentally, it has been shown that the hypoprothrombinemic activity of orally administered dicumarol is nullified in sheep pretreated with phenobarbital (Shetty et al. 1972).

TABLE 28.4—Pharmacologic characteristics of heparin and coumarin derivative anticoagulants

Characteristic	Heparin	Coumarin derivatives
Mechanism of action	Antagonist to thrombin and activated factors IX, X, XI, and XII	Inhibit hepatic synthesis of vitamin K-dependent clotting factors (II, VII, IX, and X)
Onset of action	Immediate	Delayed 12–24 hr
Duration of action	4 hr	2–5 days
Route of administration	Parenteral	Oral
Laboratory control test	Clotting time, partial thromboplastin time	Prothrombin time
Antidotal therapy	Protamine, fresh blood	Vitamin K, fresh blood or plasma
In vitro activity	Yes	No

Coumarins may inhibit metabolism of phenytoin. Some physiologic factors may increase the action of coumarins; e.g., hepatic dysfunction, hypermetabolism, and vitamin K deficiency resulting from poor absorption. Other physiologic factors may decrease response to anticoagulants, e.g., pregnancy and diuresis.

ADMINISTRATION. The dosage of oral anticoagulants in dogs is based on the schedule used in humans. Dicumarol is given on the first day at 5 mg/kg; the average daily maintenance is one-third to two-thirds the first day's dose and is dependent on daily prothrombin time determinations. When prothrombin activity is reduced to less than 25%, the drug must be discontinued.

Dicumarol is available in 25, 50, and 100 mg capsules and tablets. Warfarin is available in tablet form (2-25 mg) and for parenteral use (25 mg/mL).

OTHER ORAL ANTICOAGULANTS. In addition to dicumarol and warfarin, other oral anticoagulants have been developed. These include phenprocoumon, acenocoumarol, and the indandione derivatives. These compounds have little if any clinical use in animals.

FIBRINOLYTIC AGENTS. The basic event of fibrinolysis is abstracted in Fig. 28.2. Pharmacologic acceleration of this process involves drugs that enhance the conversion of the inactive precursor plasminogen to the active fibrinolytic enzyme plasmin (Sherry and Gustafson 1985). Plasminogen exists in two phases, the plasma or soluble phase found in the circulating blood and the gel phase bound to fibrin in the formed clot. Thus when a plasminogen-activating agent comes in contact with the clot, fibrin-bound gel-phase plasminogen is activated to plasmin locally with selective fibrinolysis. There is increased tendency for systemic bleeding if, instead, soluble-phase plasminogen is also activated. Plasmin formation would then occur throughout the circulation rather than being localized to the formed clot. Indeed, the presence of plasmin in peripheral blood indicates a pathologic fibrinolytic state. Such a condition reflects overactivation of plasminogen, which overcomes the neutralizing capacity of an endogenous antagonist to plasmin called α_2-antiplasmin.

Fibrinolytic activity can be activated or inhibited by several additional endogenous and exogenous agents. Common activators are hormones (androgens, corticosteroids, growth hormone), enzymes (streptokinase, staphylokinase), epinephrine (exercise, stress), and agents from the body fluids (urokinase, thrombin). Inhibition may result by preventing activation of plasminogen (ε-aminocaproic acid, calcium, and antibodies to streptokinase or staphylokinase) or prevention of action of plasmin (antiplasmin α_1, α_2-globulin) (Szabuniewicz and McCrady 1977).

Clinical Aspects. Overactivity or underactivity of the fibrinolytic mechanism may result in hemorrhage or vascular thrombi respectively. Overactive fibrinolysis has been recognized in a variety of pathologic conditions in humans (e.g., shock, blood disorders, hepatic cirrhosis, snakebite, and following lung surgery). In these conditions, excessive fibrinolytic activity may be present in association with rapid digestion of prothrombin by plasmin or inhibition of other factors (V, VII, and VIII). Two drugs are available for treatment of hyperfibrinolytic conditions: *Aminocaproic Acid*, USP (Amicar, Caprocid), and a biologic inhibitor, aprotinin (Transylol). Aprotinin is a kallikrein or protease enzyme inhibitor. In humans, underactive fibrinolysis is postulated to play a role in occlusive vascular disease, as in myocardial infarction, pulmonary thromboembolic disease, massive postsurgical adhesions, and such unrelated processes as inflammation and malignancy. It appears possible to enhance fibrinolytic activity with drugs. Those undergoing clinical trials for human use are sulfonylurea in nondiabetic subjects (tolbutamide, chlorpropamide), anabolic steroids (ethylestrol, methenolone), clofibrate (Atromid-S), and biguanidine (phenformin, metformin).

Experimentally, postoperative adhesions have been successfully prevented in the dog with urokinase (Gervin et al. 1973). Anticoagulants (heparin or coumarins) are effective only in prevention of thrombi and have little or no effect on fibrin already formed.

Streptokinase is available for clinical use. It is a stable, vacuum-dried powder containing streptococcal enzymes. Streptokinase activates human plasminogen to the humoral proteolytic enzyme plasmin. Plasmin liquefies fibrin or clotted blood. The conversion of animal plasminogens to plasmins by streptokinase is variable. Local use is indicated whenever removal of fibrin or a viscous exudate is desired and drainage can be achieved. Clinical trials have demonstrated its usefulness in treatment of wounds not responding to antibacterial therapy, such as burns, ulcers, chronic eczema, ear hematoma, otitis externa, sinusitis, cysts, fractures with fistulous tracts, and osteomyelitis. Locally, it can be administered as a powder or wet pack by infusion or irrigation. Liquefaction of blood clots and fibrinous exudates may occur in 30 minutes to 12 hours.

Parenteral administration has been used in treatment of ulcers, eczema, dermatitis, edema, cellulitis, hematoma, trauma, and pneumonia. For parenteral use, the solution may be administered intramuscularly or intravenously. The daily dose for large animals is 5000-10,000 units/45 kg. The recommended total daily dose for small animals is 5000-10,000 units. Therapy may be given 1 or 2 times daily for up to 5 days.

Streptokinase-streptodornase is available in vials containing 100,000 streptokinase units, 25,000 streptodornase units, and 500 plasminogen units. It is recommended that antibacterial agents be administered simultaneously with the enzyme preparation. Anaphylactic reactions may occur following parenteral use. The product is contraindicated in the presence of a blood dyscrasia.

Fibrinolysin (Thrombolysin, Actase) is an enzyme preparation derived from a fraction of human plasma. It is prepared by action of streptokinase on human profibrinolysin and is potentially useful in treatment of thrombosis and embolism. The drug has several unpleasant side effects. In humans a dose of 50,000-100,000 units/hr by IV drip for 1-6 hr/day is recommended; this dose may be given 3-4 days. An effective antagonist of fibrinolysin is aminocaproic acid.

Urokinase (Win-Kinase, Abbokinase, Breokinase), excreted in human urine, is an activator of plasminogen. It is believed that this preparation may have some advantages over streptokinase. It purportedly prevents serosal postoperative adhesions in 80% of the dogs when administered as a lavage in a dose of 5000-10,000 units/kg into the peritoneal cavity.

Bisorbin lactate (EN 1661) is a synthetic fibrinolytic drug in the investigational phase; it resembles urokinase in action.

Tissue Plasminogen Activator. Tissue-type plasminogen activator (t-PA) predominantly exerts its effect in association with fibrin clots. Its specificity for clots is therapeutically attractive. Unlike other plasminogen activators, t-PA does not induce a systemic proteolytic state. Though the commercial product is recombinant DNA produced human-type tissue plasminogen activator, its efficacy has been demonstrated in cats (Pion 1988). In addition, the local application of t-PA has been found efficacious in reducing intraocular fibrin deposition (Gerding et al. 1992). The major clinical use to date has been the lysis of aortic thromboemboli in cats. Intravenous administration of t-PA resulted in a rapid return to function. However, 50% of the animals treated died acutely after treatment. This was attributed to the rapid reperfusion of the rear extremities, which resulted in hyperkalemia and heart failure. A factor that may limit the use of t-PA is the expense of the drug.

ANTIPLATELET DRUGS. Platelets have a central role in the initiation and propagation of thrombus formation. They release a variety of substances that promote coagulation, and they also form the initial platelet plug. Platelets begin to adhere and aggregate in response to a myriad of stimuli. The central process in aggregation is alteration of cAMP levels in the platelet. Increased cAMP is inhibitory, while decreased cAMP is proaggregatory. It is important to remember that a variety of stimuli influence platelet function in vivo, but many of the in vitro methods used to assess platelet reactivity and the effectiveness of antiplatelet drugs suffer from the inability to truly recreate the in vivo environment. Another factor that leads to difficulties in assessing clinical efficacy based on experimental work is that platelet reactivity varies between individuals and with health status.

A variety of drugs are used to reduce platelet function. Clinically this should be beneficial in the prevention of thrombotic disease, especially if affecting arteries. In humans the efficacy of some of these drugs in the prevention of myocardial infarction and stroke has been proven. The most common indications in veterinary medicine are to prevent thrombi associated with feline cardiomyopathy and to reduce the severity of pulmonary endarteritis associated with heartworm disease. The efficacy of antiplatelet drugs in alleviating the proliferative changes in arteries associated with heartworm infestation remains controversial (Boudreaux et al. 1991a; Keith et al. 1983; Schaub et al. 1983). Platelet inhibition may also be beneficial in membranous glomerulonephritis, mild DIC, and pulmonary thromboembolism as well as in the reduction of metastasis. In horses platelet inhibition may be of benefit in the treatment of thrombotic disorders such as laminitis and navicular disease.

Aspirin. The only commonly used antiplatelet drug in veterinary medicine is aspirin (acetylsalicylic acid, ASA). Aspirin is a nonsteroidal anti-inflammatory drug (NSAID) that inhibits the activity of cyclooxygenase. Other NSAIDs, such as phenylbutazone and flunixin meglumine, share the same mechanism of action, yet aspirin is unique in that even at low doses it causes irreversible inhibition of platelet cyclooxygenase. Aspirin acetylates this enzyme, which leads to decreased production of eicosanoids by the platelet. The most pivotal eicosanoids for hemostasis are prostacyclin (PGI_2) and thromboxane A_2 (TA_2). PGI_2 is a potent vasodilator and inhibitor of aggregation, while TA_2 is a vasoconstrictor and a strong aggregatory stimulus.

Aspirin is rapidly absorbed after oral administration. Hydrolysis of the acetylsalicylic acid yields salicylate and acetic acid. In the liver the salicylate is conjugated with glucuronic acid, which can then be excreted by the kidney. Animals, such as cats, with a relative deficiency of glucuronyl transferase activity will have prolonged ASA half-lives, which can lead to cumulation and toxicity.

Once ASA has been administered, rapid and irreversible inhibition of platelet cyclooxygenase occurs. Since platelets do not produce appreciable amounts of new enzymes, this results in decreased platelet aggregation response because of lower TA_2 levels throughout the life span of the platelet. Aggregation response will return to normal as new platelets enter the bloodstream. Endothelial cell cyclooxygenase activity is also inhibited but recovers more rapidly. This inhibition is considered deleterious since endothelial cells produce PGI_2, which is antithrombotic. Proposed explanations for the more rapid recovery of endothelial cell cyclooxygenase activity include reduced sensitivity to ASA of the endothelial cell cyclooxygenase, ability to synthesize new cyclooxygenase, and the pharmacologic distribution of ASA (Hirsh et al. 1992b). The last theory postulates that platelets are exposed to ASA in the enterohepatic circulation before ASA is hydrolyzed. At low doses endothelium will primarily be exposed to circulating salicylate rather than ASA. Higher doses will result in circulating ASA leading to endothelial cell cyclooxygenase inhibition. The differential inhibition of platelet and endothelial cell cyclooxygenase has resulted in research efforts to find an ideal dose of ASA that will maximally limit proaggregatory platelet TA_2 and minimally decrease levels of antithrombotic PGI_2. In addition, low dosages should minimize the gastrointestinal side effects seen with ASA. The goal of finding an optimum low ASA dose has proven elusive. In healthy dogs individual variation in the amount of ASA required to inhibit aggregation in vitro is marked. Experimental infestation and embolization with heartworms lead to a pronounced increase in the amount of ASA needed to maintain this level of inhibition (Boudreaux et al. 1991a).

Dosage recommendations for platelet inhibition vary widely. In healthy dogs a dose of 0.5 mg/kg BID was found to be more effective than higher doses (Rackear et al. 1988). A dose of 10 mg/kg has been recommended to reduce the sequelae of heartworm infestation and adulticide treatment (Keith et al. 1983). In cats 25 mg/kg twice weekly has been found to inhibit platelet aggregation without evidence of toxicity (Greene 1985). Experimental studies in horses showed that oral ASA (12 mg/kg) significantly increased bleeding times for 48 hours posttreatment (Trujillo et al. 1981). A lower dose (4 mg/kg) prolonged bleeding times for 4 hours posttreatment (Cambridge et al. 1991).

Ticlopidine. Ticlopidine is an antiplatelet drug that is undergoing extensive testing for use in the prevention of thrombotic diseases. In humans it has been proven to be as effective as ASA in the prevention of stroke. The mechanism of action of ticlopidine is unclear. It is postulated that the drug affects platelet membranes, possibly by inhibiting the formation of fibrinogen receptors (Di Minno et al. 1985). The drug limits platelet aggregation response to a variety of stimuli. Cyclooxygenase is not inhibited, so endothelial PGI_2 levels are not affected. Inhibition of aggregation persists for the life span of the platelet. Onset of antiplatelet effect is approximately 2-5 days after treatment is initiated, possibly indicating that an intermediate breakdown product is the agent actually responsible for the clinical response. Experience with ticlopidine in veterinary medicine is limited. In healthy animals 62 mg/kg daily inhibited platelet aggregation responses. In heartworm-infected and heartworm-embolized dogs, higher dosages were necessary (Boudreaux et al. 1991b). Ticlopidine administration was associated with a reduction of pulmonary lesions caused by the heartworms.

Dipyrimadole. Originally marketed as a vasodilator, dipyrimadole has been shown to have a synergistic effect with ASA. It inhibits cAMP phosphodiesterase, which leads to increased cAMP levels in the platelet. If used alone, its effect on platelets is minimal (Boudreaux et al. 1991a).

BLOOD GROUPS

Antigens. Blood cells of each species are grouped according to antigens located on the red blood cell (RBC) surface, which determine the immunological specificity of the cell. The number of antigens that have been detected varies among species. Although canine blood has been characterized by at least 11 blood groups (Stormont 1982), 8 are generally recognized and are designated as DEA (dog erythrocyte antigen) 1.1,1.2, and 3 through 8 (Dodds 1985). Of these, DEA 1.1, 1.2, and 7 are the most common clinically significant antigens. The cat has 3 blood groups, designated A, B, and AB. Types A and B are unrelated to human blood groups. Both are allelic, with the A allele expressing dominance over B. The incidence of each blood type is characterized by marked geographic differences both outside and in the United States. Type A is by far the most common, with an incidence ranging from 99% in the United States to 70% in Australia (Cotter 1991; Giger et al. 1989; Auer and Bell 1981). A very low incidence of type AB (0.4%) has been reported (Auer and Bell 1981; Giger and Bucheler 1991; Authement et al. 1987). In the United States, only 0.1% or fewer cats have been identified as having type AB blood. Type A is also the most common in purebred cats; approximately 10% have type B blood. Breeds such as Abyssinians, Persians, Himalayans, and Rex appear to have a higher incidence of type B (Norsworthy 1992). Some catteries have exclusively type B cats. No Siamese cats have been reported to have type B. Cats lacking both type A and B antigens have not been identified. Ferrets thus far have not proven to have demonstrable blood groups that correspond to human or animal typing.

Large animals have numerous blood groups. Bovine blood has 11 phenogroups in the A system, 1000 in the B system, and 100 in the C system. While blood group variation in the horse is smaller, at least 30 factors have been segregated into 8 genetic systems (Stormont 1982).

Isoantibodies. Plasma contains isoantibodies whose activity is directed toward antigens on RBCs from animals of the same species. Naturally occurring isoantibodies are genetically determined and are present when an animal receives its first blood transfusion. A transfusion reaction may occur with the first transfusion if the recipient plasma contains isoantibodies directed toward the donor RBC antigens. A less severe reaction can occur if the donor plasma contains isoantibodies directed toward the recipient RBC antigens. However, the incidence of clinically important natural isoantibodies is low, and incompatible antigen-antibody reactions are uncommon with initial blood transfusions (Stormont 1982; Dodds 1985). Anti-DEA 7 is the most common isoantibody in dogs, present in about 50% of the canine population. About 45% of the blood tested in dogs contains DEA 7 (Cotter 1991). Shortened survival of DEA 7 blood following transfusion into DEA 7-negative dogs has been documented (Cotter 1991). However, routine cross-matching procedures generally do not test for this reaction (Cotter 1991). Cats with either A or B types have naturally occurring isoantibodies, but the anti-A antibody is stronger and responsible for most of the serious incompatibility reactions. In Australia, the blood of approximately 35% of type A cats contains isoantibodies against type B cells. However, these antibodies are only weakly agglutinating when the titer is less than 1:2, and thus transfusion reactions are absent or mild (Auer and Bell 1981; Giger and Bucheler 1991). Destruction occurs extravascularly due to IgM and IgG. In contrast, approximately 70% of type B cats have strong isoagglutinins (titers > 1:8) to type A. Thus, cats with type B blood are at a greater risk for serious transfusion reactions (Auer and Bell 1981; Giger and Bucheler 1991). Cats with type AB blood apparently do not have isoantibodies to either type A or B. Destruction of RBCs occurs intravascularly and is complement- and IgM-mediated (Giger and Bucheler 1991). In cows, anti-J are the most important isoantibodies. Bovine RBCs do not agglutinate easily, but isohemolysins are important. Anti-R isoantibodies are most important in sheep, for which both isoagglutinins and lysins exist (Hunt and Moore 1990).

In addition to naturally occurring isoantibodies, administration of whole donor blood containing antigens foreign to the recipient will stimulate formation of new isoantibodies directed against donor RBCs. Antigens DEA 1.1 and 1.2 (often referred to as type A) (Cotter 1991) are the most likely canine antigens to sensitize a recipient, and cross-matching procedures concentrate on these antigens (Cotter 1991). For example, administration of blood containing DEA 1.1 antigens to a DEA 1.1-negative recipient will result in the formation of anti-DEA 1.1 antibodies in the recipient. Formation of new antibodies will take 10-14 days. Approximately 25% of random primary (i.e., first) transfusions in dogs cause DEA 1 antibody formation (Tangner 1982). As a result, the recipient may develop a delayed transfusion reaction to the first transfusion, or severe immunological reactions can develop upon subsequent readministration of DEA 1 blood. The incidence of transfusion reactions following a random second blood transfusion has been estimated to be 15% in the dog (Stormont 1982; Dodds 1985). A foreign antigen's potential for stimulating antibody production varies with each antigen. DEA 1.1 and 1.2, which together occur in about 60% of the canine population, are the most likely to stimulate antibody production in canine recipients. Thus, the administration of blood from DEA 1.1 or 1.2 dogs should be avoided, particularly in animals that may require a second transfusion at a later date. Destruction of transfused RBCs is accelerated when transfused into incompatible animals. In cats, mean survival time (time when one-half of the transfused cells have been removed from the circulation) of autologous (from the same animal) washed RBCs is 38 ±2 days. Mean survival time of same-type transfusions (e.g., type A cat receiving type A) is 30 days, and that of different-type transfusions is less than 15 days. If type A blood is transfused into a type B cat, the survival time is less than 2 hours (Norsworthy 1992). Repeated transfusions are characterized by an even shorter RBC mean survival time of less than 5 days (Marion and Smith 1983a; Turnwald 1985). In cows, horses, and goats, the short survival times characterizing RBCs from seemingly compatible animals have been attributed to naturally occurring isoantibodies (Cotter 1991).

Cross-matching detects the presence of both natural and induced isoantibodies in plasma of either the recipient (major cross-match) or the donor (minor cross-match) (Authement et al. 1987). It does not prevent sensitization; rather, it detects what has already occurred (Cotter 1991). The major cross-match is the most important of the two and can be relatively easily performed on fresh blood. Cross-matching is particularly essential for animals that have received a transfusion within the past 4 days (Dodds 1985; Lees 1985; Marion and Smith 1983b; Cotter 1991). Feline typing reagents are not readily available. However, major cross-matching may detect incompatible transfusions (Cotter 1991). Cross-matching may be of limited value in horses and cows. Shortened RBC survival has been documented at days 3 and 4 posttransfusion in cross-matching compatible animals of both species (Hunt and Moore 1990). Nonetheless, major and minor cross-matching is frequently performed for horses (Hunt and Moore 1990; Morris 1983).

The life span of compatible, transfused, nonstored RBCs should be similar to that of normal RBCs. Transfusion of incompatible cells can result in immediate destruction or delayed destruction, depending on rapidity of antibody production. Decreased survival as early as 3-4 days posttransfusion has been noted for several large animal species (Cotter 1991); increased destruction at 2-21 days posttransfusion has been noted for dogs and cats (Tangner 1982; Marion and Smith 1983a). Prolonged storage of RBCs will also reduce survivability (Marion and Smith 1983b).

DONORS. Canine donors should be young, healthy, and cooperative, with no history of a blood transfusion. Blood collection is easier in shorthaired, lean animals. Dogs should weigh at least 20 kg and cats 4 kg (Pichler and Turnwald 1985; Authement et al. 1987). Cats should have a packed cell volume (PCV) of at least 35% (Homeida et al. 1986). Dogs preferably should be DEA 1- and 7-negative. Greyhounds are often considered to be the ideal canine donor choice because their incidence of these antigens is low (Authement et al. 1987). Female donors should be neutered. Donor animals should be free of blood-transmitted infections. Dogs should be tested for ehrlichiosis, brucellosis, microfilaremia, hemobartonellosis, and babesia; cats should be tested for leukemia, immunodeficiency and infectious peritonitis virus, toxoplasmosis, and hemobartonellosis. Splenectomy of donor animals to cause recrudescence of blood-borne diseases to enhance detection is controversial. Routine care for donor animals should include vaccinations and internal and external parasiticide treatment. Supplemental care for small-animal donors should include adequate dietary intake of vitamins (particularly B_{12}, folic acid, and pyridoxine), minerals (iron), and proteins of meat origin. Records should be kept on donors, particularly with regard to date and amount of collections (Pichler and Turnwald 1985; Lees 1985).

Equine donors should be negative for A, C, and Q RBC antigens (Morris 1983). Male ponies with no previous history of blood transfusion are reasonable alternative donors in the event that cross-matching cannot be performed; these animals generally are negative for clinically important antigens. Bovine donors should not be pregnant and should be free of bovine leukosis virus, anaplasmosis, brucellosis, tuberculosis, noncytopathic bovine virus, diarrhea virus, salmonellosis, *Sarcocystis bovicanis,* and other indigenous blood parasites (Hunt and Moore 1990). Donors should not have been vaccinated for Johne's disease, anaplasmosis, or adult-age brucellosis (Hunt and Moore 1990).

COLLECTION

Materials

RECEPTACLES. Two types of containers are available for collection of blood (Authement et al. 1987; Norsworthy 1992). Vacuum bottles are simple to use because the vacuum allows collection from the jugular vein in small animals. However, the bottle is penetrated during collection, which may allow bacterial contamination of collected blood. Other disadvantages of glass-bottle collection include (1) inability to separate blood components (e.g., plasma or platelets); (2) activation of platelets and some coagulation factors; (3) potential for air embolism; and (4) breakage of the bottle. In contrast, plastic bags remain sterile, separation of components is easy if units with satellite bags (in which the components can be collected) are purchased, and activation of blood components is not as likely as with glass. Plastic bags for single-unit, small-animal, whole-blood collection are less expensive than glass bottles. However, collection is more difficult into plastic bags than into glass bottles because (1) sedation may be needed in small animals; (2) the time necessary for collection is longer; (3) clotting is more likely to occur in the collection tubing; and (4) arterial hemorrhage may complicate femoral arterial collection. Materials designed for blood collection can be purchased from several commercial sources (e.g., Baxter). Products specifically designed for collection from small animals (including small collection bags) can be purchased from Animal Blood Bank, PO Box 6211, Vacaville, CA, 95696 (916-678-3009). A vacuum apparatus is also available (Animal Blood Bank, California) that precludes the need to use arterial sites for collection into plastic bags in dogs. Small plastic bags designed for collection of blood from cats can also be purchased; however, anticoagulant must be added to these bags. Syringes can be used to collect blood from small animals or pediatric animals (Pichler and Turnwald 1985; Lees 1985). For large animals, 1-3 liter plastic transfer bags are available for direct-transfer transfusion of large quantities of whole blood (Eicker and Ainsworth 1984). Anticoagulant-flushed extension sets are used when harvesting multiple units of blood (Hunt and Moore 1990). Blood can also be collected in open-mouthed containers if bags or bottles are not available (Hunt and Moore 1990).

ANTICOAGULANTS. Anticoagulants used for blood collection include ACD (acid, citrate, and dextrose), CPD (citrate, phosphate, and dextrose), heparin, and sodium citrate (Oberman et al. 1981; Authement et al. 1987; Norsworthy 1992). Each has its advantages and disadvantages. Maintenance of normal RBC physiology is an important consideration in selection of the most appropriate anticoagulant. The RBC undergoes significant changes in physiology during storage. The oxygen-carrying capacity of RBCs will change as adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (2,3-DPG) content decline. The oxygen dissociation curve thus shifts to the left, and delivery of oxygen to tissues by the transfused blood is decreased. However, these metabolic changes are largely reversible. Up to 50% of depleted 2,3-DPG is replaced within 24 hours of transfusion, although replacement occurs at the expense of host RBCs (Oberman et al. 1981; Lees 1985). In addition to pH and related changes, stored RBCs may become spherical and rigid and thus less deformable. Once the cells are transfused, their destruction by the host is accelerated if they maintain their abnormal shape (Auer et al. 1982). ACD (14 mL/100 mL blood) will preserve blood for up to 3 weeks. However, CPD (14 mL/100 mL blood) will preserve canine RBCs better and longer (4-6 weeks) due to enhanced preservation of pH, ATP, 2,3-DPG, and RBC deformability (Pichler and Turnwald 1985; Lees 1985). Feline blood can be stored in ACD for at least 30 days (Marion and Smith 1983b). ACD can be prepared by diluting a mixture of 1.8 g (3.6 mL) of 50% dextrose, 1.6 g sodium citrate, and 0.5 g citric acid with enough distilled water to make 50 mL. After sterilization by autoclave, the solution will be sufficient for collection of 450 mL blood. ACD is also commercially available in prepackaged quantities (Blynco Development Company, Sherburn, MN), which can be dissolved in sterile water and used to collect 1 gallon of blood (Hunt and Moore 1990).

Heparin (250-625 units/mL) (Authement et al. 1987) is limited to collection of small quantities of blood (50 mL), such as that needed for pediatric patients or cats. Blood collected with heparin cannot be stored (Authement et al. 1987) since heparin contains no preservatives and will be inactivated within 24-48 hours. Heparin also activates platelets, rendering them nonfunctional, an undesirable effect if the host is deficient in platelets. Sodium citrate (1 part 3.5% solution to 9 parts blood) can also be used for collection of small quantities of blood in dogs and cats. It is the anticoagulant generally used for collection of blood from large animals (Hunt and Moore 1990). Although sodium citrate contains no preservatives or energy sources, it is rapidly metabolized and excreted and therefore safe to the recipient. Collected blood can be refrigerated up to 35 days prior to use.

Collection Procedure. A total of 20-25 mL blood can be collected per kilogram weight of donor dog every 14-21 days. Up to 6 mL per pound, up to a maximum of 50 mL, is recommended for collection from cats (Pichler and Turnwald 1985; Authement et al. 1987; Norsworthy 1992). Up to 20% of a donor's body weight (10-15 mL/kg) can be collected safely at 2- to 4-week intervals (Hunt and Moore 1990). This total can be divided into multiple withdrawals during the prescribed time period, as long as intervals are at least 7 days in dogs and 10 days in cats. The jugular vein is the safest and most efficient site of collection in all animals, but in the dog and cat, suction or vacuum is needed (Pichler and Turnwald 1985). The placement of a sterile jugular catheter is recommended in large ruminants (Hunt and Moore 1990). The femoral artery can also be used for plastic-bag collection in dogs, but this route requires moderate sedation and added care to avoid hemorrhage. Cardiac puncture as a means to collect blood is contraindicated except in terminal (euthanasia) cases or in ferrets (Pichler and Turnwald 1985).

Regardless of the site of blood collection, a sterile preparation is necessary. The puncture must be "clean" to avoid activation of platelets and factors. Blood should be gently mixed throughout collection to equally disperse the anticoagulant. Collected blood should be labeled and dated prior to refrigeration, and the collection should be recorded in the donor's record. The amount of blood collected can be measured by weighing (1 g = 1 mL).

STORAGE AND BLOOD COMPONENTS

Whole Blood and Packed Red Blood Cells. Whole blood contains all blood constituents with the exception of coagulation proteins. Fresh whole blood is whole blood that is administered within 6 hours of collection; coagulation proteins remain active until that time. Packed RBCs are collected from whole blood that either has undergone centrifugation or has been stored at 10° C until red cells have settled by sedimentation. Blood-collection units with integral transfer containers should be used if preparation of RBCs is anticipated. The removal of 225-250 mL of plasma from 500 mL of whole blood will generally result in residual RBCs with a hematocrit between 70 and 80%. As with whole blood, packed RBCs must be refrigerated at 1-6° C and, when stored properly, will have the same expiration date as whole blood. However, packed cells with a hematocrit greater than 80% undergo accelerated aging during storage and have a decreased mean survival time following transfusion. Whole blood or packed RBCs must be maintained (Oberman et al. 1981).

Collected whole blood or packed RBCs should be either used within 24 hours or, in the case of ACD- or CPD-anticoagulated blood, stored at refrigerator temperatures (1-6° C) for the previously described period. Preservation of RBCs can be enhanced by gentle mixing at intervals throughout the storage period and by uniform temperatures. Blood stored in a standard refrigerator should be placed as far back on the shelf as possible to minimize temperature fluctuations, which decrease RBC life span. Refrigerated blood that is subsequently warmed to greater than 10° C should be used within 24 hours (Auer et al. 1982; Lees 1985; Authement et al. 1987; Turnwald 1985). Methods for collection and preparation of component parts have been described by Authement et al. (1987).

Plasma. Storage requirements for blood component parts (e.g., plasma, cryoprecipitate) are different from those for whole blood and packed RBCs. Plasma that has been separated from RBCs can be prepared and stored in several ways. Fresh plasma must be separated from RBCs and administered within 6 hours of collection. Frozen plasma (which contains electrolytes and proteins such as albumin and fibrinogen) can be separated from whole blood at any time following collection up to the expiration date of the whole blood. However, the viability of factors depends on the rapidity with which the blood is frozen after collection, as well as the duration of freezing and the storage temperature. The vitamin K-dependent factors (II, VII, IX, and X) remain stable in frozen plasma (Cotter 1991). Fresh frozen plasma differs from frozen plasma in that coagulation factors V and VIII remain stable; however, it must be frozen within 6 hours after collection, preferably at –40 to –80° C. It can be stored at these temperatures for 1 year or in a household freezer for 3 months, at which time it becomes frozen plasma (Cotter 1991; Authement et al. 1987). Units should be stored individually in boxes. A rubber band should be placed around the plasma bag so that a crease is formed during freezing. The rubber band is removed when the unit is frozen. The loss of the crease prior to administration indicates the unit has been inadvertently thawed (Authement et al. 1987).

Platelets. Platelets and platelet-rich plasma require centrifugation within 6 hours of collection. Platelet yield is greatest when centrifugation occurs at high speeds (1200 G) for a short time (2.5 minutes) at 20° C. After preparation, platelets which are not immediately used should be continuously rocked or intermittently mixed for up to 72 hours at room temperature. Platelets can be stored at 1-6° C without agitation for 48 hours (Authement et al. 1987). However, refrigerated platelets do not maintain their function or viability as well as those stored at room temperature. Platelet products cannot be stored (Marion and Smith 1983b).

Cryoprecipitate. Cryoprecipitate contains concentrated sources of coagulation factor VIII, von Willebrand factor (vWf), fibrinogen, and fibronectin (Cotter 1991). It is the white foamy precipitate formed following centrifugation of partially thawed (slurry consistency) fresh frozen plasma that has been frozen for 6 months or less (Authement et al. 1987). When frozen immediately after collection in a satellite bag, the component can be stored for another year at –40 to –80° C.

CLINICAL USE

Blood. Blood transfusion in small animals is indicated in cases of acute hemorrhage or anemia in which the PCV is less than 20%. Packed cells are preferred in the normovolemic animal so that the administration of isoantibodies and other foreign protein can be avoided.

Blood for therapy of chronic anemia generally is limited to animals with a PCV of less than 10%. Component therapy is indicated for special cases.

ADMINISTRATION. Blood administration requires sterile preparation at the site. Blood should be gently mixed prior to administration. A blood administration set should be used to remove clots and large particles. Filters do not remove microaggregates that may accumulate during storage (Marion and Smith 1983b). An infusion set with a side-arm lever connector is available for the administration of blood collected in a syringe for small animals (Marion and Smith 1983b). A large-gauge intravenous catheter should be used (20 ga in dogs, 22 ga in cats, 23 ga in pediatrics). Larger needles should be used for administration of packed cells; forcing blood through small-gauge needles results in turbulence, which causes hemolysis of RBCs. Whole blood or packed cells may be mixed with normal saline to reduce viscosity (Turnwald 1985). Coadministration of other fluids should be avoided (Authement et al. 1987; Turnwald 1985).

The site of administration is partially dependent on patient size. A large vein is preferred. Intraperitoneal administration may be used for pediatrics. Up to 40% of administered blood will be absorbed in 24 hours, and 82% in 1 week (Turnwald 1985), although the life span of the RBC is probably reduced. Intramedullary administration is also recommended in pediatric patients. Usually the femur—but often the humerus—is the site of administration. Absorption is rapid, with 93% of administered blood absorbed in 5 minutes. Regardless of the site of administration, a filter (80 or 170 μm) should be used to remove macroaggregates which form in blood during storage. Filters can be purchased as part of a blood administration set (straight-type [4C2116] or Y-type [4C2197] blood recipient sets; Fenwal Laboratories, Division of Travenol, Deerfield, IL) or separately but adaptable to a syringe for transfusion of smaller volumes (Hemo-nate Filter).

Blood can be warmed in a 40° C water bath up to 37° C to avoid hypothermia and cardiac arrhythmias in the host animal. Commercially available blood-warming baths and coils are also available (V5420, McGaw Laboratories, Inc., Sabana Grande, Puerto Rico).

The dose of blood necessary to change the PCV can be calculated based on the patient's body weight and the present PCV. Generally, patient PCV and protein do not change until more than 20 mL of blood/kg recipient weight have been transfused. Accurate calculations of total blood volumes necessary to achieve a specific posttransfusion PCV in the recipient can be made from the following formula, in which

$$1 \text{ mL donor blood} = \text{recipient weight (kg)} \times 90 \text{ mL/kg} \times \frac{\text{desired PCV} - \text{recipient PCV}}{\text{PCV of donor}}$$

where 90 mL/kg for dogs (or 70 mL/kg for cats) is the blood volume. Finally, the amount of blood needed for a transfusion can be roughly but rapidly estimated, assuming a donor PCV of 40%, by the formula

milliliters donor blood = 1 mL whole blood
per pound body weight of recipient
per 1% change in PCV desired

(Turnwald 1985). For example, to obtain a PCV of 25% in a 30 lb dog with a PCV of 15%, one would need to transfuse 30 × (25 − 15), or 300 mL, whole blood.

RATE. Regardless of the amount of blood to be transfused, baseline vital signs should be measured and the initial rate of administration should be slow: 0.25 mL/kg during the first 10-30 minutes. In large ruminants, particularly in instances where cross-matching is not feasible, 200 mL can be injected intravenously and a period of 10 minutes allowed to elapse before administering the remaining blood (Hunt and Moore 1990). During this time, the patient should be monitored for volume overload (particularly if it is a cardiac patient) and transfusion reactions. For the remaining period, the rate should be 1-5 mL/kg/hr, although a rate of 22 mL/kg/hr may be used in hypovolemic patients. Fluid therapy is also indicated in hypovolemic (including shock) patients. A rate of 4 mL/kg/hr should be used to administer blood in cardiac patients (Turnwald 1985).

Plasma. Plasma therapy may be indicated for patients whose serum albumin is less than 1.5 g/dL; and fresh frozen plasma may be indicated for patients whose clotting factors are deficient. Cryoprecipitate is indicated for hemophilia, von Willebrand's disease, and other specific syndromes. Plasma and related products containing foreign proteins should be administered cautiously. A total dose of 5-10 mL/kg is recommended with each transfusion. Since plasma contains the majority of donor proteins (including antibodies), transfusion reactions are not uncommon and, as with whole blood, may occur with the initial transfusion. Thus, administration should probably be slower than 2-5 mL/kg/hr.

Transfusion Reactions. When reactions between donor and recipient cells/antibodies are moderate to severe, the reaction is considered to be a transfusion reaction (Authement et al. 1987). Adverse reactions to blood transfusions can be either immunologically or nonimmunologically (Lees 1985; Turnwald 1985) mediated. Immunological responses include immediate (acute) or delayed (chronic) transfusion reactions. *Acute hemolysis* is due to an immediate reaction between donor and recipient antigens and isoantibodies. It can occur with an initial transfusion, but it is more likely to follow subsequent transfusions. The signs of an acute reaction due to hemolysis include nausea, vomition, salivation, tachycardia, hypovolemia, prostration, urticaria, and fever. The use of DEA 1- and 7-negative blood will reduce the incidence of acute transfusion reactions in dogs. *Delayed transfusion reactions* are likely if an unexplained decrease in the PCV occurs 2-21 days after the transfusion. These usually occur within 7-10 days following transfusion and are more likely with repeated transfusions due to sensitization of the donor to recipient RBC antigens. Jaundice may be present. Cross-matching can help reduce the incidence of acute and delayed transfusion reactions. Reactions can also result from white blood cell antigen/antibody reactions.

Nonimmunological adverse reactions to blood transfusion include fever, which indicates bacterial contamination of the blood; vascular overload, indicated by clinical signs of coughing, dyspnea, vomition, and pulmonary edema; energy expenditure in the very debilitated recipient following massive transfusion of energy-depleted blood (i.e., following prolonged storage); and air embolism if glass bottles are used (Lees 1985; Marion and Smith 1983b). Overdosage of the anticoagulant used in the donor blood may also occur following massive transfusion, thus impairing the recipient's coagulation system. Citrate toxicity has been reported following transfusions of blood using ACD or CPD. This results from the chelation of recipient calcium by the anticoagulant in the donor blood and is manifested as hypocalcemic tetany. Liver disease in the recipient may exacerbate this problem (Lees 1985; Authement et al. 1987).

AUTOTRANSFUSION. Autotransfusion involves collection of blood and readministration to the same patient (Niebauer 1991; Zenoble and Stone 1978). Blood can be collected from a healthy patient in anticipation of a future need for blood (within 3 weeks). When using this technique, 3-6 collections should be made over a 10-14 day period. Autotransfusions may also be used in patients suffering hemorrhage into a body cavity from which the blood can be efficiently collected for readministration. Such blood is immediately available and is minimally physiologically affected, and transfusion reactions are avoided. Blood collected from body cavities requires filtering to remove clots and other materials. No anticoagulant is necessary if the blood has been in contact with a peritoneal or pleural surface for longer than 45 minutes. Blood can be simultaneously collected and administered using a butterfly catheter, stopcock, in-line transfusion filter, and syringes (Turnwald 1985). The major disadvantage of this method is that biogenic amines released by defibrination will not be removed from the blood and can cause severe reactions.

BLOOD SUBSTITUTES. Two types of blood substitutes are currently being developed for their ability to carry and deliver substantial amounts of oxygen to tissues: free hemoglobin and fluorocarbons (Lowe 1986; Gould et al. 1985). Free hemoglobin solutions are characterized by a short half-life (20 minutes) and oxygen saturation lower than blood, both of which will decrease oxygen availability in tissues. Fluorocarbons are chemicals which are miscible with blood and can carry as much as 5.25 mL of oxygen per 100 mL of blood, depending upon oxygen tension. While the oxygen-carrying capacity of these compounds is not adequate for total blood replacement, their low viscosity makes them potentially useful in disorders characterized by abnormalities in microcirculation. In addition, the use of these agents in nonvascular tissue (such as the peritoneal cavity) may help supplement oxygen exchange in tissues during respiratory failure.

Oxyglobin® (Biopure Corporation: www.oxyglobin.com) is a hemoglobin-based oxygen-carrying fluid derived from polymerized bovine hemoglobin. Oxyglobin has an average molecular mass of 180 kDa, with 50% of the hemoglobin polymers between 65 and 130 kDa. As such, it has colloidal properties similar to dextran 70 and hetastarch. However, because it is a polymerized hemoglobin, the molecules are much larger than those of hemoglobin, and the compound is not likely to be filtered by the kidney (thus, avoiding renal side effects of hemoglobinuria).

Oxyglobin® increases plasma and total hemoglobin concentration and thus increases arterial oxygen content. Because it is a free solution (rather than in RBCs), antibody formation generally associated with administration of intact RBCs is avoided. However, antigenicity to bovine hemoglobin may result in antibodies, and caution is recommended with repeat administration 10 or more days apart. Repeated administration of the product apparently has not been studied. Because it is a foreign protein, anaphylactic reactions are possible.

Oxyglobin® is eliminated similarly to hemoglobin by reticuloendothelial cells. Its elimination half-life in dogs is estimated to range between 30 and 40 hours. As such, 90% of the drug will be gone within 5-7 days after infusion. As a protein, the compound provides oncotic pressure (draw), and its use in patients already suffering from volume overload (e.g., congestive heart failure) or accidental overdose (>10 mL/kg/hr) can be associated with circulatory overload and its negative sequelae (e.g., pulmonary edema, pleural effusion, increased central venous pressure, dyspnea, or coughing).

Oxyglobin® will mildly decrease PCV immediately postinfusion and will increase total and plasma hemoglobin concentration for at least 24 hours. PCV and RBC counts will not be accurate measures of anemia for 24 hours following administration. Adequate hydration is important, but overhydration should be avoided because of the plasma-expanding properties of Oxyglobin. Administration of other colloidal solutions should be avoided. The most likely side effect is circulatory volume overload. Central venous pressure (CVP) or clinical signs indicative of circulatory overload should be monitored during and immediately following administration of Oxyglobin.

Transient changes or side effects reported by Biopure Corporation following administration of Oxyglobin® include yellow-orange discoloration of the skin, sclera, and gums; red–dark green discoloration of feces; brown-black discoloration of urine; vomiting; diarrhea; and decreased skin elasticity within 48 hours of dosing. The frequency and/or intensity of these clinical signs were dose dependent. The product is intended for one-time use only at a recommended dosage of Oxyglobin® dose of 30 mL/kg IV at a rate of up to 10 mL/kg/hr.

Conditions studied in controlled canine clinical trials included immune-mediated hemolysis ($n = 30$), blood loss (gastrointestinal, traumatic, surgical, rodenticide intoxication) ($n = 25$), and ineffective erythropoiesis (idiopathic, RBC aplasia, ehrlichiosis) ($n = 9$). Relative to pretreatment, plasma hemoglobin concentration significantly increased ($p = 0.001$), and clinical signs associated with anemia (lethargy/depression, exercise intolerance, and increased heart rate) significantly improved ($p = 0.001$) following treatment with Oxyglobin®. Treatment success was defined as the lack of need for additional oxygen-carrying support (i.e., blood transfusion) for 24 hours following the completion of infusion with Oxyglobin®. Success in the treatment group was 95%, compared with 32% in untreated control dogs.

Oxyglobin® may be warmed to 37° C prior to administration. It cannot be frozen but is stable for 24 months. It is approved for use in dogs but apparently has been studied in and is safe in cats. The price will be about $30/kg, although animals may not need the full 30 mL/kg; according to the manufacturer, 10 mL/kg may be sufficient in some cases. Oxyglobin has been used in a number of other species with no apparent adverse effects. Care should be taken to use or dispose of any opened product within 4-5 days. The foil wrap in which the product is enclosed is an oxygen barrier. Exposure to oxygen following removal of the wrap will result in methemoglobin formation of the hemoglobin, which can be detected by brown discoloration of the solution.

BONE MARROW TRANSPLANTATION. Although this technique is not yet clinically practical, it has proven successful and may provide an avenue of therapy for cases of aplastic anemia or pancytopenia in future (Harris and Beck 1986). Transplantation requires matching of donor and recipient major histocompatibility gene complex. The recipient must be "conditioned" to receive the graft by total body irradiation so that the tendency to reject the graft is decreased. Bone marrow is collected from the donor by multiple bone marrow aspirations from long bones using heparin as the anticoagulant. Dimethyl sulfoxide is used as the preservative. The marrow is then transfused intravenously. The cell numbers needed for a successful transplantation depend on the degree of donor-recipient gene matching. Complications include host-versus-graft rejection (the host rejects the transplant) and graft-versus-host rejection, in which the graft is so successful that it rejects (and kills) the host.

The hypothalamus and pituitary control the function of the thyroid, adrenal glands, and gonads. Neurons and endocrine gland cells share the characteristics of being able to secrete chemical mediators and being electrically excitable. Chemical messengers can be secreted as a neurotransmitter or as a hormone. The neuroendocrine systems consist of clusters of peptide- and monoamine-secreting cells in the anterior and middle portions of the ventral hypothalamus. Their fibers project via nerve fibers to terminals in the outer layer of the median eminence. The capillary plexus of the median eminence is proximate to the nerve terminals of the hypophysiotropic neurons which make corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), gonadotropic hormone–releasing hormone (GnRH), and growth hormone–releasing hormone (GHRH). The concentrations of the releasing and inhibitory hormones in the median eminence are 10–100 times as great as in other parts of the hypothalamus because the hormones are stored in the nerve terminals (Rijnberk 1996). The process of neurosecretion is characteristic of the hypothalamic nuclei, which release releasing hormones into the portal hypophysial vessels, which mediate the release of the anterior pituitary hormones such as growth hormone (GH), prolactin (PRL), thyrotropin (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and the proopiomelanocortin (POMC)-derived peptides adrenocorticotropic hormone (ACTH), β lipotropin (β LPH), α melanotropin (α MSH), and the opioid β endorphin (β END). For each of the anterior lobe hormone systems (ACTH, LH, FSH, TSH, GH, and PRL) there is a closed-loop feedback system. Anterior lobe hormone and hypophysiotropic hormone secretions are suppressed by hormonal products of the respective end-organs, such as thyroid, gonadal, and adrenal glands. Some hormones, like PRL, regulate their own secretion by inhibition via short-loop feedback on the hypothalamus. The somatotropes account for 50% or more of the anterior pituitary lobe cells, while other types of anterior lobe cells account for between 5 and 15% of the gland (Rijnberk 1996). Table 30.1 outlines the location of neuroendocrine substances in the nervous system and endocrine organs. Tables 30.2–30.4 show the key features of the structure and function of the hypothalamic regulatory and pituitary hormones. Many of these peptides find their clinical use as agents used for diagnostic tests of pituitary or endocrine end-organ function. Therefore, the related hypothalamic and anterior pituitary hormones will be discussed concomitantly.

The supraoptic (SO) nuclei and periventricular (PV) neurons of the hypothalamus terminate in the posterior

TABLE 30.4—Hormones of the hypothalamus and the pituitary gland

Hormone	Site of action (target organ)	Biologic activity
Hypothalamus		
Gonadotropin-releasing hormone	Anterior pituitary (AP)	Release LH and FSH
Thyrotropin-releasing hormone	AP	Release TSH
Corticotropin-releasing hormone	AP	Release ACTH
Somatotropin-releasing hormone	AP	Release somatotropin
Somatotropin-inhibitory hormone	AP	Inhibit somatotropin output
Prolactin-inhibitory hormone	AP	Inhibit prolactin output
Prolactin-releasing hormone	AP	Release prolactin
Adenohypophysis		
Pars distalis (anterior lobe)		
Somatotropin (growth hormone)	General soma	Body growth (bone, muscle, organs), protein synthesis, carbohydrate metabolism, regulation of renal functions (glomerular filtration rate) and water metabolism; increases cell permeability to amino acids; favors lactation
Adrenocorticotropic hormone (ACTH, corticotropin)	Adrenal cortex	Maintenance of structural integrity of adrenal cortex; regulation of glucocorticoid secretion by zona fasciculata
Thyroid-stimulating hormone (TSH; thyrotropin)	Thyroid	Maintenance of normal structure and function of the thyroid gland; production of thyroxin and analogs
Prolactin (lactogenic hormone)	Mammary gland	Possibly favors lactation
Gonadotropins		
Follicle-stimulating hormone (FSH)	Ovary Testis seminiferous tubules	Growth and maturation of ovarian follicles; germ-cell production (spermatogenesis)
Interstitial cell-stimulating, or luteinizing, hormone (LH)	Ovary	Synergistically with FSH causes estrogen secretion, follicle maturation, and ovulation; corpus luteum development in some species
	Testis Leydig cells	Stimulation of interstitial tissue, androgen secretion
Pars intermedia		
Intermedin (melanocyte-stimulating hormone)	Melanophore cells of amphibia and reptiles	Melanophore-expanding activity with resultant maintenance of skin color (of negligible importance in mammals)
Neurohypophysis		
Antidiuretic hormone (vasopressin)	Renal tubules (distal convoluted)	Regulation of water excretion by resorption of water, pressor effect only in high doses
Oxytocin	Mammary myoepithelium	Letdown of milk by contraction of myoepithelium
	Uterine myometrium	Contraction of uterine musculature to aid parturition and sperm transport

pituitary lobe and secrete vasopressin (antidiuretic hormone; ADH) and oxytocin into the circulation.

ANTERIOR PITUITARY HORMONES AND ASSOCIATED REGULATORY HORMONES

The anterior pituitary hormones can be classified into three general categories: ACTH-LPH, glycoproteins (LH, FSH, and TSH), and somatomammotropins (GH, PRL) (see Table 30.3).

CORTICOTROPIN AND RELATED PEPTIDES

Corticotropin-Releasing Hormone (CRH). CRH-secreting neurons are found in the anterior part of the paraventricular nuclei, and their nerve endings terminate in external layers of the median eminence. CRH is synthesized as part of a 196-amino-acid prohormone and undergoes enzymatic modification to an amidated 41-amino-acid peptide that is identical in humans, dogs, rats, and horses (Mol et al. 1994; Rijnberk 1996). CRH stimulates synthesis and secretion of ACTH i.e., POMC, by pituitary corticotrophs. CRH has receptors in both the cytoplasm (matrix and secretory granules) and the nucleus of corticotrophs, but its mechanism of action at the plasma membrane or nucleus remains to be established. CRH appears to exert its ACTH-releasing activity through both the adenylate cyclase and calcium-calmodulin signal transduction systems (Klonoff and Karam 1992; Tyrell et al. 1994).

Adrenocorticotropin

BIOSYNTHESIS. Adrenocorticotropin (ACTH) is a 39-amino-acid peptide hormone (molecular weight = 4500) that is one of several products from the metabolism of the 267-amino-acid precursor molecule POMC (Fig. 30.1; molecular weight = 28,500; Rijnberk 1996: p. 63, Fig. 4-5). Between species there is significant sequence homology in the ACTH amino acid structure. Canine ACTH differs by only one C-terminal amino acid from ACTH of other species (Mol et al. 1991). The other fragments of POMC with biological activity include β-lipotropin (β-LPH), α-melanocyte-stimulating hormone (α-MSH), β-MSH, and the opioid β-endorphin, as well as the N-terminal fragment (see Rijnberk 1996: p. 63, Fig. 4-5). ACTH is metabolized to ACTH_{1-17}, which is identical to α MSH, and to corticotropin-like intermediate-lobe peptide (CLIP), which represents ACTH_{18-39}. These fragments are observed in species with developed intermediate lobes, such as the rat and horse, as well as fish, reptiles, and amphibians. Beta LPH is secreted in equimolar amounts to ACTH. The 91 amino acids of β LPH include the amino acid structure for β MSH (41–58), γ LPH (1–58), and β endorphin (61–91). The first (N-terminal) 23 amino acids of ACTH, which are identical in humans, cattle, pigs, and sheep, produce all of its biological effects (Klonoff and Karam 1992; Tyrell et al. 1994). The sequence of the remaining amino acids varies among species (Chastain and Ganjam 1986). MSH causes pigment granules in melanocytes to disperse so that skin will darken. Although genetic factors associated with skin color are more important in the higher vertebrates, MSH may cause transiently increased pigment synthesis in mammals.

STRUCTURE. ACTH is a peptide that contains 39 amino acids in a straight-chain molecule in sheep, pigs, cows, and humans. The first 24 and last 7 amino acids are identical and there are minor differences in amino acids 25 through 32 (see Fig. 30.2). The amino acid sequence of canine β-END differs from the human sequence by 4 amino acids (Young and Kemppainen 1994). The distribution of molecular forms of β-END in the canine intermediate lobe and anterior pituitary more closely resembles the distribution in rats than that in other species such as sheep or horses, in which acetylated and shortened forms exist in substantial amounts. In all species studied to date, ACTH and related peptides are synthesized and cleaved from the common precursor molecule POMC. Posttranslational processing of POMC differs in the pars distalis and pars intermedia of the pituitary gland. In the pars distalis, POMC is processed to form ACTH, β-LPH, some γ LPH, and β endorphin. In the pars intermedia, however, POMC is processed to ACTH and β-LPH; ACTH is then further processed to α MSH and CLIP, and β-LPH is further processed to β-MSH, β-END, and β-END metabolites. As a result, ACTH and β-LPH are intermediates to α MSH and the opiate β-END. The pattern of POMC-derived peptide secretion from the pars intermedia has been characterized in rats, horses, pigs, sheep, dogs, and cats. The plasma POMC peptide concentrations found in cats is similar to that in rats but is markedly different from that in dogs, in which the secretion of POMC peptides in the pars intermedia is normally low (Peterson et al. 1994b). The role of N-POMC1-48 is now known to promote adrenocortical cell replication.

REGULATION OF SECRETION. Beta LPH and β END are secreted in a pattern similar to ACTH, increasing in response to stress and paralleling ACTH in a variety of disease conditions. The regulation of ACTH is most directly influenced by the hypothalamic hormone CRH, which stimulates ACTH in a pulsatile fashion. Arginine-vasopressin (ADH) is also a potent stimulus for ACTH secretion (van Wijk et al. 1994). The pulsatility of ACTH release appears to occur in most species. Although a diurnal variation of cortisol was postulated by older studies, more recent studies with sampling at 30-minute intervals for 48 hours have not confirmed a diurnal variation in ACTH in dogs or cats (Peterson et al. 1994c).

Four mechanisms that regulate ACTH secretion have been identified: (1) episodic secretion and possible

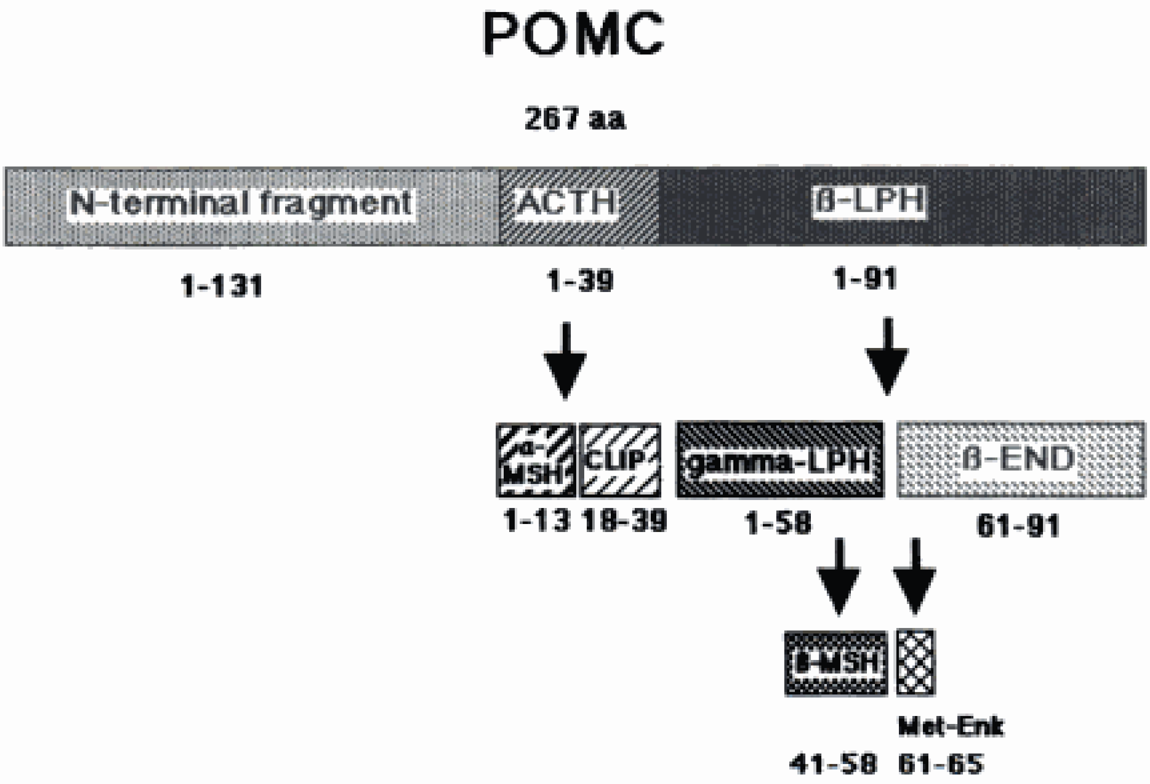

FIG. 30.1—Relationships of peptides derived from proopiomelanocortin (POMC). Following synthesis in the anterior or intermediate lobe of the pituitary, POMC is cleaved to form adrenocorticotropin (ACTH) and β lipotropin (β LPH). ACTH is further degraded, particularly in the intermediate lobe, to α-melanocyte stimulating factor (α MSH) and corticotropin-like intermediate-lobe peptide (CLIP). β-LPH is cleaved to produce γ LPH and the endogenous opiate β endorphin (β END). γ LPH is cleaved to produce β MSH, and β END is further processed to produce another opioid, Met-enkephalin (Met-Enk).

FIG. 30.2—Amino acid sequences of human, pig, cattle, and sheep ACTH. Amino acids 1–13 are also present in α MSH. Note areas of species homology in shaded boxes. (Reprinted from Klonoff and Karam 1992: Fig. 36.2.)

diurnal variation, mediated by the central nervous system (CNS) and hypothalamus; (2) response to stress (cats are much more sensitive than dogs), also CNS and hypothalamus mediated; (3) feedback inhibition by cortisol at both the hypothalamus and pituitary; and (4) immunological factors (IL-1, IL-6, tumor necrosis factor, etc.) which act at the hypothalamus to increase CRH (Rijnberk 1996).

Facilitatory and inhibitory pathways, involving GABAergic, cholinergic, adrenergic, dopaminergic, and serotoninergic systems, are all involved in hypothalamic regulation of ACTH and therefore cortisol secretion. Drugs manipulating these systems have been used to pharmacologically manage pituitary-dependent hyperadrenocorticism in the dog and horse. Ergot alkaloids (dopamine agonists) and serotonin antagonists (cyproheptadine) have been utilized to manipulate ACTH release without much clinical success. The monoamine oxidase B inhibitor L-deprenyl is currently under study in pituitary-dependent Cushing's disease due to its ability to decrease the degradation of dopamine, which has been postulated to be depleted in canine pituitary-dependent hyperadrenocorticism (Cushing's disease) (Klonoff and Karam 1992).

Many factors stimulate ACTH: pain trauma, hypoxia, hypoglycemia, surgery, cold, pyrogens, and ADH. CRH is often used to release ACTH from the pars distalis, and the drug haloperidol can be used to stimulate pars intermedia secretion, with pars distalis effects being removed by dexamethasone. In cultured canine anterior pituitary cells, it appears that CRH stimulates ACTH secretion, but arginine-vasopressin, oxytocin, and angiotensin II do not (Kemppainen et al. 1992).

Negative-Feedback Systems. Exogenous corticosteroids suppress the ACTH response to stress. Negative feedback of cortisol occurs via both the hypothalamus and pituitary. Feedback occurs in three ways:

1. Fast feedback is sensitive to the rate of change in cortisol and probably occurs via a nonnuclear receptor.
2. Slow feedback is sensitive to the cortisol concentration in plasma. This feedback loop is tested by the low-dose dexamethasone suppression test.
3. Short-loop feedback by ACTH occurs on the release of CRH by neurons in the hypothalamus and corticotrope receptors in the corticotropic cells of the anterior pituitary. The feedback is mediated through a type I mineralocorticoid-preferring receptor (MR) and a type II glucocorticoid-preferring receptor (GR). The highest levels of GR in the dog brain are found in the septohippocampal complex and the anterior lobe of the pituitary (Reul et al. 1990; Keller-Wood 1990; Klonoff and Karam 1992; Tyrell et al. 1994).

Function. ACTH stimulates the secretion of glucocorticoids, mineralocorticoids, and adrenal androgens by increasing the activity of cholesterol desmolase, the enzyme that is rate limiting for steroid production and converts cholesterol to pregnenolone. ACTH also stimulates adrenal hypertrophy and hyperplasia. Steroids are not stored in the adrenal cortex but are immediately released upon stimulation of the zona fasciculata. ACTH causes growth of both the zona fasciculata and glomerulosa. The biological activity is conveyed by the amino terminal end of the molecule. ACTH stimulates adrenocortical growth and steroidogenesis by increasing cellular cAMP (Tyrell et al. 1994).

LPH induces lipolysis in adipocytes of some species, but its function, other than serving as a precursor peptide for the endogenous opiate β END, is unknown for most species (Klonoff and Karam 1992; Kuret and Murad 1990).

Diagnostic Uses of CRH and ACTH. The most important applications of CRH and ACTH are as diagnostic agents to test adrenocorticotroph and adrenal functional reserve.

CRH Stimulation Test. The CRH stimulation test is used mainly as a research tool to assess pituitary ACTH secretory capacity. In animals administered exogenous glucocorticoids, the ACTH and cortisol response to CRH is diminished. In dogs and cats, ovine CRH is administered at 1 μg/kg intravenously and plasma is sampled for ACTH measurement at 0 and 0.5 hours for peak effect (see Table 30.5). Other sampling times have been employed in research reports (Crager et al. 1994; Moore and Hoenig 1992; Peterson et al. 1994b,c). Studies of normal dogs and dogs with pituitary-dependent hyperadrenocorticism have shown that ACTH secretion is less sensitive to CRH than it is to lysine vasopressin (LVP). It was also found that adrenocortical tumors develop an aberrant sensitivity to LVP, with adrenal tissue appearing to directly respond to LVP (van Wijk et al. 1994).

TABLE 30.5—Dosage protocols for CRH stimulation test

Preparation	Horses and cattle	Dogs	Cats
Ovine CRH (μg/kg IV)	NA	1	1
Sampling times (hr)	NA	0, 0.5	0, 0.5

Note: NA = not available.

Preparations of ACTH. Synthetic human $ACTH_{1-24}$ is called cosyntropin. Repositol ACTH gel from animal (porcine) sources is no longer available commercially. However, when comparing dosage protocols, 1 unit of porcine ACTH is approximately equal to 10 μg of cosyntropin. Synthetic ACTH is well absorbed by the intramuscular (IM) route. The biological half-life of all forms of ACTH is 10–20 minutes, and the effect on the adrenal cortex lasts for 12–48 hours.

ACTH Stimulation Test. The main use of ACTH is for the differential diagnosis of adrenocortical hyperplasia from adrenocortical neoplasia (primary) in dogs, cats, and horses (see Table 30.6) and for the definitive diagnosis of primary adrenal hypofunction. ACTH is well absorbed following IM injection. Following injection of aqueous synthetic ACTH, plasma cortisol concentrations peak at 30–90 minutes, largely because of the short half-life of ACTH. Therefore, most sampling protocols with aqueous ACTH in dogs and cats recommend sampling times at 1 hour after administration for a peak effect. The administration of 250 μg synthetic ACTH to dogs resulted in similar cortisol patterns whether the dose was given IV or IM, despite the fact that there were much higher peak ACTH concentrations with the IV dose. The peak cortisol concentration was at 60–90 minutes (Hansen et al. 1994). However, in cats, the IV dose of synthetic ACTH appeared to provide a greater response than the IM dosage (Peterson et al. 1994b,c).

GLYCOPROTEIN HORMONES AND ASSOCIATED RELEASING HORMONES. Only the thyroid-related peptides TRH and TSH will be discussed in this chapter. Gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), placental (human) chorionic gonadotropin (HCG), and pregnant mare serum gonadotropin (PMSG) are discussed in Chapter 31 on reproductive hormones.

Thyrotropin-Releasing Hormone. Thyrotropin-releasing hormone (TRH) is a tripeptide: PyroGlu-His-Pro NH_2. Neurons secreting TRH are located in the medial portion of the paraventricular nuclei, and their

linked carbohydrate groups. The human, cow, mouse, dog, and rat α-subunit genes are similar (Yang et al. 2000b). All species have a single mRNA species that is between 730 and 800 bases long. The mRNA encodes the precursor of the α subunit and a leader sequence of an average of 24 amino acids.

The TSH β subunit is approximately 18 kD, consists of approximately 110–118 amino acids, and contains one N-linked complex carbohydrate (Green and Baenzinger 1988). TSH, like LH, contains sulfate groups that terminate certain chains; such sulfation is found only to a small extent in FSH and not at all in HCG. The genes for the β subunit of TSH of mouse, cow, human, dog, and horse have been cloned, and recombinant canine TSH has been expressed in vitro (Yang et al. 2000a,b). Each mRNA is approximately 700 bases in length with minor variations. The TSH β mRNA encodes the precursor TSH β subunit with a 20-amino-acid leader sequence and a 117- or 118-amino-acid coding region.

ACTION. TSH binds to specific receptors on the thyroid plasma membrane. TSH receptors from dog, pig, human, and rat have been completely cloned. The extracellular domain of the receptor contains 398 amino acids with five sites for N-linked glycosylation. The intracellular domain has 346 amino acids with seven putative transmembrane segments. The stimulatory guanine nucleotide regulatory protein binds to the third intracellular loop. The receptor has a glycoprotein component and a ganglioside that may be involved in TSH activation of adenylate cyclase. Only intact TSH binds to the receptor, and the β subunit does not possess biological activity (Chan et al. 1987; Field 1975). Binding of TSH to its receptor activates adenylate cyclase and subsequent accumulation of cAMP but is not dependent on the interaction of the TSH from that species with the receptor. This results in the stimulation and dissociation of the regulatory and catalytic subunits of cAMP-dependent protein kinase (protein kinase A) with subsequent phosphorylation of various cellular proteins resulting in an increase in thyrocyte iodide uptake, thyroid hormone organification, and thyroid hormone secretion. This cAMP-mediated pathway appears to be important in both thyroid hormone secretion and thyroid glandular growth (Chayoth et al. 1985).

The binding of TSH is also known to activate the phospholipase C signaling system. Activation of phospholipase C results in hydrolysis of phosphotidylinositol 4,5-biphosphate (PIP_2) with formation of diacylglycerol (DAG) and inositol-1,4, 5-triphosphate (IP_3). The former activates a Ca^{++}-phospholipid-dependent protein kinase (protein kinase C) and the latter increases intracellular Ca^{++} concentrations. The effect of TSH on phospholipase C is slower and requires larger amounts of the hormone than its activation of adenylate cyclase, suggesting a high-capacity and low-affinity TSH binding site. The physiological significance of activation of PIP_2 hydrolysis by TSH is not known but is suspected to be involved in thyroid glandular proliferation (Chayoth et al. 1985; Taguchi and Field 1988).

PREPARATIONS. Biochemically purified native TSH is purified from bovine pituitary glands and is stored in a lyophilized form for reconstitution and parenteral administration. A study evaluated the effects of freezing reconstituted bovine TSH and demonstrated that bioactivity remained intact for at least 3 months at −20° C (Kobayashi et al. 1990).

Two bovine thyrotropin products have been available in the past. Currently, recombinant human TSH has replaced the bovine products in human clinical use in the United States and there are no approved veterinary thyrotropin products on the market.

TSH STIMULATION TEST. The administration of exogenous bovine TSH followed by the measurement of serum T_4 and/or T_3 provides important information in the diagnosis of hypothyroidism, used primarily in the dog, cat, and horse, because it tests thyroid secretory reserve. Although the variable availability and high cost of bovine TSH has made this test less practical, the TSH stimulation test continues to be the most definitive noninvasive test for the diagnosis of primary hypothyroidism.

Protocols for this test vary widely in the dog; they are summarized in Table 30.8. Although the TSH dose and serum sampling times are often dictated by practical and economic considerations, increasing the TSH dose administered generally delays the time of the T_4 peak and, up to a limit, results in a higher serum T_4 response and a plateau that is maintained for a longer period of time. The route of administration may be intravenous, intramuscular, or subcutaneous; however, the most consistent and rapid response is seen after intravenous dosing. For the dog, the suggested protocol is to draw a baseline blood sample for serum T_4 determination and then administer 0.1 IU/kg TSH intravenously (maximum dose 5 IU), followed by a blood sample at 4 hours post-TSH (Ferguson 1984, 1994; Peterson and Ferguson 1989). Studies using 1 IU of bovine TSH per dog have indicated that the mean increase in serum T_4 and T_3 above baseline at 6 hours

TABLE 30.8—Protocols for TSH stimulation test

	Dose	Route	Sampling times (hr)
Dogs	0.1 IU/kg IV (max. 5 IU)	IV	0, 4
	1 IU/dog	IV	0, 4
Cats	1 IU/kg	IV	0, 6
	1 IU/cat	IV	0, 4
Horses	5–10 IU	IV	0, 4, 6

Sources: Beale et al. 1990; Chen and Li 1987; Ferguson 1984, 1994; Peterson and Ferguson 1989.

Note: Preparation used is bovine TSH (Thytropar, Rhone-Poulenc Rorer). For older protocols in the dog, see Ferguson 1984 for a review.

post-TSH was significantly lower following TSH at 1 IU than TSH at 5 IU but was not significantly different at 4 hours post-TSH for the two doses of TSH evaluated. Based on the criteria for adequate response to TSH, TSH at 1 IU led to classification of 35% of the dogs as having a decreased response to TSH at 4 hours and 35% at 6 hours. TSH at 5 IU resulted in no dogs having a decreased response at 4 hours and 1 dog in 20 (5%) at 6 hours (Beale et al. 1990).

Assuming a pharmacological dosage of TSH is used, the diagnosis of hypothyroidism in the dog is usually confirmed when the post-TSH serum T_4 concentration is below the normal range for basal T_4 (usually <1.0 μg/dL or <13 nmol/L in the dog) and rarely increases greater than 0.2 μg/dL (2.6 nmol/L) above the baseline. In pituitary forms of hypothyroidism, the thyroid gland should remain responsive to TSH. The rare cases of long-standing secondary (pituitary) or tertiary (hypothalamic) hypothyroidism with subsequent thyroid atrophy may require 2 or 3 consecutive daily doses of TSH to eventually demonstrate thyroid responsiveness (Fig. 30.3; Ferguson 1984, 1994).

A study of normal dogs evaluated the predictive value of blood sampling times after 5 IU of IV TSH: in 80% of the animals, a doubling of the serum T_4 concentration was not achieved by 4 hours but was achieved in all cases by 6 hours post-TSH. Animals that responded favorably to thyroid replacement therapy have on average virtually no increase in serum T_4 concentration following TSH. An advantage of the TSH stimulation test is that post-TSH T_4 concentrations tend to be less variable because the thyroid is maximally stimulated.

STRUCTURAL HOMOLOGY AMONG SPECIES. There is 80–90% homology at the amino acid level among the sequences of most of the mammalian TSH β molecules. As an example of avian species, the amino acid sequence of the quail TSH β subunit shows homologies of about 70% to that of mammalian species, about 60% to that of amphibians, and about 50% to that of teleost fish. There is evidence that the functional domains of the TSH β subunit and the TSH receptor have diverged cooperatively during evolution. Many regions of identical sequences are apparent in various β subunits of glycoprotein hormones and the regions around residues 51–57 and 75–80 in the β structures are suggested to be involved in interaction with the common α subunit (Maurer et al. 1984; Lawrence et al. 1997; Kato et al. 1997; Nagai et al. 1998).

TSH RECEPTORS AND BIOLOGICAL ACTION. Thyroidal TSH receptors from dog, pig, rat, mouse, and human have been cloned and sequenced. The extracellular domain of the receptor contains 398 amino acids with five sites for N-linked glycosylation. The intracellular domain has 346 amino acids with seven putative transmembrane segments, similar to other G-protein-coupled receptors. The stimulatory guanine nucleotide regulatory protein binds to the third intracellular loop. The receptor has a glycoprotein component and a ganglioside that may be involved in TSH activation of adenylate cyclase. Only intact TSH binds to the receptor and the β subunit alone does not possess biological activity. Binding of TSH to its receptor activates adenylate cyclase and subsequent accumulation of cAMP, but the interaction is not species specific, as the long-standing use of bovine TSH in human and veterinary medicine demonstrates. The binding results in the stimulation and dissociation of the regulatory and catalytic subunits of cAMP-dependent protein kinase (protein kinase A) with subsequent phosphorylation of various cellular proteins resulting in an increase in thyrocyte iodide uptake, thyroid hormone organification, and thyroid hormone secretion. This cAMP-mediated pathway appears to be important in both thyroid hormone secretion and thyroid glandular growth.

The binding of TSH is also known to activate the phospholipase C signaling system. Activation of phospholipase C results in hydrolysis of phosphotidylinositol 4,5-biphosphate (PIP_2) with formation of diacylglycerol (DAG) and inositol-1,4, 5-triphosphate (IP_3). The former activates a Ca^{++}-phospholipid-dependent protein kinase (protein kinase C) and the latter increases intracellular free calcium concentrations. The effect of TSH on phospholipase C is slower and requires larger amounts of the hormone than its activation of adenylate cyclase, suggesting a high-capacity and low-affinity TSH binding site. The physiological significance of activation of phosphoinositide hydrolysis by TSH is not known but is suspected to be involved in thyroid glandular proliferation.

GLYCOSYLATION PATTERNS: RELEVANCE TO BIOACTIVITY AND IMMUNOREACTIVITY. The pituitary glycoproteins LH, FSH, and TSH are produced and secreted in multiple molecular forms. In vivo, microheterogeneity of the carbohydrate constituents of the individual hormones causes heterogeneity in affinity for the receptor and in metabolic clearance of the hormone. In vitro, immunoreactivity is affected by this heterogeneity. Much has been learned from studies of human and equine chorionic gonadotropin because of the use of these agents as pharmaceuticals. For example, highly sialylated human FSH variants exhibit lower receptor binding, bioactivity, and immunoactivity compared to less sialated counterparts. Each isoform appears to have a different affinity for the receptor. For example, FSH glycosylation variants appear to induce or stabilize distinct receptor conformations that result in different degrees of activation or inhibition of a given signal transduction pathway.

The oligosaccharide chains of pituitary glycoprotein hormones such as human thyroid-stimulating hormone (hTSH) have been shown to be important in biosynthesis, subunit association, secretion, and bioactivity. However, the exact biological significance of these glycosylation isoforms remains controversial. Human TSH glycosylation variants more basic in isoelectric point were found to be significantly more active than

hormones differ from vasotocin, which is found in nonmammalian vertebrates, by only one amino acid. Posterior pituitary hormones are synthesized in the hypothalamus and transported to the posterior pituitary, where they are released into the circulation.

ANTIDIURETIC HORMONE. Two 9-amino-acid peptides are secreted by the neurohypophysial system: ADH and oxytocin. They are synthesized by the magnocellular neurons of the supraoptic nuclei and the lateral and superior parts of the paraventricular nuclei. ADH regulates the water permeability of the distal tubules and collecting duct of the nephron. It also is a vasoconstrictor and influences cardiovascular function.

Structure. ADH has a molecular weight of 1084 and is characterized by a 6-amino-acid ring and a 3-amino-acid side chain with a disulfide linkage. The prohormone for ADH includes the ADH sequence and neurophysin II, which binds to ADH. Following synthesis of the peptide, secretory granules containing the prohormone move down the axon to the nerve terminal in the posterior lobe of the pituitary. Upon exocytosis, equimolar amounts of the neurophysin and ADH are released. The neurons also project to the choroid plexus, where they also release ADH into the cerebrospinal fluid.

Stimuli for Release. The primary physiological stimulus for ADH release is an increase in plasma osmolality. However, hypovolemia, pain, exercise, and some drugs may stimulate ADH release.

Mechanism of Action. ADH binds to two types of receptors. V_1 receptors are found on vascular smooth muscle cells and cause vasoconstriction. V_2 receptors are found on the renal tubule cells and are involved in the mediation of antidiuresis through increased water permeability and water reabsorption in the collecting ducts. ADH increases cAMP in the tubule, which increases water permeability at the luminal surface, resulting in increased urine osmolality and decreased urine volume. V_2 receptors outside the kidney also mediate the release of the coagulation factor VII and von Willebrand factor. Desmopressin acetate (DDAVP; 1-desamino-8-L-arginine vasopressin) is a long-acting synthetic analog of predominately V_2 or antidiuretic activity. Table 30.11 summarizes the actions of ADH and the respective ADH receptors (V_1 and V_2) mediating the actions.

Absorption, Metabolism, and Excretion. ADH must be administered parenterally and has a very short half-life of about 20 minutes.

Preparations. Natural and synthetic ADH are available commercially for the diagnosis and treatment of diabetes insipidus. Natural ADH (Pitressin) from cows and pigs is available as a water-soluble product. Dogs, cats, horses, and humans produce arginine ADH and pigs produce lysine ADH.

Diagnostic Use. Diabetes insipidus (DI) is caused by the deficiency of ADH (central DI) or by absence of a renal response to this anterior pituitary hormone (nephrogenic DI). The main presenting signs, in the absence of other conditions, are polyuria and polydipsia.

Central DI is due to the absolute deficiency of ADH. In partial central DI, some endogenous ADH secretion remains. These conditions are the result of the destruction of the supraoptic and paraventricular nuclei of the hypothalamus, which have axons terminating in the posterior pituitary. The damage may be due to head trauma, surgical transection of the pituitary stalk (usually only transient DI), or primary or metastatic tumors, or, most commonly in veterinary medicine, the cause is not known (idiopathic DI).

Nephrogenic DI results when the renal tubule is insensitive to ADH. In this condition, ADH does not increase intratubular cAMP concentrations, a necessary prerequisite to the increased water permeability normally induced by ADH. This abnormality of ADH responsiveness may also be partial or total. Primary causes of nephrogenic diabetes are rare. However, secondary nephrogenic DI may result from pyometra, liver

TABLE 30.11—Actions of antidiuretic hormone

Target organ	Receptor type	Action
Renal glomerulus	V_1	Mesangial cell contraction
Vasa recta	V_1	Decrease medullary blood flow
Juxtaglomerular cells	V_1	Suppress renin release
Arterioles	V_1	Constriction
Liver	V_1	Increase glycogenolysis
Anterior pituitary	V_1	Increase ACTH release
Baroreceptors	?	Desensitization of baroreflex
Cortical and medullary collecting tubules	V_2	Increase H_2O permeability
Papillary collecting ducts	V_2	Increase H_2O permeability
Thick ascending loop of Henle	V_2	Increase Na^+, K^+, Cl^- reabsorption
Baroreceptors	?	Sensitization of baroreflex

disease, hyperadrenocorticism, hyperthyroidism, hypercalcemic disorders, renal failure, and pyelonephritis.

DI is diagnosed if the urine specific gravity is dilute (<1.008) in the face of dehydration and/or an elevated plasma osmolality. However, it is not infrequent for the animal to present in a hydrated state and to have a normal or only slightly elevated plasma osmolality. A modified water deprivation test is recommended to confirm that endogenous ADH and urine osmolality will not rise in the face of moderate dehydration. Following carefully monitored gradual water withdrawal over three days, water is completely withdrawn on the fourth day and the urine osmolality and plasma osmolality are monitored. If greater than 5% dehydration is achieved and no urine concentration is observed, then exogenous ADH is administered to test the ability to respond to exogenous hormone.

ADH can be administered in two ways in this test:

1. 0.55 units per kg intramuscular aqueous ADH (Pitressin Synthetic, Parke-Davis; Vasopressin USP, Quad) up to a maximum of 5 units. Urine volume and osmolality (or specific gravity) should be measured at 30, 60, and 120 minutes after administration.

2. The administration of 1 milliunit/mL of aqueous ADH (Pitressin Synthetic, Parke-Davis; Vasopressin USP, Quad) in lactated Ringer's or 5% dextrose. This solution is then administered over 1 hour at the rate of 10 mL/kg body weight. Urine samples should be obtained at 15-minute intervals for 90 minutes following ADH administration.

In an animal with complete central DI, the urine osmolality will not have risen above isoosmolality (300 mOsm/kg) with dehydration; and subsequent ADH administration will increase urine osmolality at least 50%. In an animal with partial central DI, the urine osmolality will increase above isoosmolality but will increase an additional 10–50% following exogenous ADH. Animals with nephrogenic DI do not concentrate their urine upon dehydration above isoosmolality and also do not respond to exogenous ADH.

Therapeutic Uses. Aqueous ADH or ADH analogs are currently the only formulations available for the treatment of total and partial central DI. The synthetic ADH analogs DDAVP (Desmopressin acetate, Rorer, injectable and nasal, USV Laboratories) and LVP (Lysine-8-vasopressin, Diapid Nasal Spray®, Sandoz Pharmaceuticals) are the most commonly used. Both of these preparations can be administered intranasally or into the conjunctival sac. The latter route appears to be better tolerated by the animals. Ocular or conjunctival irritation is a rare problem.

DDAVP is a drug with greater potency and slower metabolism than the natural ADH molecule. Administration of 5–20 µg of DDAVP (2–4 drops) in single or divided doses controls polyuria in most animals. The peak drug action is seen at 2–6 hours, and its duration may last from 10 to 27 hours. The clear advantage of this medication is that it does not require parenteral administration. However, the conjunctival route results in variable amounts of drug reaching the bloodstream and variable duration of effect even in the same patient. DDAVP is also quite expensive, and therefore it might be prudent to use the drug only when polyuria is observed or to prevent excessive nocturnal urine production.

LVP (Lysine-8-vasopressin) is another product which is available for managing DI via nasal or conjunctival administration. However, its duration of action is shorter and its expense is greater than the other products. As a result, it has not found much application in veterinary medicine (Chastain and Ganjam 1986; Ferguson et al. 1992).

DDAVP has also been used for bleeding disorders (von Willebrand's disease and hemophilia A). In pharmacologic doses, it increases plasma levels of factor VIII:C and von Willebrand factor, by preferentially increasing levels of larger von Willebrand factor multimers and by increasing platelet adhesion. Controlled studies on the use of DDAVP in dogs are lacking, but the clinical impression is that DDAVP is beneficial in some but not all von Willebrand dogs (Nichols and Hohenhaus 1994).

Toxicity. Immediately following a dose, in order to prevent water intoxication, dogs should not be given unlimited quantities of water. The transiently high levels of ADH will prevent the excretion of a free water load by the kidney and result in overhydration and possible neurological sequelae such as cerebral edema. Cerebral edema may be manifest by depression, vomiting, salivation, ataxia, muscle tremors, and convulsions. Animals with central or nephrogenic DI disease may also be successfully managed by providing free access to water at all times and by housing the animals outdoors. Another inexpensive maneuver which reduces the urine output is the restriction of dietary sodium using homemade diets or the commercial diets designed for use in congestive heart failure (e.g., Hill's H/D). Such products generally contain less than 0.1% sodium on a dry weight basis (Ferguson et al. 1992).

Other Drugs for Treatment of Central Diabetes Insipidus. Oral agents have also been used primarily as adjuncts to ADH therapy of central DI. Chlorpropamide (Diabinese®, Pfizer), a sulfonylurea hypoglycemic agent used to treat non-insulin-dependent diabetes in humans, has produced inconsistent antidiuretic effects in the dog and cat. Chlorpropamide's effect is to enhance the effect of ADH on the renal tubules and collecting duct by increasing intracellular cAMP. It may also stimulate pituitary ADH release. As a result, it is only effective in the presence of sufficient endogenous (partial central DI) or exogenously administered ADH. Careful dosage studies for chlorpropamide have not been performed in the dog. Reported doses include 250 mg every 12 hours and 10–40 mg/kg/day. Reduction in urinary volumes ranging from 18 to 50% have been reported. Maximal antidiuretic effects take 1–2 weeks to develop. Side effects of hypoglycemia can be minimized by frequent feedings and periodic monitoring of blood glucose concentrations.

Carbamazepine (Tegretol®, Geigy Pharmaceuticals), an antiepileptic, and clofibrate (Atromid®, Ayerst Laboratories), an antihyperlipidemic drug, are also effective in some cases of central DI. In contrast to the other drugs, these agents may increase the secretion of ADH and therefore would be rational therapy only in partial central DI. However, there have been no reports in the veterinary literature of the use of these drugs for the successful treatment of DI.

Thiazide diuretics when used together with salt restriction may serve to potentiate the effect of exogenous or endogenous ADH (see below) (Ferguson et al. 1992; Klonoff and Karam 1992; Tyrell et al. 1994).

Treatment Of Nephrogenic Diabetes Insipidus. Treatment for nephrogenic DI should, if possible, start with correction of the underlying cause of the nephrogenic DI (hypercalcemia, renal infection, hyperadrenocorticism without a compressive pituitary tumor). Except for institution of a low-sodium diet, the thiazide diuretics are the only agents that have been shown to be effective in the treatment of nephrogenic DI.

Thiazide diuretics have a paradoxical antidiuretic effect in central and nephrogenic DI. These agents may reduce the reabsorption of sodium in the ascending loop of Henle, resulting in enhanced urinary sodium loss, mild reduction in plasma osmolality, and, therefore, diminished thirst. The reduction in water intake causes contraction of the extracellular volume, and proximal tubular sodium reabsorption is increased and the glomerular filtration rate decreased. The urine volume is thereby reduced without overt concentration of the urine osmolality. Hydrochlorothiazide (Hydrodiuril®, Merck, Sharp, and Dohme) at a dosage of 2.5–5 mg/kg has succeeded in reducing water intake by 50–85% in cases of ADH-resistant polyuria. Due to the kaliuretic effect of the thiazides, serum potassium should be monitored and oral potassium (Kaon Elixir®, Adria) administered if the animal becomes anorexic (Ferguson et al. 1992).

OXYTOCIN. Oxytocin induces contraction of smooth muscle, most importantly of the myoepithelial cells of the mammary gland, which result in milk ejection. Furthermore, it also results in uterine smooth muscle contraction, an effect that increases during pregnancy. Its clinical use in the management of milk letdown and uterine contraction (induction of parturition and treatment of pyometra) is described in detail in Chap. 31.

Oxytocin affects the transmembrane ionic currents in uterine smooth muscle cells, resulting in sustained uterine contraction. Oxytocin-induced myometrial contractions can be inhibited by tocolytic agents such as β-adrenergic agonists, magnesium sulfate, and inhalation anesthetics (Klonoff and Karam 1992; Tyrell et al. 1994).

HORMONES AFFECTING REPRODUCTION

FREDERICK N. THOMPSON

Reproductive Endocrinology
General Effects and Utility of Reproductive Drugs
    Progestins
    Gonadotropins and Gonadotropin-Releasing Hormone
    Prostaglandin F$_{2\alpha}$
    Gonadal Steroids, Ergonovine, Oxytocin, Glucocorticoids, and Melatonin
Specific Drug Usage in Large Animals
    Induction of Ovarian Activity in the Pig
    Use of Melatonin to Advance the Breeding Season
    Use of Testosterone in the Cow
    Use of Altrenogest in the Mare
    Use of Altrenogest in Swine
    Progestins
    Use of GnRH and Analogs
    Prostaglandin F and Analogs
    Induced Parturition
    Postpartum Usages of Oxytocin, Estrogen, and Prostaglandin
    Induction of Superovulation
    Induction of Lactation in the Cow
Specific Drug Usage in Small Animals
    Drugs to Stimulate the Gonads
    Drugs for Abortion and Evacuation of the Uterus in the Bitch and Queen
    Postponement of Estrus
    Treatment of Pseudopregnancy, Uterine Inertia, Cryptorchidism, and Prostatic Hypertrophy

REPRODUCTIVE ENDOCRINOLOGY. The ultimate control of reproduction rests in neural processes. Gonadotropin-releasing hormone (GnRH) secreted from the hypothalamus is transported by the portal system to the pituitary, where it increases secretion of the gonadotropins—follicle-stimulating hormone (FSH) and luteinizing hormone (LH)—in both sexes. Frequent administration of GnRH may result in decreased LH and FSH secretion via down-regulation (tachyphylaxis) of pituitary GnRH receptors. The gonadotropins stimulate the secretion of gonadal steroids (testosterone in the male and estrogens and progesterone in the female). During the estrous cycle ovarian follicles produce estradiol, an estrogen, predominately in response to pulsatile secretion of the gonadotropins. Following ovulation mediated by a surge secretion of LH, progesterone is secreted from one corpus luteum or several corpora lutea (CL). The CL requires pituitary hormones for support (luteotropic factors). The luteotropic factor(s)—LH and prolactin—and estradiol are species-specific. A decrease in luteotropic factor secretion will result in decreased CL function and abortion in the pregnant animal. The life span of the CL is lengthened with pregnancy, resulting in continued progesterone secretion, which is necessary for pregnancy maintenance. Late in diestrus in the cycling (nonpregnant) large animal, prostaglandin F$_{2\alpha}$ (PGF$_{2\alpha}$) released from the endometrium mediates CL regression (luteolysis). Estrus follows CL regression within a few days. Such utero-ovarian relationships whereby uterine PGF$_{2\alpha}$ results in luteolysis do not exist in the bitch.

Gonadal steroids in the female, estrogen and progesterone, have prominent stimulatory effects upon the endometrium and the mammary gland, while increased circulating concentrations may result in pathological changes in target organs. Gonadal steroids mediate reproductive behavior and gametogenesis in both sexes. Ovarian steroids generally decrease gonadotropin secretion (negative feedback). The exception to this is a positive feedback effect of estradiol, in the relative absence of progesterone, upon gonadotropin secretion immediately prior to ovulation that results in a surge secretion of both gonadotropins. LH mediates ovulation. Exogenously administered gonadal steroids may inhibit gonadotropin secretion, result in uterine and mammary gland pathology, and interrupt gonadal function.

Testosterone in the male mediates behavior and stimulates male sex accessory glands. Increased circulating testosterone from either an exogenous or endogenous source may result in prostatic hypertrophy and hyperplasia. Additionally, testosterone administration results in decreased gonadotropin secretion and interruption of spermatogenesis.

GENERAL EFFECTS AND UTILITY OF REPRODUCTIVE DRUGS

Progestins. The sources of progesterone include the CL in animals undergoing estrous cycles (cycling) and the placenta in certain species. Progesterone and its synthetic analogs (progestins) mimic the effects of a CL and thereby inhibit estrus during administration. Following withdrawal there is a shortened interval to estrus, with synchrony of that event in large animals. These effects are mediated by increased gonadotropin (FSH and LH) secretion. Synchronization of estrus in large animals by progestins or other drugs facilitates artificial insemination and thereby genetic improvement. Progestins are effective both in the cycling female and also in the prepubertal and postpartum anestrus animal; following withdrawal, ovarian activity is increased, especially in conjunction with gonadotropin administration. Progesterone itself will inhibit estrus but must be given at least daily. This short half-life discourages usage in the production setting. Progestins are used to inhibit the onset of the reproductive cycle in dogs and cats.

Gonadotropins and Gonadotropin-Releasing Hormone. Stimulation of the gonad in either sex is achieved via use of GnRH; the nonpituitary gonadotropins, human chorionic gonadotropin (HCG) and pregnant mare serum gonadotropin (PMSG, also known as equine chorionic gonadotropin); or pituitary gonadotropin preparations themselves (FSH and equine pituitary extract, EPE).

GnRH is a hypothalamic decapeptide that increases LH and FSH secretion. In some instances GnRH therapy may be appropriate to achieve ovulation or luteinization of an ovarian cyst. The effects of GnRH in elevating gonadotropin secretion are brief, lasting generally only several hours.

HCG and PMSG are large-molecular weight glycoproteins secreted during pregnancy in the woman and mare, respectively. These nonpituitary gonadotropins mediate a long-lasting biological effect (> 24 hr); only a single injection is necessary. PMSG is secreted from the endometrial cups of pregnant mares in early pregnancy in order to maintain a luteotropic (CL stimulatory) effect upon the primary and secondary CL in the mare. Its gonadotropic activity is primarily FSH-like activity to increase ovarian follicular growth. PMSG is frequently used to stimulate ovarian follicular growth in the anestrous sheep or goat. Because of difficulty in standardizing PMSG, this drug is frequently not available in the USA. HCG is secreted from the chorionic portion of the placenta of the woman. HCG, in contrast to PMSG, has biologic activity that is primarily LH-like, and it, therefore, induces ovulation. HCG can be used, e.g., to induce ovulation in the mare after an appropriate follicular size has been documented. Such treatment in the mare shortens the period of estrus and allows more accurate prediction of the time of ovulation. HCG is also used in a diagnostic manner to assess the presence of a testicle. A HCG test challenge (10,000 IU) IV will result in increased testosterone secretion in the presence of a testicle as soon as 30 minutes postinjection. This may be desirable to ascertain the status of a supposedly gelded horse. The various uses of GnRH, HCG, and PMSG are described later in this chapter.

The pituitary gonadotropins are extracted from animal pituitaries. FSH and EPE are used to stimulate follicular growth and superovulation in animals that will serve as embryo donors.

Prostaglandin $F_{2\alpha}$. The primary source of $PGF_{2\alpha}$ is the endometrium in large domestic animals, where it is released late in diestrus in the cycling animal and near term in the pregnant animal. $PGF_{2\alpha}$ mediates a decrease in circulating progesterone via luteolysis (CL regression) and decreased placental progesterone production. The mechanism of $PGF_{2\alpha}$-mediated luteolysis involves an antisteroidogenic effect via activation of protein kinase C and a cell death effect mediated by increased intracellular free calcium (Niswender et al. 1994). $PGF_{2\alpha}$ and its analogs are used to decrease estrous cycle length and thereby hasten the onset of estrus and to induce abortion and parturition. In the cow $PGF_{2\alpha}$ is used to stimulate uterine contractions to facilitate placental delivery or for another ecbolic effect. As a luteolytic agent, $PGF_{2\alpha}$ shortens the life span of the CL and, therefore, decreases the interestral interval. Used strategically, in most large animal species except the pig, $PGF_{2\alpha}$ results in synchrony of estrus in a group of animals. Since $PGF_{2\alpha}$ does not result in luteolysis in the pig until after day 14 or 15 of the cycle, it has limited utility in this species to synchronize estrus, but it is used in the pig to induce parturition. In the bitch $PGF_{2\alpha}$ is used to treat uterine infections via luteolytic and ecbolic effects.

Gonadal Steroids, Ergonovine, Oxytocin, Glucocorticoids, and Melatonin. The use of gonadal steroids, such as estrogen and testosterone, in large animals is now limited. Testosterone is used to androgenize cows in order to produce a "teaser" animal to identify cows in estrus. A variety of esters of estradiol (benzoate, propionate, cypionate, and valerate) that increase duration of activity are available. These products will induce estrus but generally not ovulation. Estrogens are used as abortifacient agents in early pregnancy in the cow and for antinidatory activity in the bitch. Administration of estrogen to the postpartum cow is advocated as an adjunct to treatment of mild uterine infections because it promotes uterine blood flow and contractility. Estradiol valerate is used along with a progestin (norgestomet) for estrous synchronization in ruminants. Estradiol valerate mediates luteolysis via $PGF_{2\alpha}$ release.

Ergonovine has a direct effect on the uterus and increases uterine contractions and vasoconstriction (Brazeau 1975). It is used in the postpartum animal to enhance involution and placental expulsion.

Oxytocin is synthesized in the hypothalamus and stored in the posterior pituitary. Following secretion, this hormone mediates contractility of the estrogen-dominated myometrium during parturition and contractility of the myoepithelial cells surrounding the alveoli in the mammary gland. As a result, milk ejection is mediated with no effect upon milk synthesis. Following intravenous (IV) bolus administration, its effect is

ment or ovulation occurs sooner than expected after treatment (Lofstedt and Patel 1989). An apparent explanation is found in the fact that altrenogest has only a minimum effect on LH secretion (Squires et al. 1983). Therefore, some mares have CLs at the end of the altrenogest treatment period, and a luteolytic dose of prostaglandin may be required to achieve the desired effect.

Although not approved for the maintenance of pregnancy, altrenogest has been administered with this objective. Experimentally, 6 out of 7 control mares aborted following administration of endotoxin, but abortion did not occur in the altrenogest-treated mares (Daels et al. 1991). To ascertain if altrenogest has an adverse effect on pregnancy and subsequent events, the drug was given from day 30 to day 320 of pregnancy. No adverse effect was detected on periparturient events, viability and growth of the offspring, or subsequent reproductive performance of the mares (Shoemaker et al. 1989). Similarly, reproductive performance of offspring from mares given altrenogest during gestation was not affected in either sex (Squires et al. 1989).

Use of Altrenogest in Swine. Swine producers are particularly interested in synchronizing estrus in gilts in order to reduce the number of replacement gilts. This also allows for more efficient use of labor and facilities. Although altrenogest is not approved for use in the pig in the US, it is effective in synchronizing estrus in the gilt (Kraeling et al. 1981; Webel and Day 1982). When gilts that had been previously observed in estrus were fed 15-20 mg altrenogest daily for 18 days, approximately 95% expressed estrus 4-7 days after treatment. Only approximately 75-85% of the gilts with unknown reproductive histories were so synchronized. Farrowing rate and litter size in gilts was unaltered in most trials; however, an increase in cystic follicles (Redmer and Day 1981) and a decreased farrowing rate in a commercial situation have been noted (Wood et al. 1992).

Progestins

SYNCRO-MATE B IN CATTLE. Syncro-Mate B (SMB; Merial Limited, Athens, GA) treatment is composed of an ear implant containing the progestin norgestomet (6.0 mg) and an injectable solution of norgestomet (3.0 mg) and estradiol valerate (5.0 mg). This treatment synchronizes estrus in heifers and postpartum cows. Animals are given an ear implant for 9 days, and norgestomet and estradiol valerate are injected IM at the time of implantation. The estradiol is intended to bring about luteolysis via prostaglandin release. Norgestomet inhibits LH secretion and thereby inhibits CL function. Insemination without respect to estrous detection is recommended by the manufacturer beginning 48 hours after implant removal. A high percentage (77-100%) of cattle exhibit estrus after treatment but first-service conception rates are variable (33-68%) (Odde 1990). This variability in conception rates is a function of the percentage of the animals in a herd undergoing estrous cycles before treatment. Herds with fewer than 50% of the animals cycling before treatment had reduced conception rates. A 30% conception rate was found in noncycling heifers treated with SMB, compared with a 48% conception rate in cycling heifers (Brown et al. 1988).

Reasons for failure to conceive after SMB include luteal dysfunction due to insufficient LH secretion after implant removal (Hixon et al. 1981) and stage of the cycle when implanted (Brink and Kiracofe 1988). Those implanted prior to day 11 of the cycle had a 47% conception rate compared to 37% for those implanted after day 11. Separation of calves from suckled beef cows at the time of implant removal increased conception rates (Kiser et al. 1980). Some cows treated during metestrus do not experience CL regression during treatment (Burns et al. 1993). Therefore, synchrony of estrus is not achieved. Increasing the norgestomet dose to 6.0 mg when animals were implanted during metestrus resulted in more pregnancies (Fanning et al. 1992). The use of GnRH in conjunction with SMB has increased pregnancy rates. Suckled beef cows that received 250 μg GnRH 30 hours after norgestomet implant removal had increased pregnancy rates after a timed insemination (Troxel et al. 1993). Another adjunct to SMB treatment has been the use of $PGF_{2\alpha}$. When beef heifers treated with SMB for 7 days were given $PGF_{2\alpha}$ on either day 6 or 7, a good estrus and pregnancy response occurred (Heersche et al. 1979). Similarly, injection of $PGF_{2\alpha}$ 2 days before implant removal has resulted in a good synchrony of estrus (Odde et al. 1984).

SYNCRO-MATE B IN GOATS. SMB treatment during the breeding season resulted in a good synchrony of estrus in dairy goats (Bretzlaff et al. 1992). Goats were implanted with half of the cattle implant for norgestomet and given an IM injection with 0.375 mg norgestomet plus 0.625 mg estradiol valerate. Implants were removed after 9 days. Those implanted early in the cycle responded less with respect to synchrony of estrus than those implanted later in the cycle.

MELENGESTROL ACETATE IN CATTLE. Melengestrol acetate (MGA; Upjohn Co., Kalamazoo, MI) is an orally active progestin supplied as a premix which is fed at 0.5 mg daily for 14 days. Estrus is expected 16-20 days after the start of 14 days of MGA feeding. The advantages of MGA include ease in administration, lower relative costs, and the potential to induce estrus in noncycling animals. Since fertility at the first estrus after MGA is reduced (Zimbelman et al. 1970), $PGF_{2\alpha}$ is given 17 days after MGA withdrawal (Brown et al. 1986). $PGF_{2\alpha}$ induces luteolysis in the MGA-synchronized animals. Use of MGA without $PGF_{2\alpha}$ in natural mating situations has resulted in desired results (Patterson et al. 1990). In this case bulls were joined with heifers 15-18 days after MGA withdrawal. It was determined that 83% of the animals conceived within the first 30 days of the breeding season. Calf removal for 48 hours on days 16-17 after a 14-day MGA regimen has facilitated the estrous response (Patterson et al. 1990). In this case, $PGF_{2\alpha}$ was administered on day 31.

MELENGESTROL ACETATE IN SHEEP. MGA has been used to induce estrus in anestrous ewes (Safranski et al. 1992). MGA (0.125 mg twice daily) was fed for 9 days beginning in the spring. This treatment resulted in a significant increase in the percentage of ewes lambing and the number of lambs born per ewe exposed to rams. The administration of PG-600 in addition to MGA did not further enhance ewe productivity.

RELEASE OF PROGESTERONE INTRAVAGINALLY

CONTROLLED INTERNAL DRUG RELEASE (CIDR) DEVICE CONTAINING PROGESTERONE. These intravaginal progesterone-releasing devices are marketed for cattle (CIDR-Bovine, Eazi Breed), sheep (CIDR-S), and goats (CIDR-G) by AHI Plastic Co., Hamilton, New Zealand. The CIDR-B has 10% progesterone (1.9 g) incorporated. These devices remain in place for 7 days, with $PGF_{2\alpha}$ given at the time of removal in cycling animals or administration of 400 IU PMSG in anestrous animals. Placement of the CIDR-B for 15 days in cows and heifers resulted in 87% of the animals being mated by 96 hours and pregnancy rates were 50% over a 4-day period (Mcmillan and Macmillan 1989).

PROGESTERONE-RELEASING INTRAVAGINAL DEVICE (PRID). The PRID is composed of stainless steel coils coated with silicone rubber containing 6.75% progesterone. Estradiol benzoate (10 mg) in a gelatin capsule is sometimes attached to the PRID (Peters and Ball 1987). The PRID is efficacious in synchronizing estrus and ovulation in cattle. Placement for either 6 or 7 days, with $PGF_{2\alpha}$ administration either the day before PRID removal or the day of removal, resulted in good estrous synchrony of and pregnancy rates in heifers (Smith et al. 1984). PRID placed in beef cows for 12 days beginning the first eight days of the estrous cycle along with an injection of estradiol valerate (5.0 mg) resulted in good estrous synchrony (Sprott et al. 1984).

Polyurethane sponges impregnated with a variety of progestins (flurogestone acetate, FGA, Cronolone; chlorgestone acetate, CAP, Chlormadinone; medroxyprogesterone acetate, MAP, Provera) have been used to synchronize estrus in cycling ewes or in combination with PMSG to induce estrus in prepubertal or anestrous ewes (McDonald 1986). Puberty induction in lambs has utilized a progestin sponge for 10-14 days followed by 400-600 IU of PMSG. The same scheme is utilized in seasonally anestrous ewes, with 500-800 IU of PMSG at the time of progestin withdrawal.

Use of GnRH and Analogs

GENERAL. There are three GnRH preparations. Gonadorelin (Cystorelin®, Merial Limited; Factel®, Fort Dodge) is a hypothalamic decapeptide that stimulates the secretion of both FSH and LH. GnRH analogs include fertirelin acetate (Fertagyl®; Takeda Chemical Industries, Ltd., Osaka, Japan) and buserelin (Receptal®; Hoechst-Roussel Agri-Vet Co., Bucks., UK). A comparison of the biological activity of these products in terms of FSH/LH secretion in heifers has been reported (Chenault et al. 1990). Fertirelin acetate was 2.5-10 times more potent than gonadorelin, whereas buserelin was approximately 10-20 times more potent than fertirelin acetate. The use of GnRH around the time of insemination to increase fertility in cattle has yielded mixed results. Buserelin (10 µg) given to dairy cows at the time of insemination did not improve fertility. However, pregnancy rates were significantly improved when buserelin was given 12 days postinsemination (Drew and Peters 1994).

FOLLICULAR CYSTS. Ovarian follicular cysts in cows are defined as follicle-like structures that persist rather than ovulate. These are more than 25 mm in diameter and have been present for 10 days or more in the absence of a CL (Kesler and Garverick 1982). Occurrence is frequent in the postpartum dairy cow but rare in beef cows. Treatment recommendations are either HCG 5000 IU IV or 10,000 IU IM (Youngquist 1990). Most cows respond with the establishment of an estrous cycle within 3-4 weeks. Alternatively, this condition may be treated with 100 µg GnRH, which generally results in luteinization of the cystic structure, with estrus occurring in 18-23 days. The administration of $PGF_{2\alpha}$ 9 days after GnRH will often shorten the interval to estrus.

INDUCTION OF OVARIAN ACTIVITY IN THE MARE. The administration of the GnRH agonist buserelin to anestrous mares resulted in follicular growth, with ovulation induced by HCG (McCue et al. 1992). Mares received twice daily subcutaneous (S/Q) injections of buserelin (10 µg) beginning midwinter for a maximum of 28 days, with 2,500 IU HCG IV given when follicle size was more than 35 mm. This resulted in induction of estrus in 72% of the mares. Pregnancy rate and embryonic mortality were not altered.

Prostaglandin F and Analogs

CATTLE. $PGF_{2\alpha}$ administration results in luteolysis in cattle beginning on day 5 of the estrous cycle (Lauderdale 1972). Because of this effect, $PGF_{2\alpha}$ is followed by estrus 2-5 days postinjection. There are three prostaglandin products available for cattle: dinoprost tromethamine ($PGF_{2\alpha}$ tham salt) (Lutalyse®; Upjohn Co., Kalamazoo, MI), and two $PGF_{2\alpha}$ analogs, cloprostenol (Estrumate®; Mobay Corp., Shawnee, KS) and fenprostalene (Bovilene®; Syntex Animal Health, Inc., West Des Moines, IA). Dosages are 25 mg dinoprost tromethamine, 500 µg cloprostenol, and 1.0 mg fenprostalene.

$PGF_{2\alpha}$ given twice 10-12 days apart to a herd will result in the majority of the animals expressing estrus

3-5 days after the second injection (Lauderdale 1979). Pregnancy rates were not altered by breeding in estrus compared to a timed insemination 80 hours after the second injection. However, such a scheme of two injections may result in only 70% of the animals expressing estrus at the expected time (Burfening et al. 1978). The reason for this less-than-perfect synchrony is that animals injected during days 10-15 of the cycle were more likely to express estrus compared to those injected during days 5-9 of the cycle (MacMillan and Henderson 1984). A single $PGF_{2\alpha}$ injection scheme is satisfactory whereby animals are inseminated as they are observed in estrus for 4 days and then $PGF_{2\alpha}$ is injected on day 5, with breeding continuing on days 5-9 (Lauderdale et al. 1980).

MARE. Prostaglandins are used in mares to control the estrous cycle by induction of estrus because of diagnostic or therapeutic considerations, to synchronize with the stallion, or because of a missed breeding date (Meyers and LeBlanc 1991). Other reasons for control of estrus include shortening the first cycle postpartum to avoid breeding on foal heat, treatment for a persistent CL, synchronization of mares for embryo transfer, and ensuring that luteal structures are regressed following use of progestins to suppress estrus. Two products are approved for the mare: dinoprost tromethamine (Lutalyse®) 10 mg IM and fluprostenol (Equimate®; Miles) 250 µg IM.

Most mares will respond to the luteolytic effects of $PGF_{2\alpha}$ by day 5 of the cycle. The follicular status of the mare affects the interval from $PGF_{2\alpha}$ to estrus and ovulation (Neely 1983). When a large follicle is present at the time of $PGF_{2\alpha}$ administration, the mare will generally express estrus and ovulate within 6 days; however, the mare may ovulate within 24-72 hours and not show estrus. In contrast, if $PGF_{2\alpha}$ is administered when follicles are regressing, there may be a delay in expressing estrus because a longer period is required for follicular growth with sufficient estrogen secretion to elicit estrus. Ovulation during diestrus, not an infrequent event in the mare, could negate any intended effect of $PGF_{2\alpha}$.

Two injections of $PGF_{2\alpha}$ 14-18 days apart results in good synchrony of estrus in mares (Bristol 1987). Approximately 60% of the treated mares expressed estrus by 4 days after the second $PGF_{2\alpha}$ injection, and about 90% were in estrus by 6 days. The duration of estrus (3-10 days), as well as the time of ovulation (2-12 days), is highly variable. $PGF_{2\alpha}$ can be combined with HCG to decrease the variability in time of ovulation. An injection of 2000-3300 IU HCG IV when follicles are larger than 35 mm will generally induce ovulation within 24-48 hours (Ginther and Pierson 1989). GnRH is not effective in this regard unless it is given on a daily basis beginning on day 2 of estrus (Brinsko 1991).

GOAT. The use of $PGF_{2\alpha}$ in this species allows for planned breeding to a superior buck and facilitates estrous synchronization. A total of 2.5 mg $PGF_{2\alpha}$ is effective in mediating luteolysis in goats weighing up to 65 kg, although 8 mg $PGF_{2\alpha}$/doe has been used in some studies (Ott 1986). Estrus can be expected on an average of 50 hours after $PGF_{2\alpha}$ in those animals injected between days 4 and 16 of the estrous cycle. Two injections of 8 mg $PGF_{2\alpha}$ 11 days apart during the breeding season resulted in good synchrony of estrus and fertility.

Induced Parturition

CATTLE. Parturition may be induced in cattle by glucocorticoids and $PGF_{2\alpha}$. The reasons for induced parturition include allowance for more time postpartum before the next breeding season, an attempt to reduce calf size and therefore dystocia, prevention of excessive udder edema in dairy cattle, and to take advantage of available forage for milk production, as in New Zealand (Barth 1986). Generally, induction of parturition 1-2 weeks prematurely does not alter dystocia scores even though calf size has been reduced and does not adversely affect the calves. Some large European beef breeds calve up to 2 weeks beyond the normally accepted gestation lengths and consequently beef producers may elect to induce parturition in cows that have not calved when expected. This procedure generally results in placental retention, but subsequent fertility is not affected (Wagner et al. 1974).

Dexamethasone (20-30 mg) or flumethasone (8-10 mg) IM is 80-90% effective in parturition induction, with calving occurring 24-72 hours posttreatment. Calves can be expected to attain normal levels of immunoglobulins when induction is done within 2 weeks of term. Retention of placental membranes has exceeded 75% in some cases. Long-acting glucocorticoids (dexamethasone trimethylacetate, 20 mg; triamcinolone acetonide, 30 mg; flumethasone suspension, 10 mg; and betamethasone, 20 mg) are used primarily in New Zealand (Barth 1986). Treatment is given once IM approximately 1 month before calving. The mean interval to parturition is 15 days. The incidence of retained placentas is decreased relative to the short-acting glucocorticoids, but calf mortality is high (17-45%).

Calving may be induced with $PGF_{2\alpha}$ (25-30 mg) or cloprostenol (500 µg) IM with results similar to that found with short-acting glucocorticoids. The interval from injection to calving is 24-72 hours (Barth 1986). A combination of treatments with dexamethasone and cloprostenol has resulted in a shorter interval from treatment to delivery and a greater percentage induced compared to either drug alone or two injections of cloprostenol.

Reasons for terminating a pregnancy in this species include pregnancy in young heifers, reduced feed efficiency in pregnant feedlot heifers and cows, and pathologic pregnancies such as hydropic conditions (hydramnios and hydrallantois) and fetal mummification (Barth 1986). Prevention of the establishment of a

native treatment for metritis in the cow (Wichtel 1991). An advantage to PGF$_{2\alpha}$ treatment is that milk withdrawal is not necessary. PGF$_{2\alpha}$ (for doses, see the section on PGF and analogs) is the appropriate treatment to achieve luteolysis in cases of pyometra. Research data support the recommendation of whole-herd prostaglandin (25 mg dinoprost tromethamine or 500 µg cloprostenol) treatment of postpartum dairy cows once or twice between days 14 and 40 in herds with poor reproductive performance or a high incidence of uterine infections. Such treatment has resulted in decreased intervals from parturition to conception and increased first-service conception rates (Young and Anderson 1986; Etherington et al. 1988). This is attributed to either hastened uterine involution or the luteolytic effect that is helpful to eventual fertility.

TABLE 31.2—Superovulation in the cow

Day of cycle	Time	Treatment 1[a]	Treatment 2
10	A.M.	2500 IU PMSG	6 mg FSH
	P.M.		6 mg FSH

[a]Mapletoft 1986. [b]Artificial insemination.

Induction of Superovulation

CATTLE. Valuable cattle may be induced to ovulate multiple follicles (superovulation) so that embryos can be transferred to recipient animals to increase the number of progeny. In cattle, superovulation results in about 10 ovulations, compared to the normal, single ovulation (Seidel and Seidel 1991). Superovulation, on the average, results in about 6 usable embryos. The ideal response is 5-12 embryos from one-third of the donors. The donor superovulation injection program is begun between day 9 and 14 of the estrous cycle with FSH given over 4 days and PGF$_{2\alpha}$ given on days 3 and 4 (Mapletoft 1986) (Table 31.2). A problem with FSH products has been contamination with LH, which results in a decreased number of transferable embryos. FSH products include FSH-P (Schering-Plough), derived from pituitaries of domestic animals, and Super-Ov (Ausa International, Inc., Tyler, TX), derived from pig pituitaries. The Super-Ov product contains a controlled level of LH (Donaldson and Ward 1986), which results in a more uniform number of transferable embryos.

SWINE. The major reason for performing embryo transfer in swine is disease prevention (Martin 1986). Sows may be superovulated with an injection of PMSG (1200-1500 IU) at weaning. Alternatively, PMSG (1200-1500 IU) may be given 24 hours after the first injection of PGF$_{2\alpha}$ in sows that were either pregnant (16-45 days) or pseudopregnant. Pseudopregnancy is created by the use of estradiol injections on days 11-15 of the cycle (Kraeling et al. 1975).

Estrogen is luteotropic in the sow, resulting in CL maintenance. Pseudopregnant and pregnant sows are given PGF$_{2\alpha}$ twice (15 mg followed by 10 mg) at a 12-hour interval to bring about synchrony of estrus. Estrus can be expected within 4-7 days. The superovulatory response to PMSG has averaged between 30 and 45 ovulations.

GOATS AND SHEEP. The drug regime for superovulation in these species depends upon the reproductive status (Amoah and Gelaye 1990). During the breeding season, PGF$_{2\alpha}$ is used to mediate luteolysis, and gonadotropins are given to increase the ovulatory rate. The anestrous animal is given a progestin followed by gonadotropin treatment. Dairy goats were superovulated successfully during the breeding season by placement of an intravaginal sponge (MAP; 60 mg) for 11 days, 125 µg cloprostenol IM on days 1 and 9 of sponge treatment, and twice daily injections of FSH-P

then 0.2 mg/kg every 8 hours afterward) (Feldman et al. 1993). Treatment continued until abortion was complete. All bitches aborted within 9 days of beginning treatment. Early in pregnancy (beginning day 5 of diestrus) a $PGF_{2\alpha}$ dosage of 250 µg/kg S/Q twice a day for 4 consecutive days is recommended (Romagnoli et al. 1991). This treatment was 80% effective in Beagle bitches (Oettle et al. 1988). Failures were attributed to the refractoriness of CL due to their transitional status.

Bitches treated on or before days 8 or 9 of diestrus did not have a vaginal discharge associated with the loss of pregnancy; loss occurred before implantation. Those treated on days 12-14 of diestrus had a bloody-mucoid discharge around day 28 (Romagnoli et al. 1991). The interestrous interval may be shortened by this treatment, particularly when $PGF_{2\alpha}$ is given early in diestrus. A bitch given $PGF_{2\alpha}$ between diestrus days 10 and 12, e.g., was in estrus 42 days later (Johnston 1990).

Significant side effects are noted in the bitch given $PGF_{2\alpha}$, a median lethal dose is 5 mg/kg (Sokolowski and Geng 1977). Side effects are emesis, ataxia, anxiety, abdominal cramping, hyperpnea, diarrhea, and hypersalivation. Vomition resulted from the administration of 0.5 mg/kg $PGF_{2\alpha}$, and only one- fourth this dose was required to elicit defecation (Moncada et al. 1985). A transient hypothermic effect occurs for approximately 3 hours post-$PGF_{2\alpha}$. Generally, side effects are observed within 5 minutes after administration and persist for 20-40 minutes. Atropine administration prior to $PGF_{2\alpha}$ and walking the animal after $PGF_{2\alpha}$ administration have reduced side effects (Braakman et al. 1993). These effects tend to diminish after 4 or 5 injections. Because of the adverse effects, $PGF_{2\alpha}$ should only be administered to healthy young bitches.

Pregnancy has been terminated in queens after day 40 of pregnancy following either 0.50 or 1.00 mg/kg $PGF_{2\alpha}$ once or twice (Lein 1986). Abortion followed 8-24 hours post-$PGF_{2\alpha}$. Luteolysis occurred in pseudopregnant queens after day 21-25 in response to either 220 or 440 µg/kg $PGF_{2\alpha}$.

MECHANISMS TO EVACUATE THE INFECTED CANINE UTERUS. Uterine infections (metritis/pyometra) most commonly occur a few weeks postovulation during diestrus and shortly after whelping. Administration of either estrogenic or progestogenic preparations increases the incidence. $PGF_{2\alpha}$, in addition to causing luteolysis, results in cervical dilatation and uterine contractions (Burke 1982; Nelson et al. 1982; Sokolowski 1980). $PGF_{2\alpha}$ (25-1000 µg/kg S/Q or IM) is recommended twice daily for 3-5 days or until the vaginal discharge is scant and uterine size is considerably reduced (Lein 1986). Antibiotics are also used. In a large study, the successful $PGF_{2\alpha}$ dose varied from 26.8 to 258 µg/kg twice a day for 2-26 days (Gilbert et al. 1989). Clinical cure from symptoms was achieved in 33 of 40 bitches. It has been recommended that a further dose of $PGF_{2\alpha}$ be given 3-5 days after the intensive $PGF_{2\alpha}$ regimen to ensure that the uterus is not filling again with exudate (Burke 1982). Bitches should be bred at the next opportunity since pyometra may develop after the next nonpregnant cycle. Queens with pyometra may be similarly treated.

Oxytocin (2-3 U/45.5 kg) IM and ergonovine (0.2 mg/13.5 kg) PO or IM have been used to evacuate the uterus in the postpartum bitch with metritis (Johnston 1993). Oxytocin may be repeated at 30- to 40-minute intervals. Prior administration of estradiol cypionate (0.25 mg) IM enhances the effectiveness of oxytocin and ergonovine.

ANTINIDATORY ACTIVITY OF ESTROGENS IN THE BITCH AND QUEEN. Diethylstilbestrol (DES), a nonsteroidal compound with estrogenic activity, has been recommended as being antinidatory in the bitch (Shille 1982). However, DES given daily (0.075 kg) orally for 7 days during estrus did not interrupt pregnancy (Bowen et al. 1985). Benzoate, valerate, and cypionate estradiol delay absorption and metabolism of estradiol; consequently, they have a longer duration of action. Estradiol benzoate has been recommended (0.01 mg/kg) S/Q twice daily on days 3 and 5 postcoitum (Braakman et al. 1993). Estradiol cypionate given at 44 µg/kg IM during estrus or early diestrus prevented pregnancy (Bowen et al. 1985). Estradiol cypionate, however, resulted in a 25% incidence of pyometra when given during diestrus. Administration of 250 µg estradiol cypionate to queens 40 hours after coitus resulted in delayed ovum transport with degeneration of ova in 3 of 4 cats (Herron and Sis 1974).

Dogs are susceptible to estrogen toxicity (Bowen et al. 1985; Legendre 1976; Schalm 1978; Teske 1986). One problem with estrogens in the bitch has stemmed from the administration of estradiol cypionate, a long-acting (21-28 days) preparation (Shille 1982). The effects were more frequently noted with higher dosages in older dogs. Exogenous estrogen or that elaborated from tumors in the dog causes bone marrow depression characterized by thrombocytopenia followed by hemorrhages and pancytopenia. Cystic endometrial hyperplasia and pyometra are also sequelae. The queen is regarded as more tolerant of estrogens; however, estrogens potentially may suppress bone marrow activity in this species as well. Estrogen treatment also extends the period of estrus. The antinidatory mechanism of estrogens is via altered embryo tubal transport (Shille 1982) and biochemical environment of the uterus and the oviduct (Makler and Morris 1971).

MIFEPRISTONE (PROGESTERONE RECEPTOR ANTAGONIST). Mifepristone (RU-486, Roussel-Uclaf) is a synthetic steroid that interacts with the progesterone receptor and blocks the effect of progesterone upon the myometrium. Mifepristone is not available in the US. This is an effective abortifacient in the bitch without direct side effects (Concannon et al. 1990, Lavoud 1989). Administration of mifepristone (5-10 mg/kg) IM during the second half of pregnancy for 5-7 days resulted in abortion 5-7 days later (Taverne et al. 1989).

manifested in behavioral and/or physical changes, including congestion of the mammary glands and inappropriate lactation. These signs may also be associated with withdrawal of progestin therapy. Spontaneous remission will occur without treatment; however, treatment may be desired. Ergoline derivatives and other dopamine agonists reduce prolactin secretion and thus seem appropriate. Bromocriptine (Parlodel, Sandoz) tablets orally at either 30 μg/kg daily for 16 days or 10 μg/kg for 10 days have been effective (Janssens 1986). Vomiting occurred in about 25% of the animals. The owners were instructed to mix the bromocriptine in the food and to give 0.5 mg/kg metoclopramide, a dopamine antagonist and antiemetic, a half an hour before the meal if the first dose of bromocriptine elicited vomition. Cabergoline, another ergoline derivative, was found to be effective at 5 μg/kg/day IM for 7 days (Jöchle et al. 1989). Vomition again was a significant side effect. Testosterone has also been used to treat pseudopregnancy (Purswell 1994). A single dose of either testosterone cypionate or enanthate (0.66 mg/kg) has been effective and without side effects. Mibolerone has been recommended at 0.016 mg/kg orally daily for 5 days (Brown 1984).

UTERINE INERTIA. Oxytocin results in myometrial contractions during delivery. The dosage for uterine inertia in the dog is 5-20 U/dog IM (Table 31.1). This dosage may be repeated at 30- to 40-minute intervals, although the bitch may become refractory (Johnston 1993). Postpartum oxytocin promotes uterine involution and milk letdown.

CRYPTORCHIDISM. Cryptorchidism is the failure of one or both testes to be present in the scrotum of the dog by 6-8 weeks of age (Feldman and Nelson 1987). The testes migrate from the caudal pole of the kidney to the scrotum via guidance from the gubernaculum testis. At birth the testes in the dog are usually within the abdomen near the internal inguinal ring (Jones and Joshua 1982). The testes move through the inguinal canal and are in the scrotum by 10-14 days of age. Because this condition has a genetic basis, dogs with this condition should not be used for breeding purposes. The ethics of medical management of this condition should be considered by the veterinarian and the owner (Feldman and Nelson 1987). The most common method of treatment is serial injections of HCG. Dogs younger than 16 weeks of age are the best candidates. The IM injection of 100-1000 IU HCG 4 times in a 2-week period resulted in descent in 21 of 22 dogs. None of the 28 controls had complete descent.

BENIGN PROSTATIC HYPERTROPHY. Benign prostatic hypertrophy occurs in dogs over 5 years of age with an incidence thought to be at least 80%. Signs associated with this problem are constipation, blood in the urine or semen, and increased frequency of urination. The treatment of choice is castration; however, if this is declined there are medical alternatives. Megestrol acetate (Ovaban) decreases 5 α-reductase in prostate tissue, thereby interfering with the conversion of testosterone to dihydrotestosterone, the agent that mediates the hypertrophy. Megestrol acetate (0.55 mg/kg) given orally to dogs for 8 weeks inhibited the hematuria and blood in the ejaculate (Olson et al. 1987). This drug is not recommended to be given for more than 32 days and undoubtedly will interfere with sperm production. The antiandrogen finasteride (Proscar®; Merck) at a dose of 1.0 mg/kg daily is recommended (Johnston 1993).

INTRODUCTION

Hypothyroidism. Hypothyroidism is the most common endocrinopathy of the dog and is diagnosed with some frequency in the horse, but spontaneous hypothyroidism is rare in the cat and other domestic species. Less commonly, hypothyroidism can be caused by iodine deficiency or by the ingestion of goitrogenic substances (compounds that interfere with thyroid hormone synthesis by the thyroid gland) in the environment or food.

Clinical signs of hypothyroidism common to most species generally reflect the reduction in basal metabolic rate of the body and include lethargy, mental depression, weakness, inability to train, and/or nonpruritic hair loss (Feldman and Nelson 1987b; Ferguson, 1989a, 1993; Ferguson and Hoenig 1991b; Ferguson et al. 1992; Peterson and Ferguson 1990).

Hyperthyroidism. Hyperthyroidism is now the most common endocrine disorder in the cat and is only occasionally seen in other domestic species. Hyperthyroidism, or thyrotoxicosis, is caused by excessive concentrations of the circulating thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), most commonly the result of hyperplastic or benign adenomatous malignant thyroid glands in cats and adenocarcinomas in dogs. Hyperthyroidism occurs most frequently in middle-aged to geriatric cats, and discussion of therapeutic agents will focus on those used in this species. The most common clinical signs associated with hyperthyroidism that can be directly related to thyroid hormone excess are weight loss in spite of ravenous appetite, hyperactivity, polydipsia, polyuria, diarrhea, intermittent fever, vomiting, and symptoms of cardiovascular disease such as tachycardia and dyspnea. Often the cats shed excessive amounts of hair, or the coat may be matted. Rarely, hyperthyroid cats present in a way similar to what has been called "apathetic hyperthyroidism," when the cats are lethargic and often anorectic, perhaps representing an end-stage form of the disease (Feldman and Nelson 1987b; Ferguson and Hoenig 1991a; Peterson and Ferguson 1990).

THYROID PHYSIOLOGY

Iodine Metabolism. Thyroid hormones are the only iodinated organic compounds in the body. The two major secretory products of the thyroid gland, thyroxine (L-T_4) and 3,5,3′-triiodothyronine (L-T_3), contain 65% and 59% iodine, respectively. The minimum iodine requirement of most animals is unknown, but the daily amount needed in the ration to prevent goiter in all animals is generally accepted to be 1 µg/kg body weight. The daily recommended amount of iodine in the dog is 15 µg/kg and, while it has not been carefully studied in the cat, is believed to be about 100 µg/cat/day. Although true nutrient requirements for this micronutrient are not well established, most commercial dog and cat food preparations include at least three to five times this minimum requirement for iodine when fed in recommended amounts. As a result, iodine deficiency has become a rare condition in domestic animals. During pregnancy, the recommended minimum daily requirement for iodine is increased fourfold. Areas of iodine deficiency in North America include the Great Lakes region and eastern British Columbia (Belshaw et al. 1974; Kaptein et al. 1994; Peterson and Ferguson 1990).

Ingested iodine is converted to iodide in the gastrointestinal tract and absorbed into the circulation. The dog has plasma iodide concentrations of 5–10 µg/dL, which are 10–20 times the levels in human plasma. In the thyroid gland, iodide is concentrated or "trapped" by active transport mechanisms of the basolateral plasma membrane of the thyroid follicular cell, resulting in intracellular iodide concentrations that are 10–200 times that of serum. This process is stimulated by the interaction of thyrotropin (thyroid-stimulating hormone; TSH) with follicular cell surface receptors leading to the stimulation of cyclic AMP (cAMP) (see Fig. 32.1). Other tissues, including the salivary glands, gastric mucosal cells, renal proximal tubule cells, placenta, ciliary body, choroid plexus, and mammary glands, can take up considerable amounts of radioiodide in a TSH-independent fashion.

Diagnostically, radioactive iodide, or pertechnetate (TcO_4^-), which, unlike iodine, cannot be organified, can be used to assess the anion transport function (uptake) by the thyroid gland. Iodide trapping can be inhibited by other anions, such as thiocyanate (SCN^-), NO_3^-, and ClO_4^-. Thiocyanate is a metabolic product of some naturally occurring compounds in plants and may result in goitrogenic (antithyroid) activity of the plant. Oral administration of perchlorate following the administration of a tracer dose of radioiodine can be used to diagnose congenital defects in the thyroidal organification of iodide (perchlorate discharge test) (Greenspan 1994; Taurog 1971).

Thyroid Hormone Synthesis. Thyroglobulin (Tg), an iodinated glycoprotein with a molecular weight of 660,000, serves as a synthesis and storage site for thyroid hormones and their precursors in the thyroid follicle. After synthesis within the endoplasmic reticulum of the thyroid follicular cell, membrane vesicles containing noniodinated Tg fuse with the apical membrane and are released (by exocytosis) into the follicular cell lumen, where Tg is stored as colloid.

Once inside the thyroid cell, iodide diffuses down a concentration gradient to the apical surface of the cell, where it is oxidized by the enzyme thyroid peroxidase (TPO) to iodine (Fig. 32.1). It is then incorporated into tyrosine residues of Tg in a process called organification, forming monoiodotyrosine (MIT) and diiodotyrosine (DIT). Thyroxine (T_4) is then formed by coupling two DIT molecules, and 3,5,3′-triiodothyronine (T_3) is formed by coupling one MIT molecule with one DIT molecule (Burrow et al. 1989; Greenspan 1994; Peterson and Ferguson 1990; Taurog 1991).

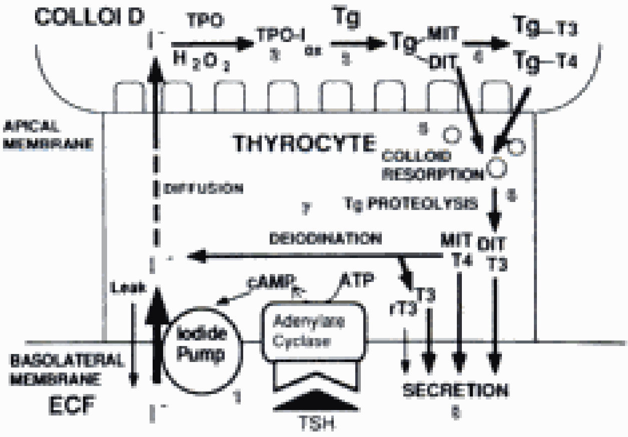

FIG. 32.1—Iodide uptake, organification, and secretion by the thyroid cell. Step 1: Iodide uptake. Inorganic iodide (I$^-$) is actively translocated into the thyrocyte from the extracellular fluid (ECF) to the cytosol of the follicular cell. The maintenance of the sodium gradient via the Na$^+$,K$^+$-ATPase pump appears to be important for this process. This step is stimulated by thyrotropin (TSH) interaction with a plasma TSH receptor and activation of adenylate cyclase. Steps 2 and 3: Oxidation and organification. After diffusion to the apical plasma membrane, the iodide is oxidized by the thyroid peroxidase enzyme (TPO) (step 2) and organified onto tyrosine residues of preformed thyroglobulin (Tg) (step 3) to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). Step 4: Coupling. The MIT and DIT residues on Tg couple to form T_3, and two DIT residues couple to form T_4. Step 5: Colloid resorption. Under the stimulus of TSH, follicular colloid containing Tg is resorbed into the thyrocyte. Step 6: Tg proteolysis. Thyroid hormones, MIT, and DIT are released from Tg under the stimulus of TSH. Step 7: Deiodination. Also stimulated by TSH at the time of secretion, deiodinase enzymes convert T_4 to T_3 and reverse T_3 (rT_3), and iodotyrosines are deiodinated to allow recycling of iodide. Step 8: Secretion. T_4, T_3, and rT_3 are released into the bloodstream. (Reprinted from Peterson and Ferguson 1990, Fig. 95-1.)

When iodine intake is adequate, production of T_4 is favored. However, in iodine-deficient states and impending thyroid failure, the intrathyroidal synthesis of T_3 is preferred over that of T_4. By this autoregulation, the thyroid gland produces the most active thyroid hormone (T_3 is 3–10 times more potent than T_4) while using less iodide. Conversely, chronic iodine excess may lead to excessive storage of thyroidal hormone.

The *Wolff-Chaikoff effect*, another intrathyroidal regulatory mechanism, is key to understanding the potential acute antithyroid effect of large amounts of ingested iodide. Mediated via inhibition of the TPO enzyme, iodide decreases the rate of its own relative

centrations, making it more difficult to confirm an overdosage (Braverman and Utiger 1991; Ferguson 1984; Greenspan 1994; Quinlan and Michaelson 1981; Williams et al. 1996; Bruner et al. 1998).

The tripeptide TRH is produced in the paraventricular nucleus of the hypothalamus and transported to the pituitary pars distalis by the hypophyseal portal system in the pituitary stalk. In the pituitary gland, TRH binds to specific receptors on the thyrotrope cell and stimulates TSH secretion (Fig. 32.2). In the dog, as in other species, TRH also stimulates the secretion of prolactin. The hypothalamic hormone somatostatin acts to inhibit TSH secretion and may function as a thyrotropin inhibitory factor (Reichlin 1986).

NEGATIVE-FEEDBACK REGULATION. The negative-feedback effect of thyroid hormones (in the free or unbound form) is the principal mechanism regulating TSH secretion. Tonic stimulation by TRH has a permissive role in TSH secretion. The pituitary thyrotrope cell completely deiodinates T_4 (derived from the plasma) to T_3, which subsequently inhibits TSH synthesis and secretion through alteration of nuclear receptor binding, mRNA transcription, and protein synthesis. Circulating T_4 taken up by the pituitary is the preferred source of T_3 in the pituitary, at least in the rat (Larsen et al. 1981). In human patients with hypothyroidism, thyroid replacement therapy with L-T_4 normalizes serum TSH concentrations only when the serum T_4 value is high-normal to slightly high; serum T_3 concentrations usually remain within normal range in these patients (Fish et al. 1987; Larsen et al. 1981).

There is also evidence that thyroid hormones may have a direct negative-feedback effect on the hypothalamus to inhibit the release of TRH (Fig. 32.2). Also, TSH and TRH may have "short-loop" and "ultrashort-loop" negative-feedback effects, respectively, upon the hypothalamus to inhibit TRH release. Although pulses of TSH secretion and an evening rise in serum TSH have been described in humans (possibly resulting from a fall in circadian circulating cortisol concentrations), studies in the dog and cat have failed to demonstrate such a circadian rhythm in circulating thyroid hormone concentrations (Fish et al. 1987; Larsen et al. 1981; Magner 1990; Reichlin 1986; Bruner et al. 1998).

Metabolism of Thyroid Hormone. The metabolically active thyroid hormones are the iodothyronines L-thyroxine (L-T4) and 3,5,3′-L-triiodothyronine (L-T_3) (see Fig. 32.3). Thyroxine is the main secretory product of the normal thyroid gland. However, T_3, which is about 3–10 times more potent than T_4, as well as smaller amounts of 3,3′,5′-L-triiodothyronine (reverse T_3; a thyromimetically inactive product) and other deiodinated metabolites are also secreted by the thyroid gland of most mammals (Figs. 32.2 and 32.3) (Belshaw et al. 1974; Ferguson 1984; Inada et al. 1975; Kaptein et al. 1993, 1994; Laurberg 1980).

Although all T_4 is secreted by the thyroid, a considerable amount (40–60% in the dog) of T_3 is derived from extrathyroidal enzymatic 5′-deiodination of T_4. Therefore, although it also has intrinsic metabolic activity, T_4 has been called a "prohormone," and its

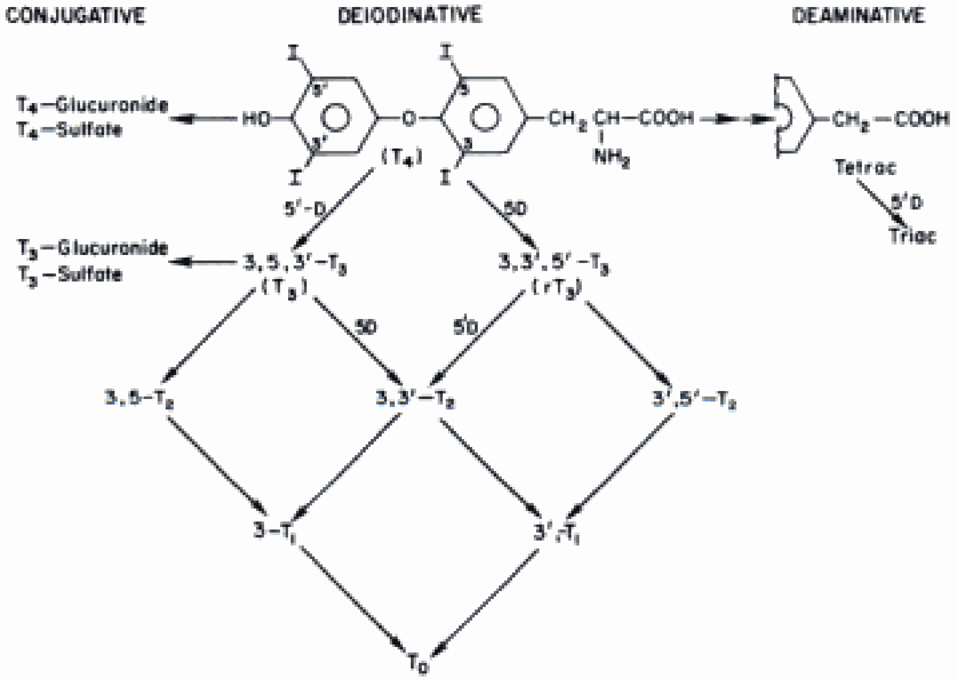

FIG. 32.3—Pathways of metabolism of thyroid hormones. 5′-D = 5′-deiodinase. 5-D = 5-deiodinase (Reprinted from Ferguson 1984.)

of thyroid hormone is known to be very large. In the dog, over 50% of the T_4 and about 30% of the T_3 produced each day are lost in the feces. In both the dog and cat, the extrathyroidal body stores of T_4 are eliminated and replaced in about 1 day, whereas stores of T_3 are lost and replaced twice daily (Kaptein et al. 1993, 1994). Such fecal wastage is responsible, in part, for the higher daily replacement doses of thyroid hormone required on a per body weight basis in dogs and cats. It is possible, but not proven, that, in some animals, dividing the daily oral replacement dose may serve to reduce the loss of hormone due to the hepatic first-pass effect, resulting in a more consistent clinical response.

Plasma Hormone Binding of Thyroid Hormone. Thyroid hormones are water-insoluble lipophilic compounds. Their ability to circulate in plasma is dependent upon binding by specific binding proteins, thyroxine-binding globulin (TBG) and thyroxine-binding prealbumin (TBPA; transthyretin), as well as by albumin itself. Thyroid hormone–binding proteins provide a hormone reservoir in the plasma and "buffer" hormone delivery into tissue (Fig. 32.4). TBPA and possibly albumin also may serve as intermediary carriers for specific tissue uptake of the hormone by tissues (Mendel 1989; Pardridge 1981). The dog has a high-affinity thyroid hormone–binding protein comparable to TBG in the human, but plasma concentrations of TBG in the dog are only 25% of those in the human. In addition to TBG, TBPA, and albumin, circulating T_4 in canine plasma appears to bind to certain plasma lipoproteins. These include a high-density lipoprotein (HDL_2) that migrates in the α_1 region on the electrophoretic pattern and a very low density lipoprotein (VLDL) that migrates in the β region. At normal serum T_4 concentrations in the dog, about 60% of T_4 is bound to TBG, 17% to TBPA, 12% to albumin, and 11% to the HDL_2. Thyroxine-binding globulin in the dog is not saturated until the total T_4 concentration is six times the normal serum T_4 values, whereas the other serum proteins are virtually unsaturable (Inada et al. 1975). The cat does not appear to have a high-affinity thyroid hormone–binding protein (such as TBG) but has only TBPA and albumin as serum thyroid hormone–binding proteins. Partly as a result of weaker serum protein binding, total T_4 concentrations are lower, the unbound, or free, fraction of circulating T_4 is higher, and hormone metabolism is more rapid in most domestic animals than in humans (Bigler 1976; Kaptein et al. 1994; Larsson et al. 1985; Larsson 1987).

Tissue Thyroid Hormone Uptake: The "Free Hormone" Hypothesis. The free hormone hypothesis, proposed by Robbins and Rall 40 years ago and restated by Mendel, states that it is the unbound fraction of hormone which is available to tissues and therefore proportional to the action, metabolism, and elimination of that hormone (Robbins and Rall 1960; Mendel 1989). This hypothesis has stood the clinical test of the past 40 years; direct or indirect measurements of free T_4 have been a mainstay in the diagnosis of thyroid disease in human medicine. There is also strong evidence that certain cell types actively transport or exchange thyroid hormone from the plasma into the cytosol. The presence of a plasma membrane protein specific for thyroid hormone transport certainly reflects the premium the cell is willing to pay to facilitate entry and possibly concentration of thyroid hormone. However, some investigators would argue that the serum binding proteins, particularly albumin and TBPA, may serve to distribute hormones to specific tissues. Most theories of thyroid hormone exchange have assigned a passive "reservoir" role to cytosolic thyroid hormone–binding proteins (CTBP; CBP in Fig. 32.4), the proteins that retain thyroid hormone in a predominantly bound state inside the cell. Little is known about the regulation of these proteins, which are often called "intracellular albumin" because of their low specificity, low affinity, and high capacity. However, in renal cytosol, the affinity of CTBP may be acutely regulated by cellular redox potential, increasing when nicotinamide adenine dinucleotide phosphate (NADPH) levels are high (Burrow et al. 1989; Hashizume et al. 1987; Kaptein et al. 1994; Mendel 1989; Pardridge 1981).

Irrespective of the mechanisms, the following observations in the clinical patient must be recognized:

1. The linear correlation between the serum free T_4 concentration, rate of hormonal degradation, and basal metabolic rate in humans.
2. The inverse correlation between the serum free T_4 concentration and the cellular distribution volume of T_4, which exists in all subjects regardless of thyroid state.
3. The positive correlation between the in vitro perfused organ free T_4 concentration and tissue T_4 uptake and T_3 production in vivo and in vitro. Most researchers agree that the steady-state tissue concentrations of hormone are the driving force for thyroid hormone metabolism and action (Mendel 1989).

In the healthy euthyroid dog or cat, about 0.1% of total concentration of serum T_4 is free (i.e., not bound to thyroid hormone–binding proteins), whereas about 1% of circulating T_3 is free (Ferguson and Peterson 1992; Kaptein et al. 1994). The proportion of free hormone may change in response to drug administration or illness. For example, plasma compounds in uremia (possibly free fatty acids) compete for hormone binding, resulting in a transient increase in free serum thyroid hormone concentrations but decreased total hormone values (Ferguson 1988, 1989b, 1994). However, it appears that the thyroid status of the animal does not change, since the absolute level of the free hormone concentrations tends to soon return to within normal range or remains relatively constant (Ferguson 1988, 1989b, 1994).

Most evidence suggests that the thyroid hormone uptake by tissues is proportional to but not limited to the free, or unbound, fraction of circulating hormone. Approximately 50–60% of the body's T_4 and 90–95%

TABLE 32.3—Relative nuclear binding affinity of thyroid hormone analogs to T_3

Analog	Relative binding affinity (T_3 = 1) In vitro	In vivo
L-T_3	1.0	1.0
D-T_3	0.6	0.7
Triiodothyroacetic acid (triac)	1.6	1.0
Isopropyl T_2	1.0	1.0
L-T-$_4$	0.1	0.1
Tetraiodothyroacetic acid (tetrac)	0.16	0.05
3,3′,5′-T_3 (reverse T_3)	0.001	0
Monoiodotyrosine	0	0
Diiodotyrosine	0	0

Source: Oppenheimer 1983.

metabolic activity, L-T_3 is 3–10 times more potent in binding to the nuclear receptors and similarly more potent in stimulating oxygen consumption (see Table 32.3). Except for the deaminated forms of T_4 and T_3 (tetraiodothyroacetic acid [Tetrac] and triiodothyroacetic acid [Triac], respectively), most thyroid hormone metabolites have little thyromimetic activity.

The effects of thyroid hormone can generally be divided into those that are rapid and evident within minutes to hours of administration, such as stimulation of amino acid transport and mitochondrial oxygen consumption, and those that require protein synthesis and a longer period of time (usually no sooner than six hours) to be manifested. Of course, the clinical manifestations may require weeks to months to clearly appreciate. About one-half of the increment in oxygen consumption produced by thyroid hormone has been related to activation of the plasma membrane-bound Na^+,K^+-ATPase, which, at least in the kidney and liver, is secondary to increases in passive K^+ fluxes caused directly and primarily by thyroid hormone via as yet undetermined mechanisms. These changes have been linked directly to the calorigenic effect of thyroid hormone. The rapid hormone effects can be observed clinically in the hypothyroid patient starting on thyroid replacement therapy by signs such as increased physical and mental activity (Braverman and Utiger 1991; Burrow et al. 1989; Greenspan 1994).

Nuclear Receptor–Mediated Effects of Thyroid Hormone. Chronic effects of thyroid hormone invariably are related to the cellular actions of the hormone requiring interaction with nuclear T_3 receptors followed by an increase in protein synthesis. Clinically, these are effects such as growth, differentiation, proliferation, and maturation. A common clinical presentation of thyroid insufficiency is bilateral symmetrical alopecia, the result of diminished turnover of shafts of hair within the hair follicle, resulting in greater numbers of telogen (inactive) hairs. Such changes are slow in onset and, upon treatment, slow to resolve.

Free thyroid hormone is translocated by passive diffusion or specific plasma membrane carriers to bind to

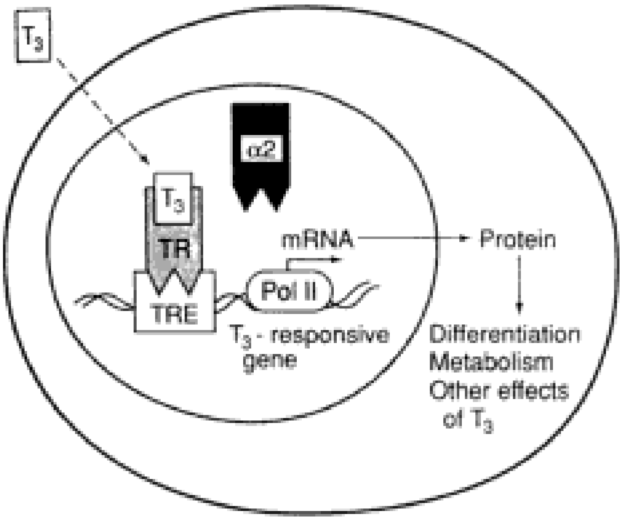

FIG. 32.6—Model of the mediation of T_3 action by nuclear thyroid hormone receptors (TR). T_3 either enters the cell (as depicted) or is derived from intracellular deiodination of T_4. Nuclear interaction between a T_3-bound TR and a thyroid hormone–responsive element (TRE) results in increased or decreased activity of RNA polymerase II (Pol II) on a T_3-responsive gene. The TRE is indicated as containing two half-sites, and the TR may bind as a dimer. Effects on mRNA levels are translated into increased or decreased cellular concentrations of proteins so as to promote differentiation, metabolic processes, and other cell-specific effects of T_3. In the absence of T_3, the TRE-bound TR may repress basal transcription. c-*erb*A_α2 (α2), the non-T_3-binding splice variant, can inhibit the effects of T_3-bound TRs by a mechanism that has not yet been established, probably involving heterodimer formation or competition for the TRE. A similar mechanism is likely to explain the dominant negative effect of the v-*erb*A oncoprotein and mutated TRs, as in the syndromes of generalized resistance to T_3. (Reprinted from Lazar and Chin 1990, Fig. 4-29.)

CTBP as a form of intracellular hormone storage, all in equilibrium with specific nuclear thyroid hormone receptors (see Fig. 32.6). The nuclear receptor for T_3 has been cloned and is a member of a family of receptors that is similar to the v-*erb* A receptor (which is a receptor for the avian erythroblastosis virus) and includes the nuclear glucocorticoid, mineralocorticoid, estrogen, progestin, vitamin D-3, and retinoic acid receptors. The human thyroid hormone receptor (hTR) exists in at least three forms: hTR-α1, hTR-α2, and hTR-β1. The α1 and β1 forms are associated with biological effects. Each receptor contains three domains: an amino terminal sequence that enhances receptor activity, a central DNA-binding domain, and a carboxyl-terminal hormone-binding domain. The thyroid hormone receptors are the specific thyroid hormone–responsive element (TRE) sites on the DNA in the absence of T_3. L-T_3 binding to the receptor results in stimulation or, in some cases, inhibition of the transcription of the genes, with changes in messenger RNA levels encoding the protein product of the genes that mediate the ultimate thyroid hormone biological response. When an action is mediated via the nuclear T_3 receptor, the binding affinity of thyroid analogs directly predicts the biological activity of that analog (see Table 32.3).

Extranuclear Actions of Thyroid Hormone. Some of the actions of thyroid hormone occur in the absence of new protein synthesis. There are direct nongenomic effects of thyroid hormone, such as the reduction of pituitary type II 5′-deiodinase enzyme, as well as stimulation of glucose and amino acid transport and Ca^{++}-ATPase activity in the red blood cell membranes of some species. A mitochondrial T_3 receptor has also been identified and has been postulated to mediate the activity of the mitochondrial ATP/ADP translocase, indirectly stimulating oxygen consumption (Greenspan et al. 1994).

Physiologic and Possible Pharmacologic Effects of Thyroid Hormone. Thyroid hormones, in physiological quantities, are anabolic. Working in conjunction with growth hormone and insulin, protein synthesis is stimulated and nitrogen excretion is reduced. However, in excess (i.e., hyperthyroidism), they can be catabolic, with an increase in gluconeogenesis, protein breakdown, and nitrogen wasting. Table 32.4 summarizes the multiple organ effects of thyroid hormones and the clinical manifestations of hormone deficit (hypothyroidism).

CALORIGENESIS AND THERMOREGULATION. Thyroid hormones increase oxygen consumption and heat production to a large extent by stimulating Na^+,K^+-ATPase in all tissues except the brain, spleen, and testis. As such, thyroid hormones determine the basal (resting) metabolic rate (BMR) of the animal. A reduced BMR results in mental dullness, lethargy, an unwillingness to exercise, hypothermia, and the tendency for the animal to seek heat (Greco et al. 1998). Once-daily administration of 0.022 mg/kg was sufficient to normalize BMR when measured by indirect calorimetry. Clinical signs in 93% of the dogs either improved or were completely resolved. This dosage was also shown to suppress TSH values to undetectable levels in most thyroidectomized dogs (Ferguson and Hoenig 1997).

EFFECTS ON GROWTH AND MATURATION. The fetus in most mammals is dependent on its own thyroid secretion. Thyroid hormones are crucial for growth and development of the skeleton and CNS. Therefore, in addition to the well-recognized signs of adult-onset hypothyroidism, prominent signs of congenital and juvenile-onset hypothyroidism are disproportionate dwarfism and impaired mental development (cretinism). With primary congenital hypothyroidism, enlargement of the thyroid gland (goiter) is also often observed. Puppies, kittens, and foals with this condition are behaviorally dull and less active and may have a shuffling gait and a poor appetite. On neurological

TABLE 32.4—Physiological effects of thyroid hormone

Site of action	Effect of hormone	Effects of deficit
Calorigenesis	Increase in BMR	Lethargy, weakness
Thermoregulation	O_2 consumption	Distal extremity hypothermia, heat-seeking
Growth and maturation	Normal CNS development	Mental retardation of cretin and dullness in adults; neuropathies
Carbohydrate metabolism	Increase in glycogenolysis and glycolysis, anti-insulin effects	Obesity despite normal or decreased appetite
Protein metabolism	Increased synthesis and degradation	Muscle weakness, poor hair coat and regrowth
Dermatologic	Normal maintenance of anagen hairs, maintenance of fatty acid turnover in skin, normal keratin turnover rates	Bilateral symmetrical alopecia, hyperkeratosis, myxedema
Cardiovascular	Stimulation of myosin ATPase, stimulation of Na^+,K^+-ATPase, increased β-receptor numbers	Decreased heart rate, pulse, pressure, and cardiac output
Neuromuscular	Normal myelin production, maintenance of balance between slow-twitch and fast-twitch fibers	Polyneuropathy, muscle atrophy, weakness, stiffness, myotonia
Gastrointestinal	Maintenance of normal electrical activity of GI smooth muscle, normal segmentation	Diarrhea or constipation
Reproductive	Maintenance of normal protein synthetic rates	*Female:* anestrus, irregular cycles, galactorrhea, stillbirth *Male:* azospermia, lack of libido
Immunologic	Stimulus of humoral and cell-mediated immunity	Recurrent infections (especially pyodermas)
Hematologic	Bone marrow stimulation, factor VIII and VIIIAg production, normal platelet synthesis and function	Nonresponsive anemia, possible bleeding tendency
Endocrine	Normal secretion of growth hormone, gonadotropins, cortisol; inhibition of secretion of prolactin	Secondary growth hormone deficiency, galactorrhea

examination, the animal is often weak and hyporeflexic or hyperreflexic (if there is muscle tremor or spasticity) and may lack conscious proprioception. Angular deformities have been observed in foals. Radiographic signs of underdeveloped epiphyses, shortened vertebral bodies, and delayed epiphyseal closure are common.

Effects on Lipid and Carbohydrate Metabolism. Thyroid hormones increase gluconeogenesis and glycogenolysis, contributing to their insulin-antagonistic properties. Cholesterol synthesis and degradation are both increased by thyroid hormones and are mediated by an increase in hepatic low-density lipoprotein (LDL) receptors. Therefore, hypercholesterolemia is a common finding in hypothyroidism. Thyroid hormones stimulate lipolysis, releasing fatty acids and glycerol. Obesity may develop in some hypothyroid animals despite a normal appetite and caloric intake.

Dermatologic Effects. Thyroid hormones in physiological quantities are necessary for normal hair and skin turnover. Thyroid insufficiency results in an increased percentage of telogen (inactive) hair follicles and an increase in keratin and sebum production. Dryness of the hair coat, excessive shedding, and retarded regrowth of hair are early signs of hypothyroidism in dogs. Alopecia, present in about two-thirds of affected dogs, is usually bilateral and symmetrical in distribution and is most obvious over points of friction, such as the ventral trunk and neck, axilla, and tail ("rat-tail" appearance), but also is common in the perineal area and the dorsum of the tail and nose. The alopecia is classically nonpruritic unless secondary seborrhea or dermatitis has developed. Thickening of the skin and/or the development of myxedema (subcutaneous accumulation of glycosaminoglycans) develop in some cases. Myxedema is most prominent in the facial features, which may take on a puffy or "tragic" appearance. The type and distribution of dermal fatty acids can even be stimulated by replacement dosages of thyroid hormone in euthyroid animals. It is possible that this effect is truly a pharmacological effect of thyroid hormones and might explain the improvement in hair coat that some dogs experience following thyroid hormone administration even when diagnostic tests fail to confirm hypothyroidism.

Cardiovascular Effects. The major physiologic effects of thyroid hormones on the myocardium are (1) a direct positive inotropic effect, (2) stimulation of myocardial hypertrophy, and (3) increased responsiveness to adrenergic stimulation. Thyroid hormones increase the sarcolemmal Na^+,K^+-ATPase activity and favor the transcription of the α, or "fast-twitch," form of the cardiac myosin ATPase, improving cardiac contractility. In addition, myocardial contractility is improved by increasing the number of L-type calcium channels and enhancing sarcoplasmic reticulum calcium uptake and release.

Thyroid hormones increase the number of β-adrenergic receptors in the heart, skeletal muscle, adipose tissue, and lymphocytes. In hyperthyroidism, tachycardia often results from this mechanism. Thyroid hormones also decrease α-adrenergic receptors in cardiac and vascular tissue. In hypothyroidism, the sensitivity to catecholamines in the peripheral vasculature is increased and may lead to peripheral hypothermia.

Neuromuscular Effects. Thyroid hormones stimulate the synthesis of many proteins associated with normal nerve and muscle activity. For example, nerve Na^+,K^+-ATPase and fast forms of the myosin ATPase in muscle are stimulated by thyroid hormones. Myopathies have also been associated with hypothyroidism in domestic animals. Severe muscle weakness and delayed reflexes may be the clinical manifestation, or the signs may be vague, such as stiffness, reluctance to move, and muscle wasting. Facial muscle and eyelid weakness (lip and lid droop) attributable to cranial nerve VII paralysis or paresis has been observed in dogs. Also, head tilt may be observed consistent with vestibular nerve disruption. These changes are likely due to the swelling of and around the dural sheath of the facial, vestibular, and cochlear nerves as they pass through bony foramina in the facial bones. Bilateral laryngeal paralysis has been associated with hypothyroidism in dogs as well. The pathophysiology of polyneuropathies associated with hypothyroidism is poorly understood but may be due to altered neuronal metabolism. Segmental demyelination and axonopathy have also been shown. Alternatively, compressive neurologic abnormalities may be the result of tissue swelling (myxedema) around the spinal cord or peripheral nerve. Clinically and electrodiagnostically, the polyneuropathy is indistinguishable from those caused by other diseases with hyporeflexia, slow nerve conduction velocities, fibrillation potentials, and positive sharp waves on electromyography. Although extremely rare, CNS signs of seizures, disorientation, and circling also have been reported in hypothyroid dogs with cerebrovascular atherosclerosis caused by the hyperlipidemia associated with hypothyroidism. Severe mental obtundation can also be observed in the syndromes of cretinism and myxedema coma.

Gastrointestinal Effects. Studies in hypothyroid dogs have demonstrated a decrease in the intestinal and gastric electrical and motor activity. Although hypothyroid dogs usually have normal bowel movements, constipation and diarrhea have also been observed.

Reproductive Effects. Normal thyroid hormone concentrations appear to be important for normal reproductive cycling of mammals. Hypothyroidism has been associated with a variety of reproductive disturbances in dogs and horses. In breeding bitches, persistent or sporadic anestrus, infertility, abortion, and high puppy mortality have been observed. Galactorrhea is a rare sign of hypothyroidism that develops in some intact female dogs whose mammae have been primed

separate doses given at 12-hour intervals. Because of the significant intracellular capacity for storage of T_4, particularly in rapidly exchanging pools like liver and kidney, the initial oral doses of thyroid hormone may be substantially distributed into tissue stores. As previously outlined, hypothyroidism reduces the deiodinative and conjugative rate of thyroid hormone metabolism. Division of the daily dose reduces the metabolic effect of a bolus of thyroid hormone on hypothyroid tissues and decreases the "one-pass" effect (i.e., hepatic metabolism and excretion of a portion of a bolus dose of hormone before ever reaching the systemic circulation). During the initial days to weeks of replacement therapy in a hypothyroid animal, the hormone stores of the liver and kidney are repleted to euthyroid levels and then can serve to "buffer" serum concentrations when the circulating hormone "store" bound to binding proteins begins to be depleted. The clinical result is that many hypothyroid animals can be maintained on once-daily T_4 therapy despite the fact that the serum half-life is much shorter. In humans, it seems that clinical improvement and suppression of serum TSH can be maintained by any replacement regimen that, over the course of a day, leads to a normal average serum concentration without leading to the acute toxic effects of thyroid hormone. Although the serum T_4 concentration might be high at one time of the day and low at another, the tissue response "integrates" the serum concentration throughout the day, thereby reflecting the average concentration. Once-daily administration also leads to greater compliance by owners. In an animal that has responded to twice-daily therapy, the reappearance of clinical signs of hypothyroidism on a once-daily regimen should be a signal to return to the successful twice-daily regimen. Because the metabolism of thyroid hormone changes with correction of hypothyroidism, dosage regimes should be reassessed by clinical and laboratory criteria after at least 4 weeks of initial therapy.

L-THYROXINE DOSAGES FOR THE CAT. As in the dog, the recommended treatment for feline hypothyroidism is daily administration of L-T_4, using an initial dose of 0.1–0.2 mg/day. This dosage should subsequently be adjusted on the basis of the cat's clinical response and postpill serum T_4 evaluation (as described below under Monitoring Therapy). Complete resolution of clinical signs can usually be expected in cats with adult-onset iatrogenic hypothyroidism. However, the mental dullness and dwarfism that develop in kittens with hypothyroidism usually persist because of the time elapsed between onset and diagnosis in these cats (Peterson and Ferguson 1990; Rosychuk 1982).

L-THYROXINE DOSAGES FOR THE HORSE. There is little published information establishing therapeutic criteria for L-T_4 dosing in the horse. The oral L-T_4 dosage required clinically appears to depend largely on the form of hormone (crude vs. synthetic) used for replacement therapy.

Synthetic L-Triiodothyronine. Although T_3 is the active intracellular hormone, there are few valid reasons to use this product for replacement therapy and some good reasons not to use it. T_3 therapy is not physiological, as it bypasses the final cellular regulatory step of 5′-deiodination of T_4 (see Fig. 32.7). T_4 does have intrinsic thyromimetic activity. Its role is particularly important in the CNS and pituitary, tissues in which normalization of the intracellular T_3 concentration depends upon the normalization of both serum T_4 and T_3. Treatment with T_3 alone may provide amounts sufficient for organs like the liver, kidney, and heart, which derive a high proportion of T_3 from plasma. However, the brain and pituitary, which derive a majority of their T_3 from T_4 intracellularly, may then be deficient in thyroid hormone. Conversely, T_3 therapy adequate for the brain and pituitary may be excessive for the liver, kidney, and heart (see Fig. 32.7, top).

At present, it cannot be recommended that T_3 therapy be instituted in the "low-T_3 syndrome" associated with nonthyroidal illness. Because of its higher oral bioavailability, it may be used to improve the clinical response in a dog with demonstrated or suspected poor T_4 absorption in which posttherapy serum T_4 and T_3 concentrations remain low despite increases in the oral daily T_4 dose. T_3 therapy may be indicated when thyroid replacement is necessary because of the simultaneous administration of drugs, such as glucocorticoids, that inhibit the conversion of T_4 to T_3.

Anecdotal reports suggest that a small fraction of hypothyroid dogs convert T_4 to T_3 poorly in the absence of obvious nonthyroidal illness and, therefore, do not respond to L-T_4 therapy. T_3 therapy has been recommended in these cases as an adjunct to T_4 or as sole therapy. The most likely cause of apparently low serum T_3 concentrations and normal or high T_4 concentrations following T_4 therapy is the presence of anti-T_3 antibodies, which, in certain T_3 radioimmunoassays, will result in an extremely low reading for the T_3 concentration. This observation is an in vitro artifact that has no relevance to the choice of replacement therapy products. Because the binding capacity of antithyroid hormone antibodies is easily overcome in most cases, it is recommended that usual dosages of L-T_4 be administered and the dose increased (if needed) until a clinical response is seen. The posttreatment serum T_3 concentration should be ignored in these dogs with T_3 autoantibodies (Ferguson 1986; Rosychuk 1982).

TRIIODOTHYRONINE (T_3) SUPPRESSION TEST IN THE CAT. As part of a workup for hyperthyroidism in cats, the administration of L-T_3 is utilized to evaluate the autonomy of thyroid secretion from the influence of pituitary TSH. L-T_3 is administered at a dose of 25 μg every 8 hours for 2 days, giving a seventh dose on the morning of the third day. A blood sample for serum T_4 measurement is taken before T_3 administration and again at 4 hours after the last dose. Presumably mediated via a fall in pituitary TSH, serum T_4 is depressed by at least 50% in normal cats, whereas little suppression is seen in cats with hyperthyroidism because TSH is already depressed. The advantages of this test are that the doses of T_3 can be given at home on an outpatient basis, with an office visit 4 hours after the last dose (Graves and Peterson 1994; Peterson and Ferguson 1990).

Effects of Thyroid Hormone Overdose (Iatrogenic Thyrotoxicosis). Except for financial reasons, the concern about mild overreplacement is minimal in most cases because the dog is very resistant to the development of thyrotoxic signs. This resistance to iatrogenic thyrotoxicosis is the result of the dog's capacity to efficiently clear thyroid hormone via biliary and fecal excretion. Animals on replacement therapy, particularly with a T_3-containing product, can develop signs of thyrotoxicosis; however, the incidence at recommended doses is rare. Animals should be monitored for signs suggesting an overdose, including polyuria, polydipsia, nervousness, weight loss, increase in appetite, panting, and fever. Diagnosis is confirmed by elevated serum T_4 and/or T_3 concentrations and the amelioration of signs by temporary discontinuation of therapy. Following accidental ingestion of massive amounts of L-T_4, dogs should be treated with activated charcoal within several hours of ingestion, possibly managed with β-adrenergic blockers if tachycardic, and heart rate and body temperature should be carefully monitored. Clinical experience has generally shown that dogs survive intoxication with few side effects despite considerable elevations in serum T_4 and T_3 concentrations.

Therapeutic Trial for Diagnosis of Hypothyroidism. Thyroid replacement therapy, without confirmatory laboratory evidence of hypothyroidism, has been suggested as a valid diagnostic step in a dog suspected to be hypothyroid. Although the major factor cited in defense of this practice is the cost of the diagnostic testing for the owner, it should be emphasized to an owner that replacement therapy is generally necessary for the remainder of the animal's life. Therefore, an incorrect diagnosis (and unnecessary long-term thyroid hormone treatment) can also be quite expensive. In one study of normal dogs given L-T_4 at the dosage of 0.5 mg/m² twice daily, the mean serum T4 response to exogenous TSH had suppressed to 56% and 46% of the pretreatment value when retested at 4 and 8 weeks on treatment, respectively. Four weeks after cessation of L-T_4 therapy, the serum T_4 response to TSH was still slightly suppressed, indicative of residual thyroid atrophy (Panciera et al. 1990). Therefore, if TSH stimulation testing is used to confirm the diagnosis of hypothyroidism in a dog that has recently been receiving thyroid hormone, TSH testing should not be performed for at least four weeks following discontinuation of thyroid hormone replacement therapy.

Monitoring Therapy. The most important indicator of the success of thyroid replacement therapy is the progress made toward ameliorating clinical signs. Before therapy is begun, the clinician and owner should have a clear idea of the goals of therapy and the time frame in which these goals can reasonably be achieved. The reversal of changes in hair coat and body weight should be assessed no sooner than after 2 months of therapy. In cases in which clinical improvement is marginal or signs of thyrotoxicosis are seen, the clinical observations can be supported by therapeutic monitoring of serum thyroid hormone concentrations ("postpill testing"). Clearly, the documentation of distinctly elevated serum T_4 concentrations following T_4 administration and elevated serum T_3 concentrations following T_3 administration, concomitant with signs of thyrotoxicosis, confirms an overdose. The interpretation of postpill serum thyroid hormone concentrations in cases of suspected underdosing can be more complicated because the timing of sampling may be critical to the proper interpretation. Ideally, therapeutic monitoring should not be attempted until steady-state conditions are reached, minimally 1 week after the initiation of therapy from a pharmacokinetic standpoint, but probably 1 month after initiation of therapy from a pharmacodynamic and clinical standpoint. With once-daily T_4 administration, the peak serum concentrations of T_4 generally should be in the high normal to slightly high range 4–8 hours after dosing and should be low normal to normal 24 hours after dosing. Given the dog's resistance to signs of thyrotoxicosis, it may be reasonable and adequate to check the serum T_4 concentration 24 hours after the previous day's dose. This is the method of choice of the author. In this situation, serum T_4 concentrations should still be in the normal range. Some endocrinologists prefer to measure "peak" T_4 concentrations at 4 or 6 hours after once-daily dosing, and some measure at "peak" and "trough" times. Animals on twice-daily administration probably can be checked at any time, but peak concentrations can be expected at the middle of the dosing interval (4–8 hours) and the nadir just prior to the next dose. Once the dog's dose is stabilized, once- or twice-yearly checks of serum T_4 (with or without T_3) concentrations are recommended.

With the advent of the canine TSH assay, monitoring therapy became possible by measurement of suppression of serum TSH. With the current generation of assay, TSH concentrations are elevated only in about 75% of cases. In those cases where it is elevated, suppression of TSH into the normal range or even lower to the undetectable range is evidence that the body has adequate amounts of thyroid hormone in the serum. Unfortunately, the assay sensitivity does not allow the distinction of normal values from low values, so establishment of overtreatment and hyperthyroidism is not yet possible. In a study of treatment of thyroidectomized dogs, it was shown that dosages as little as 0.02 mg/kg once a day will almost always suppress endogenous TSH concentrations into the normal or undetectable range. This observation establishes that the biological half-life of thyroid hormone exceeds by far the serum half-life (Ferguson and Hoenig 1997).

anorexia, vomiting, and lethargy, usually occurs within a few days after cessation of MMI, but jaundice and abnormal serum biochemical tests indicative of liver disease may not resolve for several weeks. Rechallenge with the drug will again induce clinical signs and serum biochemical abnormalities indicative of hepatic disease within a few days. A variety of hematologic abnormalities may develop in cats during treatment with MMI. Those abnormalities that do not appear to be associated with any adverse effects include eosinophilia, lymphocytosis, and transient leukopenia with a normal differential count. As with PTU treatment, more serious hematologic reactions which develop in a few cats treated with MMI include severe thrombocytopenia (platelet count < 75,000 cells/mm^3) and agranulocytosis (severe leukopenia with a total granulocyte count < 250 cells/mm^3). Most cats that develop severe thrombocytopenia also show concomitant overt bleeding (i.e., epistaxis, oral hemorrhage). Development of agranulocytosis during MMI treatment predisposes to severe bacterial infections, systemic toxicity, and fever. If serious hematologic reactions develop during MMI therapy, the drug should be stopped and supportive care given; these adverse reactions should resolve within 5 days after MMI is withdrawn. Since most life-threatening side effects (e.g., hepatopathy, thrombocytopenia, agranulocytosis) caused by MMI treatment usually develop quickly again after rechallenge with the drug, alternative therapy with either surgery or radioiodine should be considered in these cases.

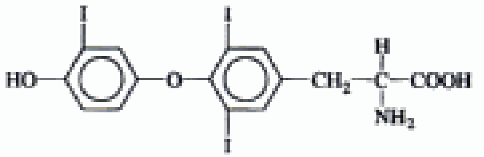
During MMI therapy, serum antinuclear antibodies (ANA) develop in a high percentage of cats. The risk of developing ANA appears to increase with the duration of MMI treatment, with ANA developing in approximately half of cats treated for longer than 6 months. The risk of developing serum ANA also appears to be greater for cats treated with higher daily MMI doses, since most cats that develop ANA are receiving doses ≥15 mg/day. ANA will disappear in most cats after the dosage is decreased. Despite the high prevalence of ANA development during long-term treatment with MMI, clinical signs associated with a lupus-like syndrome (i.e., dermatitis, polyarthritis, glomerulonephritis, hemolytic anemia, or fever) have not been observed in any of these cats. The daily drug dosage should therefore be decreased to as low as possible (while still maintaining serum T_4 values within the low-normal range), since ANA tests will become negative in many cats when the MMI dosage is decreased.

CARBIMAZOLE. The antithyroid drug carbimazole is a carbethoxy derivative of MMI that is rapidly and completely metabolized to the parent compound, which is responsible for its antithyroid activity. It is commonly used in treatment of feline hyperthyroidism outside North America. Carbimazole is a larger molecule than MMI; 10 mg of carbimazole is equimolar to 6 mg MMI. To achieve the same effect with carbimazole as with MMI, approximately twice the dosage of carbimazole is required. Clinical experience in Europe describes fewer gastrointestinal side effects for this medication. It is not apparent from the similar pharmacokinetics and the conversion of carbimazole to MMI why fewer serious side effects apparently occur with the use of carbimazole for treatment of hyperthyroidism (Peterson and Becker 1984).

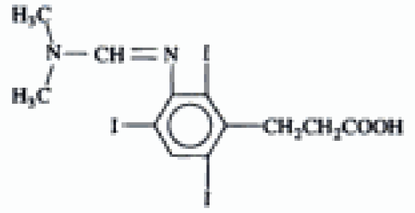
Nonthioureylene Antithyroid Agents

IPODATE. Ipodate, a biliary radiographic contrast agent, has proven in both experimental hyperthyroidism and in spontaneously hyperthyroid cats to be an alternative medical treatment for patients not tolerating MMI or PTU. The structure of this iodinated compound is compared with L-T_3 in Fig. 32.9. In a study of cats in which hyperthyroidism was experimentally induced by the administration of T_4, ipodate significantly reduced the serum T_3 concentrations and was well tolerated by otherwise healthy cats. At the dose of 15 mg/kg BID orally, some cats with spontaneous hyperthyroidism anecdotally have shown improvement of clinical signs associated with a fall in serum T_3, even when serum T_4 concentrations do not fall. Although not yet studied, higher doses may result in a fall in serum T_4. Because ipodate contains 62% organic iodine, it should not be used immediately prior to radioiodine therapy. A withdrawal period of 3–6 months before definitive radioiodine therapy is recommended in human patients. Although not yet studied in the cat, a considerably shorter period off of medication is likely sufficient to allow washout of the drug and excess iodide. In addition to blocking thyroidal and peripheral hormone synthesis and deiodination like PTU, ipodate may also interfere with the action of thyroid hormone at the cellular level (Chopra et al. 1984; Ferguson et al. 1988; Murray and Peterson 1997).

RADIOACTIVE IODINE (^{131}I) THERAPY. Although only available in specialty referral centers, radioiodine



L-Triiodothyronine



Ipodate

FIG. 32.9—Comparison of ipodate and L-triiodothyronine structures.

treatment is the most effective and appropriate cure for toxic goiter in the cat because it selectively destroys the functioning thyroid tissue after being selectively taken up and incorporated into thyroid hormone precursors in the thyroid gland. There is rarely, if ever, damage to the nearby tissue responsible for regulating serum calcium by the secretion of parathyroid hormone and calcitonin. Iodine-131 has a half-life of 8 days and produces both gamma and beta radiation. The beta particles, with a short pathlength, produce most of the local tissue destruction. Radioiodine is also used in much higher doses in an attempt to ablate thyroid adenocarcinomas in cats and dogs. Following a therapeutic dose (generally 1–5 millicuries) of ^{131}I, the serum T_4 and T_3 concentrations will normalize within 1–2 weeks. The efficacy of radioiodine is reduced by recent antithyroid medical therapy, as these drugs reduce the long-term incorporation of iodine into the thyroid gland and reduce radioiodine's therapeutic effect. The major disadvantage of radioiodine therapy is that certain radiation safety precautions must be taken. Radioiodine is secreted in saliva and excreted in urine and feces. As such, handling of the cat's hair coat or waste may result in contamination. Unlike human patients, who may receive therapeutic doses on a outpatient basis, radioiodine-treated cats must be hospitalized for periods of 1–4 weeks, depending upon the dose administered and the radiation safety regulations. Despite these drawbacks, radioiodine therapy is the least invasive cure for bilateral adenomatous goiter, has no hypoparathyroidism or toxicity associated with it, and can be implemented without anesthesia or sedation, an important consideration in the elderly cat with other medical complications (Kintzer and Peterson 1991, 1994; Meric et al. 1986).

THYROID IMAGING. Thyroid imaging is performed using radioactive iodine or $^{99m}TcO_4^-$ (pertechnetate), which is taken up by mechanisms similar to iodide but is not incorporated into iodothyronines on thyroglobulin. Because of its rapid uptake and increased safety, technetium can be given in higher diagnostic doses and provides a better image than radioiodine. A semiquantitative comparison of technetium uptake to that of the salivary glands, which also take up iodide, can be used to assess increased uptake. Thyroid imaging also aids the diagnosis when an obvious enlargement of one thyroid lobe exists. Imaging is particularly useful in the diagnosis of the 30% of cases that are unilateral, as the function of the contralateral lobe is suppressed and not apparent on the scan. Thyroid imaging is also useful in cats with adenomas that have slipped into the mediastinum or the 1–2% of cats with adenocarcinomas that have a tendency to metastasize by extension into the mediastinum (Kintzer and Peterson 1991, 1994).

GLUCOCORTICOIDS. Glucocorticoids are among the most widely used (and misused) class of drugs in veterinary medicine. Despite this, scientific information on glucocorticoid therapy in most domestic species is scarce, particularly with respect to optimal dosages and dosage intervals, physical and endocrine side effects, and efficacy in clinical applications. Therefore, therapeutic protocols are often the product of clinical experience, common sense, and information from human medicine. Though the following discussion emphasizes systemic use of glucocorticoids, it should be recognized that local application (ophthalmic, otic, intra-articular, topical, intralesional) also has similar systemic effects.

Management of Hypoadrenocorticism. Spontaneous glucocorticoid deficiency without concomitant mineralocorticoid deficiency is a relatively rare occurrence in dogs, the species that most commonly suffers from Addison's disease (gluco- and mineralocorticoid deficiency). The underlying cause is suspected to be an immune-mediated destruction of the adrenal cortex, making replacement of the physiological hormones aldosterone and cortisol (in most domestic animals) to be the primary clinical goal. Spontaneous selective glucocorticoid deficiency is rare; however, exogenous glucocorticoids may themselves induce selective atrophy of the glucocorticoid-producing part of the adrenal cortex (zonae fasciculata and reticularis) (Addison 1855; Feldman and Nelson 1987; Ferguson 1985a; Ferguson et al. 1978; Hoenig and Ferguson 1991b).

Management of Nonadrenal Disorders: Inflammatory, Allergic, and Autoimmune Disorders. Glucocorticoids are potent anti-inflammatory and immunosuppressant agents. The majority of therapeutic applications for these agents fall into these classifications. However, the adverse metabolic effects, as described below, are difficult to separate pharmacologically from the therapeutic benefits, making glucocorticoids potent, yet potentially dangerous, compounds.

Review of Physiology

BIOSYNTHESIS OF STEROIDS. The adrenal cortex synthesizes a variety of steroids from cholesterol and releases them into the circulation. Those steroids with effects on intermediary metabolism are termed "glucocorticoids" and are produced mainly in the layers of the adrenal gland called the zonae fasciculata and reticularis. The steroids with primarily salt-retaining activity are called mineralocorticoids and are synthesized in the zona glomerulosa. The adrenal gland is also capable of synthesizing steroids with androgenic and estrogenic activity. The major glucocorticoid in most domestic animals is cortisol, and in most mammals, the most important mineralocorticoid is aldosterone. In some species (e.g., the rat), corticosterone is the major glucocorticoid. It is less firmly bound to protein and therefore metabolized more rapidly. Quantitatively, dehydroepiandrosterone (DHEA) is the major androgen, with part of it being sulfated to DHEA-sulfate. Both DHEA and androstenedione are very weak androgens. A small amount of testosterone is secreted by the adrenal gland and may be of greater importance as an androgen. Little is known about the estrogens secreted by the adrenal gland. However, the adrenal androgens such as testosterone and androstenedione can be converted to estrone in small amounts by nonendocrine tissues (Aron and Tyrrell 1994; Tyrrell et al. 1994).

HYPOTHALAMIC-PITUITARY-ADRENAL AXIS. The major glucocorticoid in most domestic species is cortisol (hydrocortisone). It is synthesized from cholesterol and released into the circulation under the influence of adrenocorticotropic hormone (ACTH). The conversion of cholesterol to pregnenolone is the rate-limiting step of adrenal steroidogenesis. This step occurs via activity of the enzyme P-450sc and involves two hydroxylations and then side-chain cleavage of cholesterol. In most domestic species, as in humans, cortisol is the main glucocorticoid produced by the adrenal glands under the influence of ACTH. Production of ACTH is stimulated by corticotropin-releasing hormone (CRH), which is a hypothalamic hormone (see also Chap. 30); production of ACTH is also influenced by vasopressin (antidiuretic hormone; ADH), particularly during stress. There is also central nervous system (CNS) input into hypothalamic hormone secretion. A "short-loop" feedback system of ACTH on the corticotrophs (ACTH-producing cells) in the pituitary has also been described (see Fig. 33.1). In humans, cortisol is secreted in response to pulsatile ACTH release with diurnal variation. In humans, single daily doses of exogenous glucocorticoids are most commonly recommended to be given in the morning to mimic the adrenal gland's secretory pattern (Tyrrell et al. 1994). Although older reports claimed the existence of a diurnal cortisol variation in dogs and cats, with plasma cortisol level peaking in the morning in dogs and in the evening in cats (Feldman and Nelson 1987), more recent studies have not confirmed these observations (Kemppainen 1986). Under basal (nonstressful) conditions, the adrenal gland produces cortisol (hydrocortisone) at about 1 mg/kg body weight daily in most species.

Negative feedback of glucocorticoids on ACTH secretion occurs at both the hypothalamic and pituitary levels via two mechanisms:

1. "Fast-feedback" is sensitive to the rate of change of cortisol levels and likely occurs without interaction with nuclear steroid receptors.
2. "Slow-feedback" is sensitive to the absolute cortisol concentration and is a nuclear receptor–mediated effect which results in a decrease in ACTH synthesis. The clinical test for spontaneous hyperadrenocorticism, called the dexamethasone suppression test, is mediated by this mechanism of feedback (Keller-Wood 1990; Tyrrell et al. 1994).

Pharmacologic doses of glucocorticoids have a profound effect on endogenous glucocorticoid regulation, suppressing both hypothalamic and pituitary hormone production (Fig. 33.1). Cortisol inhibits ACTH secretion and CRH secretion through negative feedback at both hypothalamic and pituitary levels, a point that is important when considering recovery of the hypothalamic-pituitary-adrenal axis (HPAA) from exogenous glucocorticoid administration. Glucocorticoids with anti-inflammatory effects but no effects on the HPAA have not been identified to date. As a result, long-term use of supraphysiologic doses may lead to adrenocortical atrophy and decreased adrenal secretory reserve (Chastain et al. 1981; Chastain and Graham 1979; Hench 1952; Kemppainen et al. 1982; Moore and Hoenig 1992).

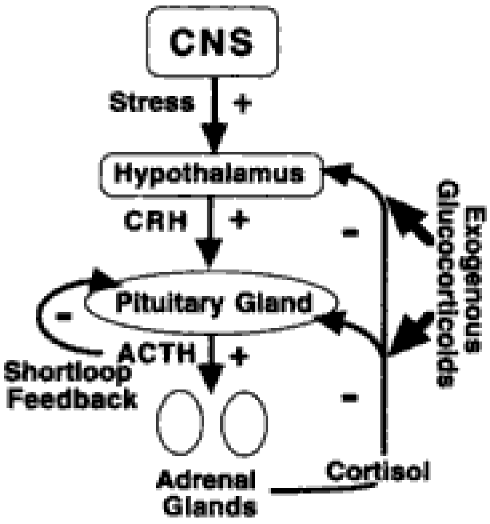

FIG. 33.1—Hypothalamic-pituitary-adrenal axis. Exogenous glucocorticoids inhibit the hypothalamic and pituitary function in a negative-feedback fashion. ACTH, through "short-loop" feedback, inhibits its own production. Therefore, recovery of the entire hypothalamic-pituitary-adrenal axis requires withdrawal of glucocorticoid and is not enhanced by the administration of exogenous ACTH. CNS = central nervous system; CRH = corticotropin-releasing hormone; ACTH = adrenocorticotropic hormone; + represents stimulation; – represents inhibition.

PLASMA BINDING, METABOLISM, AND EXCRETION. In plasma, cortisol is over 90% bound to plasma proteins. The remaining 10% free hormone is the active moiety according to the free-hormone hypothesis. Corticosteroid-binding globulin (CBG), an α_1 globulin synthesized by the liver, binds the majority of circulating hormone under normal circumstances. The remainder is free or loosely bound to albumin and is available to exert its effect on target cells. Cortisol is removed from the circulation by the liver, where it is reduced and conjugated to form water-soluble glucuronides and sulfates, which are excreted into the urine (Aron and Tyrrell 1994; Grote et al. 1993; Hammond 1990; Tyrrell et al. 1994).

MOLECULAR MECHANISM OF ACTION: STEROID RECEPTORS. The majority of steroid hormone actions are mediated by interaction with specific receptors in and on the target cell (see Fig. 33.2). The steroid hormone receptors are specific to the class of steroids (such as glucocorticoids, mineralocorticoids, androgens, estrogens). However, at very high concentrations, nonspecific effects due to direct interaction with the

coid excess; although glucocorticoids stimulate protein and RNA synthesis in the liver, they have catabolic effects in lymphoid and connective tissue, muscle, fat, and skin. While not usually a recognizable clinical problem in domestic animals, osteoporosis may result in people with Cushing's syndrome or on chronic glucocorticoid administration. The problem likely is most significant in areas of healing bone; glucocorticoids directly inhibit bone formation by inhibiting osteoblast proliferation and the synthesis of bone matrix while stimulating osteoclast activity. In addition, glucocorticoids potentiate the action of parathyroid hormone (PTH) and 1,24-dihydroxycholecalciferol (1,25(OH)$_2$-D$_3$) and inhibit the gut absorption of calcium, an effect which can be used to advantage in hypercalcemic states. In the young animal, the catabolic effects of excessive amounts of glucocorticoid reduce growth. In children, this reduced growth is not prevented by growth hormone (Aron and Tyrrell 1994; Tyrrell et al. 1994).

WATER AND ELECTROLYTE BALANCE. Glucocorticoid use invariably leads to polyuria and polydipsia via inhibition of ADH release and action, as well as alteration of the animal's psyche, resulting in increased water intake. No glucocorticoid given in large doses is completely devoid of mineralocorticoid (salt-retaining and K^+-losing) activity; therefore, excessive use may precipitate or exacerbate hypertension and induce hypokalemia. In part by increasing extracellular fluid volume, glucocorticoids increase the glomerular filtration rate and are required in physiologic amounts for maximal dilution of urine (Ferguson 1985a; Melby 1974; Nakamoto et al. 1992).

IMMUNE AND HEMATOLOGIC EFFECTS. Often the desired result of a therapeutic application, anti-inflammatory effects of glucocorticoids are primarily seen at pharmacologic doses. Glucocorticoids result in alterations in the concentration, distribution, and function of peripheral leukocytes and in inhibition of phospholipase A$_2$ activity in the plasma membranes of these cells. Glucocorticoids act indirectly by inducing lipocortin synthesis, which in turn inhibits arachidonic acid release from membrane-bound stores, and also by inducing TGF-β expression that subsequently blocks cytokine synthesis and T-cell activation. In addition to contributing to maintenance of the microcirculation and cell membrane integrity, glucocorticoids interfere with progressive dissolution and disruption of connective tissue and cells, possibly by stabilizing lysosomal membranes (Aron and Tyrrell 1994; Aucoin 1982; Barragry 1994). Although lysosomal stabilization by glucocorticoids has been demonstrated experimentally, it is hard to know what benefit these effects have in clinical situations. Glucocorticoids also decrease formation of induced histamine (histamine produced by cells during injury), the action of which is not blocked by antihistamines. They also antagonize toxins and kinins, reducing the resultant inflammation. It is important to realize, however, that most of their effects are *nonspecific;* that is, they have profound metabolic effects regardless of the initial insult.

Glucocorticoids are used to advantage to suppress both the number of cells and the actions of the immune system. The suppressive effects on cell-mediated immunity predominate over those on humoral immunity. Antibody production is generally unaffected by moderate dosages of glucocorticoids and is inhibited only at high dosages and with long-term therapy. They cause lymphopenia and eosinopenia, an effect secondary to cell redistribution and/or lysis, and lead to increased vascular demargination of neutrophils from the vascular bed to lymphoid tissue. Glucocorticoids inhibit virus-induced interferon synthesis and diminish the functional capacity of monocytes, macrophages, and eosinophils through inhibition of the formation of ILs such as IL1 (macrophages), IL2 (lymphocytes), IL3, and IL6 and other chemotactic factors (Barragry 1994; Ehrich et al. 1992; McDonald and Langston 1994; Melby 1974; Tyrrell et al. 1994).

Glucocorticoids can induce apoptosis on normal lymphoid cells and play a key role in the physiology of thymic selection. In clinics these molecules are also used for their potencies in inducing apoptosis of malignant lymphoid cells. The mechanisms of apoptosis induced by glucocorticoids fall roughly in two categories, depending on the type of lymphocytes: induction of "death genes" such as I kappa B and *c-jun* or repression of survival factors such as AP-1 and *c-myc*. By inhibiting the production of Th1 cytokines, glucocorticoids may enhance Th2 cell activity and generate a long-lasting state of tolerance (Pallardy and Biola 1998).

CARDIORESPIRATORY EFFECTS. In addition to indirect effects on electrolyte metabolism, glucocorticoids have direct positive chronotropic and inotropic actions on the heart. They appear to block the increased permeability of capillaries induced by acute inflammation, reducing transport of protein into damaged areas and maintaining microcirculation. Because glucocorticoids are necessary for maximal catecholamine sensitivity, they contribute to maintenance of vascular tone (Ferguson et al. 1978; Nakamoto et al. 1992). In shock, production of vasoactive products of lipid peroxidation (arachidonic acid cascade), such as the vasoconstrictor thromboxane A$_2$, may be decreased by glucocorticoids, but probably only in the early stage of cell disruption. Glucocorticoids cause vasoconstriction when applied directly to vessels. They decrease capillary permeability by inhibiting the activity of kinins and bacterial endotoxins and by reducing the amount of histamine released by basophils.

Glucocorticoids may induce hypertension in animals and humans through the following mechanisms: (1) activation of the renin-angiotensin (R-A) system due to an increase in plasma renin substrate (PRS), (2) reduced activity of the hypotensive kallikrein-kinin (K-K) system, prostaglandins (PGs), and the endothelium-derived relaxing factor (EDRF), nitric oxide (NO), and

(3) increased pressor responses to angiotensin II (Ang II) and norepinephrine. Furthermore, the number of Ang II type 1 receptors of vascular smooth muscle cells is significantly increased by glucocorticoids (Saruta 1996).

Glucocorticoids increase the number and affinity of β-adrenergic receptors. Glucocorticoids prevent receptor down-regulation and therefore tachyphylaxis, resulting in potentiation of the effects of β-adrenergic agonists on bronchial smooth muscle, an important effect in the asthmatic patient (Sprung et al. 1984; Tyrrell et al. 1994; Wilcke and Davis 1982).

CNS EFFECTS. Although rarely described in domestic animals, glucocorticoids (or lack of them) have marked effects on the psyche, resulting in a form of mental, as well as physical, dependence (Ferguson 1985a; Metz et al. 1982).

It is known that pretreatment of neonatal rats with dexamethasone provides protection against hypoxic-ischemic brain damage. This effect is likely mediated via glucocorticoid receptors, because glucocorticoid receptor antagonist RU38486 reverses the benefit. The neuroprotection also appears to be related to alterations in cerebral metabolism. Glucose utilization is reduced prior to hypoxia-ischemia by dexamethasone and is better maintained during hypoxia-ischemia. High-energy phosphates in the brain are higher in dexamethasone-treated animals. Thus, glucocorticoids may provide their protection against hypoxic-ischemic damage by decreasing basal metabolic energy requirements and/or increasing the availability or efficiency of use of energy substrates (Tuor 1997).

ENDOCRINE EFFECTS. Glucocorticoids, in addition to being diabetogenic, also have marked effects on hypothalamic and pituitary function. ACTH, β-lipotropin, thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and growth hormone (GH) synthesis and secretion are all suppressed; however, β-endorphin levels are unaffected. Glucocorticoids, even at "physiological" dosages (0.22 mg/kg prednisolone once daily orally in the dog), result in HPAA suppression, as indicated by reduction in the ACTH-stimulated cortisol concentration increment and by reduction of the ratio of the zona fasciculata and reticularis to zona glomerulosa in the adrenal gland. Anti-inflammatory dosages of prednisolone (0.5 mg/kg q12h orally) resulted in adrenal suppression within 2 weeks of therapy (Chastain and Graham 1979). In another study in dogs, 1 month of the same dosage of prednisolone orally resulted in profound suppression of endogenous plasma ACTH and cortisol concentrations, CRH-stimulated ACTH release, and ACTH-stimulated cortisol release. However, following withdrawal of the prednisolone, the HPAA returned to normal within 2 weeks (Moore and Hoenig 1992). A similar ability to recover from exogenous glucocorticoids was seen in the cat. A dosage of 2 mg/kg q12h of methylprednisolone given orally for 7 days resulted in suppression of ACTH-stimulated cortisol and CRH-stimulated ACTH, but these changes completely reversed by 7 days after withdrawal of the exogenous glucocorticoid (Crager et al. 1994). Higher dosages and long-acting preparations (dexamethasone, triamcinolone, depot products) may result in more pronounced HPAA suppression (Kemppainen and Sartin 1984; Kemppainen 1986; Kemppainen et al. 1982).

The effect of glucocorticoids on glucose metabolism is time- and dose-dependent: insulin and glucose concentrations, or glucose tolerance, were not significantly altered by the administration for 28 days of an anti-inflammatory dosage of oral prednisone (Moore and Hoenig 1993). However, daily administration of high dosages of dexamethasone and growth hormone is a reliable model for induction of diabetes mellitus in the cat (Hoenig et al. 2000). There also have been case reports of diabetes mellitus induced in dogs after administration of corticosteroids and methylprednisolone pulse therapy (Jeffers et al. 1991).

Pharmacologic doses of glucocorticoids generally reduce serum thyroid hormone concentrations, presumably through suppression of pituitary TSH. These effects have been well documented in the dog, are not as significant in the cat, and are not well studied in other domestic species (Ferguson and Peterson 1992; Kaptein et al. 1992; Moore et al. 1993). The metabolic consequences of these lowered concentrations of thyroid hormones are not known in the dog; however, a state of hypothyroidism is not believed to be the result (Jennings and Ferguson 1984).

In humans, large doses of glucocorticoids stimulate excessive production of acid and pepsin in the stomach and may cause peptic ulcer. They facilitate fat absorption and appear to antagonize the effect of vitamin D on calcium absorption. Therefore, glucocorticoids are employed in chronic hypercalcemic states in an attempt to inhibit gastrointestinal calcium absorption (Aron and Tyrrell 1994; Tyrrell et al. 1994).

Chemistry

SOURCE. Although the natural corticosteroids can be obtained from animal adrenal glands, they are usually synthesized from cholic acid or steroid sapogenins found in plants of the Liliaceae and Dioscoreaceae families. Further modifications of these steroids have led to the marketing of a large group of synthetic steroids with special characteristics that are pharmacologically and therapeutically important (see Tables 33.1–33.2 and Figs. 33.4–33.5).

STRUCTURE-ACTIVITY RELATIONSHIPS. The actions of the synthetic steroids are similar to those of cortisol (see above). They bind to the specific intracellular receptor proteins and produce the same effects but have different ratios of glucocorticoid-to-mineralocorticoid potency (see Table 33.1).

STEROID BASE. Figs. 33.4 and 33.5 show the steroid base, or carbon skeleton, of glucocorticoids. The struc-

TABLE 33.1—Characteristics of various glucocorticoid bases

	Potency			
Drug	Glucocorticoid[a]	Mineralocorticoid	HPAA suppression[b]	Alternate-day therapy possible?
Short-acting (duration of action: <24 hr)				
Hydrocortisone	1	++	+	No (too short)
Cortisone	0.8	++	+	Yes (not ideal)
Prednisone	4	+	+	Yes
Prednisolone	4	+	+	Yes
Methylprednisolone	5	+	+	Yes
Intermediate-acting (duration of action: 24–48 hr)				
Triamcinolone	5	0	++	No
Long-acting (duration of action: >48 hr)				
Flumethasone	15	0	+++	No
Dexamethasone	30	0	+++	No
Betamethasone	30	0	+++	No

Note: Effective anti-inflammatory time equals the HPAA suppression time in most cases. However, the therapeutic success and fewer side effects with alternate-day therapy stem from the fact that some preparations have slightly longer anti-inflammatory or immunosuppressive action than their action to suppress the HPAA.

[a] Compared with hydrocortisone on a mg-for-mg basis.

[b] HPAA = hypothalamic-pituitary-adrenal axis.

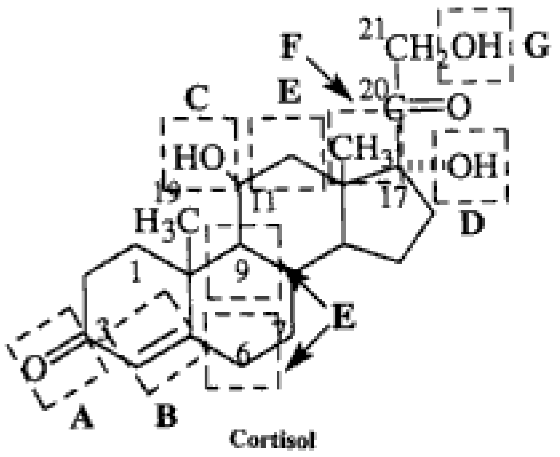

FIG. 33.4—Structure-activity relationships of glucocorticoids. Shown on the structure of the compound cortisol are the important structural sites determining the activity of a glucocorticoid base. *A:* 3 keto group essential for glucocorticoid activity; *B:* 4,5 double bond essential for glucocorticoid activity; *C:* 11 hydroxyl essential for optimal glucocorticoid activity; *D:* 17 α hydroxyl is important for glucocorticoid activity; *E:* 16 methylation or fluorination reduces mineralocorticoid activity considerably and increases glucocorticoid activity; *F:* 20 keto group is important for glucocorticoid activity; *G:* 21 hydroxyl is essential for mineralocorticoid activity and is the site of esterification.

ture of the base determines the *anti-inflammatory (glucocorticoid) potency, mineralocorticoid potency,* and the *duration of action once at the site of action.*

Alterations in the steroid base structure influence its affinity for glucocorticoid and mineralocorticoid receptors, as well as its protein-binding avidity, side-chain stability, rate of reduction, and metabolic products. Certain structures on the steroid base are essential for glucocorticoid activity (Figs. 33.4–33.5). An 11-ketol is essential for glucocorticoid activity, and compounds like cortisone and prednisone must first be reduced in the liver from the 11-carbon ketone to the ketol before full activity is seen. The 1,2 double bond provides a fourfold increase in glucocorticoid activity. The C-3 and C-20 ketone groups are also essential for glucocorticoid activity. The addition of 16-α-methyl 9-α-fluoro groups results in compounds with enhanced anti-inflammatory activity. Further substitution at the 17 ester position results in a new group of extremely potent steroids (e.g., beclomethasone and betamethasone) that are effective when applied topically for skin diseases and by inhalation for treating asthma. Modifications of the glucocorticoid molecular structure also alter the tendency for the molecule to bind with CBG in the plasma. An increase in binding to CBG results in a lower tendency for the hormone to be metabolized. Halogenation at the 9 position, unsaturation of the 1,2 bond, and methylation at the 2 or 16 position will prolong the half-life by more than 50–70%. The 11-hydroxyl group also appears to inhibit destruction, since the half-life of 11-deoxycortisol is half that of cortisol. In some cases, the agent administered is a prodrug: prednisone is rapidly reduced to prednisolone, and cortisone is rapidly converted to cortisol by the liver. The synthetic corticosteroids for oral use are in most cases rapidly and completely absorbed when given by mouth.

ESTER. Esterification of the alcohol at C-21 serves a number of potential purposes. The ester moiety determines to a significant extent the water/lipid solubility ratio and also influences the duration of action of the base compound's release from subcutaneous or intramuscular sites. Tissue esterases cleave the ester, resulting in free base, which then is distributed via the

Subsequently, laboratory findings demonstrated a deteriorating state of anemia, hypoproteinemia, leukocytosis, neutrophilia, thrombocytopenia, hyperglycemia, hyperbilirubinemia, and increased SAP and ALT. Radiographic findings included cardiomegaly, hepatomegaly, and a herniated intervertebral disk at L5-L6. Needle biopsy of the liver revealed a micronodular cirrhosis, changes consistent with glucocorticoid hepatopathy. Despite extensive supportive treatment, the dog succumbed following the development of *Haemobartonella*-induced hemolytic anemia, more vomiting, depression, anorexia, melena, and multiple cutaneous abscesses. The dog was euthanatized and necropsy revealed generalized atrophy, icterus, and thinning of the skin; hepatomegaly; severe adrenocortical atrophy; hepatic vacuolization; and pancreatic fibrosis with foci of necrosis and inflammation. Although this case represents an extreme overdosage, it illustrates the severe and potentially fatal toxicity that can result from excessive dosage or duration of glucocorticoid administration (Bellah et al. 1989).

LAMINITIS IN THE HORSE. High-dose glucocorticoids can induce or exacerbate laminitis in the horse. Steroids appear to potentiate the action of catecholamines in the equine digit. Because this constriction is more pronounced on venous beds than on arteriolar beds, the net result is often digital congestion and edema (Barragry 1994).

Principles of Rational Glucocorticoid Therapy. Because of their wide-ranging and nonspecific effects, reports of the clinical use of glucocorticoids are replete with pragmatic recommendations regarding dosage, duration of therapy, and severity of side effects. Much has been adopted from clinical use in humans, and much more is known about the fine points of glucocorticoid therapy in dogs and cats than in other species. In the following discussion, most of the specific comments will apply to the use of glucocorticoids in the dog; however, when available, appropriate information for other species will be mentioned. It is important to recognize that glucocorticoids rarely cure disease. With the possible exception of spontaneous glucocorticoid deficiency, they are used to try to suppress clinical signs long enough for a condition to run its natural course (Fauci 1976; Ferguson 1985a,b; Melby 1974; Wilcke and Davis 1982).

A well-known endocrinologist named Thorn proposed in 1966 that physicians ask themselves the following questions *before using* glucocorticoid therapy (Hench 1952). A similar approach is proposed for use in animals:

1. How serious is the underlying disorder?
2. How long will therapy be required?
3. Is the patient predisposed to any complications of glucocorticoid therapy?
4. What is the anticipated glucocorticoid *dosage?*
5. Which glucocorticoid preparation should be used?
6. Have *other types* of treatment been used to minimize glucocorticoid dosage and side effects?
7. Is an *alternate-day* regimen indicated?

These questions may help develop guidelines for practical and rational glucocorticoid therapy.

HOW SERIOUS IS THE UNDERLYING DISORDER? HOW LONG WILL THERAPY BE REQUIRED? The following general principles should be considered when glucocorticoid therapy is employed:

Diagnose the disease first, if possible. Glucocorticoids are generally only palliative and do not provide a true cure for any disease. In addition, if used before all reasonable diagnostic tests have been completed, they may mask signs of underlying disease and complicate specific diagnosis and therapy. Though a definitive diagnosis is not always possible, a presumptive diagnosis should be proposed (Ferguson 1985a,b).

Classify the disorder into one of the following categories of glucocorticoid therapy, according to a definitive or presumptive diagnosis: *physiologic replacement; intensive short-term; anti-inflammatory and antiallergic; immunosuppressive;* and *chronic palliative.* Each of these usage classifications will be discussed in more detail. By using these classifications, the clinician clearly defines the goal of therapy and can choose a starting dose and formulation appropriate for the disorder.

Use glucocorticoids to accomplish specific objectives. It is important to decide on the therapeutic end point *before* therapy is started in order to objectively assess efficacy and determine the smallest effective dose. For example, in treatment of a dog with autoimmune hemolytic anemia, the goal for initial glucocorticoid therapy might be to raise the hematocrit from 10% to 25%. In a horse with chronic obstructive pulmonary disease ("heaves"), the goal might be to suppress the allergic reaction for 1–2 weeks in order to allow the owners to change the feeding regimen to eliminate the offending allergen. By defining a therapeutic objective, the clinician can then judge the efficacy of a treatment protocol and decide when the glucocorticoid dose should be altered or alternative therapy chosen.

The length of therapy should also be anticipated. For example, immunosuppressive therapy generally requires several months of glucocorticoid use. Accordingly, a plan for instituting and later decreasing the dose should be considered from the outset. In such a case, intermittent or alternate-day therapy would not be appropriate, and an intermediate- or long-acting glucocorticoid could be used.

IS THE PATIENT PREDISPOSED TO ANY COMPLICATIONS OF GLUCOCORTICOID THERAPY? Because many of the therapeutic effects of glucocorticoids are nonspecific, clinicians should anticipate the impact on the patient of the previously outlined complications of glucocorticoid use. In doing so, the risk/benefit ratio of using these potent agents is considered.

WHAT IS THE ANTICIPATED GLUCOCORTICOID DOSAGE? WHAT GLUCOCORTICOID PREPARATION SHOULD BE USED? It is important to understand the relative potency and, perhaps more important, the relative *duration of action* of a glucocorticoid preparation, because the duration of anti-inflammatory effects usually parallels the duration of effects on the HPAA. Success with alternate-day therapy, more commonly applied in small-animal practice, depends on selecting a glucocorticoid preparation with slightly longer anti-inflammatory or immunosuppressive (beneficial) actions than HPAA-suppressive effects. *Dosages of glucocorticoids are derived by trial and error and should be constantly reevaluated.* Due to the aforementioned hazards of long-term daily glucocorticoid use, intermittent or alternate-day therapy is preferred when long-term use is necessary. As shown in Table 33.1, short- or intermediate-acting formulations, generally given orally, are most appropriate and safe for long-term use and alternate-day therapy. The goal of rational therapy is to maintain a condition in remission at the lowest effective glucocorticoid dosage (Fauci 1976; Feldman and Nelson 1987; Ferguson 1985a,b; Wilcke and Davis 1982).

Classes of Glucocorticoid Usage

PHYSIOLOGICAL REPLACEMENT THERAPY. Replacement therapy involves use of glucocorticoids in amounts similar to those of the naturally occurring glucocorticoids (cortisol in virtually all domestic species) from the adrenal gland. Ideal replacement therapy should mimic the adrenal gland's hormonal output under basal conditions, with doses increasing if the animal is stressed by illness or surgery.

Practically, this ideal is never achieved; however, the following regimens have been used successfully in adrenalectomized and Addisonian dogs and cats. As a general rule, animals produce approximately 1 mg/kg of cortisol (hydrocortisone) every day. It is not rational to employ alternate-day or intermittent glucocorticoid replacement therapy in a glucocorticoid-deficient animal, because the animal's metabolic well-being depends upon the presence of glucocorticoids *every day*. Therefore, physiological replacement therapy is aimed at providing a small daily amount of glucocorticoid. Physiological replacement therapy is rarely indicated or applied in large animals. In small animals, hydrocortisone or cortisone at 0.2–1 mg/kg/day or, more commonly, equipotent amounts of prednisolone or prednisone at 0.1–0.2 mg/kg/day once daily orally are indicated. There have been reports that the diurnal variation of cortisol results in a peak in the morning in dogs and in the evening in cats; however, more-recent studies have not confirmed this pattern (Kemppainen 1986; Scott 1982). Therefore, the timing of the single daily dosage would not appear to be critical, other than that it be provided approximately the same time each day. Because stress results in higher adrenal output of glucocorticoids, this pattern should be mimicked; in general, in moderate stress, give 2–5 times the physiologic dosage, and in severe stress (e.g., surgery), administer 5–20 times this dosage until the stressful experience has ended (Ferguson 1985a,b).

INTENSIVE SHORT-TERM AND SHOCK THERAPY. The effects of glucocorticoids in all forms of shock are still controversial; however, some evidence suggests that early treatment (probably about 4 hours postinduction in dogs) may lead to increased survival, particularly in hemorrhagic and septic shock. The nature of the formulation (particularly the ester) may affect the speed of cellular entry of glucocorticoids during shock; however, other conclusions have also been reached (Ferguson 1985a,b; Ferguson et al. 1978; Sprung et al. 1984; Wilcke and Davis 1982; Wilson 1979).

Glucocorticoids improve hemodynamics and enhance survival in canine models of endotoxic and hemorrhagic shock. However, therapy for shock should also include aggressive fluid therapy. Septic (endotoxic) shock is the most responsive form to glucocorticoid therapy; however, although human trials have shown improved short-term survival, most patients succumbed to chronic septicemia later (Sprung et al. 1984). Suspected endotoxic shock should be treated with fluid therapy and a broad-spectrum antimicrobial, with or without glucocorticoids. Glucocorticoids and antibiotics were synergistic when given within 2 hours of induction of septic shock in baboons.

The potential detrimental effects of massive doses of glucocorticoids should always be considered. However, proponents of glucocorticoid therapy for shock point out that short-term (~48 hr) glucocorticoid therapy has few negative effects, and the positive effects far outweigh the risks. Most human patients with sepsis survive beyond the acute stages of endotoxemia but succumb later to chronic septicemia (Sprung et al. 1984). Certainly, the immunosuppressive effects of glucocorticoids make their use contraindicated during chronic sepsis, and those supporting glucocorticoid use in septic shock do not generally advocate use other than during the early acute hypotensive state. Opponents to glucocorticoid use generally are not convinced that experimental studies in anesthetized animals adequately duplicate clinical situations and do not believe even short-term treatment to be innocuous, because of immunosuppressive effects (Wilcke and Davis 1982).

ANTI-INFLAMMATORY AND ANTIALLERGIC THERAPY. A large proportion of glucocorticoid use in veterinary practice is designed to combat inflammation or allergy. Unfortunately, many such diseases are difficult to definitively diagnose. Therefore, misuse of glucocorticoids is not uncommon in this category. Examples of anti-inflammatory and antiallergic use of glucocorticoids include symptomatic treatment of pruritic dermatoses, allergic pulmonary disease, and allergic gastroenteritis. Guidelines for anti-inflammatory and antiallergic dosages vary from species to species. Prednisolone or prednisone is most commonly used in small

to alternate-day use may result in signs of glucocorticoid withdrawal. Finally, alternate-day glucocorticoid therapy may fail if used exclusively; supplemental use of nonsteroidal therapy should be considered, particularly on "off" days (Fauci 1978; Ferguson 1985a,b).

In inflammatory joint disease caused by infectious or immune-mediated conditions, early aggressive therapy is usually necessary to limit subsequent joint dysfunction. Of course, the primary therapy for immune-mediated arthritis, immunosuppression, can jeopardize the health of patients with infectious arthropathies. So before initiating immunosuppressive therapy, follow a thorough diagnostic plan to exclude infectious causes (Michels and Carr 1997).

CHANGING TO ALTERNATE-DAY THERAPY. Because glucocorticoid administration to dogs for longer than 2 weeks generally results in significant loss of adrenal functional reserve, for the sake of this discussion, administration of greater than 0.5 mg/kg/day of prednisolone or an equipotent dosage of a more potent drug for longer than 2 weeks should be considered chronic therapy (Chastain and Graham 1979). However, when 0.5 mg/kg ql2h (an anti-inflammatory dosage) was administered to dogs for 35 days and stopped abruptly, it took less than 2 weeks for the HPAA to totally recover (Moore and Hoenig 1992). This contrasts drastically with the experience in humans, where normalization of cortisol secretion and pituitary function may take as long as 6–9 months (Fauci 1976, 1978). Similar studies have not been performed in large-animal species.

There is no "correct" way to taper an animal from glucocorticoids. The following guidelines are suggested. If the glucocorticoid dosage is large (>1 mg/kg/day prednisolone or an equivalent) or therapy prolonged (>2 weeks in duration), some process of gradually reducing the steroid dosage (i.e., weaning) is indicated. One highly conservative approach is to double the glucocorticoid dose for "on" days and taper the dose for "off" days by 25% per cycle (a cycle may vary from 1 day to several weeks). Another conservative method includes increasing the dose for "on" days by the same amount as the dose for "off" days is decreased. Practical experience indicates that, in many canine patients, rapid tapering has few recognizable side effects unless the animal is severely stressed. Subtle adverse effects may be missed unless the owners and clinician are vigilant. Patient tolerance defines the success of any change. If therapy is for less than 2 weeks, it is probably safe to rapidly taper the dog and have no therapy on "off" days. If clinical signs are observed on "off" days, supplement with a replacement dose of glucocorticoids on those days, or add nonsteroidal therapy. If alternate-day therapy is ineffective, use of a single dose each morning (to mimic diurnal variation) may also minimize adverse effects. Examples of two conservative approaches to weaning a dog from prednisolone and application of alternate-day therapy are shown in Table 33.4.

WITHDRAWAL FROM GLUCOCORTICOIDS. The identification of clinical signs of glucocorticoid deficiency may be very difficult. Animals cannot complain of minor aches and pains or of mood swings as do people being withdrawn from glucocorticoids. Signs of glucocorticoid withdrawal may include dullness, depression, decreased exercise tolerance, incoordination, unthriftiness and weight loss, loose stools, and behavioral changes. Significant adrenocortical suppression occurs

TABLE 33.4—Examples of alternate-day therapy and weaning a dog from prednisolone

Example of alternate-day glucocorticoid therapy, initiated after 3 weeks of daily treatment, for a 20-kg dog being treated for autoimmune hemolytic anemia:

Week 1: 20 mg prednisolone q12h
Week 2: 15 mg prednisolone q12h
Week 3: 10 mg prednisolone q12h

Three different methods for weaning from week 4 onward:

	Milligrams of prednisolone orally per day					
	Method A (most conservative)		Method B (intermediate)		Method C (least conservative)	
	Day "on"	Day "off"	Day "on"	Day "off"	Day "on"	Day "off"
Week 4	40	15	20	15	20	0
Week 5	40	10	20	10	15	0
Week 6	40	5	20	5	10	0
Week 7	40	0	20	0	5	0
Week 8	30	0	15	0	off	
Week 9	20	0	10	0		
Week 10	10	0	5	0		
Week 11	5	0	off			
Week 12	off					

Note: Supplement during stress 1–2 months after discontinuation is probably indicated.

in dogs within 2 weeks of initiating daily glucocorticoid therapy. Therefore, it is reasonable to assume that dogs and cats may require supplementation of glucocorticoids during episodes of stress, such as illness or surgery, particularly if signs of glucocorticoid withdrawal are present. It should be emphasized that short-term use of glucocorticoids in physiological amounts has few risks despite the evidence that these "physiological" quantities significantly suppress the HPAA, resulting in adrenal atrophy (Byyny 1976; Chastain and Graham 1979).

TEST OF ADRENAL RESERVE. Laboratory tests usually are not necessary to diagnose most cases of iatrogenic adrenal insufficiency; a good history usually indicates the cause of the problem. Occasionally, in the absence of an accurate history or when surgery is considered for a dog with suspected adrenal insufficiency, an ACTH stimulation test is performed to test adrenal functional reserve.

ACTH STIMULATION TEST. A venous blood sample is collected in heparin tubes and centrifuged within 15 minutes, with the plasma immediately frozen for later plasma cortisol determination. A dose of 0.25 mg (25 units or an entire vial, though less will work, regardless of the animal's size) of synthetic ACTH (Cortrosyn, Organon) is given intravenously or intramuscularly. For the dog or horse, a postinjection venous blood sample, handled as for the preinjection sample, is collected 1 hour after IV Cortrosyn injection. If cost is a concern, valuable information on adrenal secretory reserve can be obtained by giving ACTH and collecting a blood sample only at the appropriate time after injection. Blood samples are then assayed by a clinical pathology laboratory for plasma cortisol levels. In cats, peak cortisol concentrations should be measured 30 minutes after intravenous ACTH administration (Feldman and Nelson 1987).

INTERPRETATION OF TEST RESULTS. Healthy unstressed animals have basal plasma cortisol levels in the normal range that increase by 50–100% after ACTH stimulation. Some dogs, after chronic glucocorticoid treatment, may have normal basal cortisol levels but a post-ACTH increase of less than 50%. Such dogs do well until stressed and then require glucocorticoid supplementation (see below). Other dogs may have low basal levels as well as low post-ACTH cortisol levels, indicating a need for continued regular glucocorticoid supplementation as well as additional glucocorticoids during periods of stress (Ferguson 1985a,b).

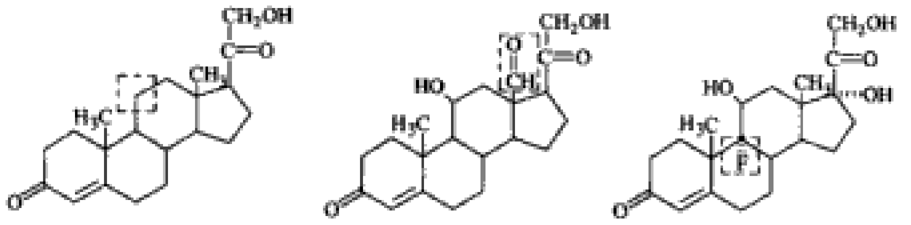
GLUCOCORTICOID SUPPLEMENTATION DURING STRESS. Animals with marginally adequate or deficient adrenal function require supplementation of glucocorticoids during periods of stress. In situations of minor stress such as minor surgery, general anesthesia, a minor illness, or even a visit to the veterinarian, glucocorticoid can be given to avoid collapse and other complications. For example, hydrocortisone or cortisone can be given at 2–5 mg/kg or prednisolone or prednisone at 0.4–1.0 mg/kg. In severely stressful situations, such as in severe illness or major surgery, higher dosages may be necessary. In preparing an animal for major surgery (including adrenalectomy), prednisolone acetate can be given intramuscularly at 0.4–2 mg/kg the night before and the morning of surgery. Alternatively, or in addition, 100–300 mg hydrocortisone can be given by IV drip. These large doses should be gradually reduced within 3–5 days to maintenance levels unless there are complications (Ferguson 1985a,b).

MISCELLANEOUS OR SPECIAL USAGES

TOPICAL AND INTRALESIONAL USAGE. Topical and intralesional glucocorticoid administration is occasionally used to manage localized lesions of the skin. Despite the route of administration, systemic effects, including suppression of the HPAA, should be expected. Acute inflammatory conditions such as pyotraumatic dermatitis and urticaria are usually managed with nonocclusive, nonheating glucocorticoid preparations. However, chronic conditions are most commonly managed with penetrating glucocorticoid creams and ointments. The potent fluorinated bases such as betamethasone, dexamethasone, triamcinolone, and fluocinolone are the most commonly preferred. The topical, intralesional, or intra-articular use of compounds (e.g., prednisone, cortisone) requiring hepatic activation is of questionable value (Coppoc 1984; Glaze et al. 1988; Kemppainen 1986; McDonald and Langston 1994; Scott 1982; Scott and Greene 1974; Wilcke and Davis 1982).

INTRA-ARTICULAR ADMINISTRATION. Intra-articular glucocorticoids have been utilized to manage the orthopedic conditions of traumatic arthritis, myositis, bursitis, and tendinitis. Used primarily in equine medicine to manage joint inflammation and pain, the practice of intra-articular glucocorticoid therapy is controversial and potentially dangerous. Glucocorticoids tend to reduce the pain for a working animal but also diminish chondrocyte collagen and synovial fluid production. The benefits cited for this practice include the reduction of proteolytic enzymes in joint fluid and reduction of joint swelling and discomfort. The hazards include encouragement of further mechanical damage, loss of joint proteoglycan, development of septic arthritis, and inhibition of chondrocyte and osteoblast activity with the end result being joint or bone breakdown. Intra-articular administration of glucocorticoids leads to systemic absorption and HPAA suppression. Furthermore, glucocorticoid administration has been considered a risk factor for laminitis. In summary, the intra-articular route of administration must be used judiciously (Barragry 1994).

OPHTHALMIC APPLICATIONS. Glucocorticoids are used topically and subconjunctivally to manage inflam-



Deoxycorticosterone **Aldosterone** **Fludrocortisone**

FIG. 33.6—Structures of common mineralocorticoid drugs used in veterinary medicine. The key elements of structure differing from cortisol are identified by the outlined areas.

is available as a sterile suspension for intramuscular injection (Percorten™-V, Novartis). It has been approved for use in the dog.

2. Fludrocortisone acetate (Florinef acetate®, Squibb) is available for oral use as 0.1 mg tablets. It has a half-life of approximately 8 hours in humans. Fludrocortisone also has substantial glucocorticoid activity.

Note: Aldosterone is only available for research, not for therapeutic use. The structures of the mineralocorticoid compounds are shown in Fig. 33.6.

Therapeutic Use. Historically, DOCA was the treatment of choice for the mineralocorticoid deficiency in acute primary adrenal failure. However, this short-acting product is no longer on the US human or veterinary market. In animals that are not vomiting, fludrocortisone acetate may be used. It is administered orally at a dose of 0.1–0.5 mg/dog twice daily (Hoenig and Ferguson 1991b).

For maintenance therapy either DOCP or fludrocortisone acetate may be used. An initial starting dose of DOCP is 2.2 mg/kg of body weight every 25 days has been recommended (Lynn et al. 1993). In the cat a dose of 12.5 mg every 3–4 weeks has been recommended (Greco and Peterson 1989). These doses and the time intervals of injections may be adjusted depending on the response to therapy as measured by serum Na^+ and K^+ concentrations.

Fludrocortisone acetate must be administered daily for the treatment of hypoadrenocorticism. In the dog the dose is 0.1–0.5 mg orally twice daily or 0.01 mg/kg divided every 12 hours orally. In the cat the dose is 0.1–0.2 mg divided every 12 hours orally. The dose may have to be adjusted based on weekly electrolyte measurements. Once the animal is stable, rechecks including serum Na^+ and K^+ measurement should be made on a monthly basis. Dogs metabolize this drug rapidly and high doses may be necessary even for less-than-optimal results (Hoenig and Ferguson 1991b).

Side Effects. Adverse effects of mineralocorticoid replacement therapy are rare but may include hypokalemia, hypernatremia, muscle weakness, and hypertension, particularly in patients with borderline renal disease (Hoenig and Ferguson 1991b). Because fludrocortisone also has glucocorticoid activity, animals on large doses may show signs of glucocorticoid excess (Lynn et al. 1993). It is important that any fluid deficits be corrected prior to treatment with mineralocorticoids.

ADRENOLYTIC DRUGS AND STEROID SYNTHESIS INHIBITORS

Therapy for Hyperadrenocorticism. Spontaneous hyperadrenocorticism is characterized by excess secretion of the glucocorticoid cortisol. In 85–90% of cases in the dog and the majority of cases in the horse, the primary species suffering from this condition, the cause is excess ACTH production by the pituitary. The term "Cushing's disease" is the term used when the adrenal glands are bilaterally hypertrophied and producing excess cortisol in response to overproduction of ACTH by the pituitary corticotrophs. In the horse, an intermediate lobe pituitary tumor is the most common cause. Accordingly, in dog and horse, there have been attempts to reduce ACTH production with dopaminergic compounds like bromergocryptine or the antiserotoninergic agent cyproheptadine. The experience with these agents has largely been unsatisfactory in the dog due to toxicity and lack of efficacy, and the use of bromergocryptine in the horse is expensive and toxic as well.

Low hypothalamic dopamine concentrations have been observed in dogs with pituitary-dependent hyperadrenocorticism. As such, dopamine deficiency has been proposed as an underlying etiology for this condition. L-Deprenyl (Anypril®, Pfizer Animal Health), a monoamine oxidase B enzyme inhibitor that inhibits the breakdown of dopamine, has recently been approved for the treatment of pituitary-dependent hyperadrenocorticism in the dog.

Medical therapy for hyperadrenocorticism in the dog has been primarily aimed at reducing glucocorticoid production by the adrenal cortex. The two most frequently used drugs are mitotane and ketoconazole (Feldman and Nelson 1987; Ferguson et al. 1991; Hoenig and Ferguson 1991a). Both drugs are used for hyperadrenocorticism regardless of etiology. This is not true for L-deprenyl. Because it influences dopamine concentrations, it is only approved for

TABLE 34.5—Suggested initial protocol for the uncomplicated diabetic animal assuming SID insulin administration

7:50	Check blood glucose
7:55	Feed one-half of caloric needs
8:00	Administer insulin, 0.5 units/kg subcutaneously
10:00	Check blood glucose
noon	Check blood glucose
2:00	Feed one-half of caloric needs
4:00–24:00	Check blood glucose every 2–4 hr

Note: Blood glucose concentrations only need to be monitored until glucose concentrations start rising after the insulin peak action has been seen.

As soon as the veterinarian has established a consistent response, the animal can be discharged. The owner should monitor and record urine glucose and ketones at home. In addition, weekly blood glucose checks by the veterinarian should be performed initially at the time of insulin peak.

Insulin dose can be increased by 10–25% per day. Feeding time can be adjusted to optimize response if needed.

adjunct treatment in ketosis therapy. It has been suggested that insulin therapy is particularly beneficial in those cases of ketosis that occur within the first week of lactation and are nonresponsive to glucose or glucocorticoid therapy alone (Herdt and Emery 1992). A dose of 200–300 IU of protamine zinc insulin per animal repeated as necessary at 24- to 48-hour intervals was administered.

Adverse Effects. Acute hypoglycemia may result from excessive insulin dose or inadequate food intake. The brain is particularly sensitive to glucose deficiency, and nervous system dysfunction is seen. Initially, confusion, nervousness, trembling, or hyperexcitability may be seen, which progress to convulsions if the hypoglycemia is not treated. Karo® syrup or other glucose-containing solutions can be used orally; however, the intravenous administration of dextrose solutions may be necessary to alleviate the hypoglycemic symptoms. Glucagon may also be used intramuscularly (see below).

The body itself combats hypoglycemia through the release of insulin-antagonistic hormones, primarily catecholamines, glucagon, glucocorticoids, and growth hormone. This frequently leads to hypoglycemia-induced hyperglycemia, also called Somogyi rebound (Cryer and Gerich 1990).

Antibody formation has been documented in diabetic dogs (Harb-Hauser et al. 1998) and diabetic cats (Hoenig et al. 2000). While this has not been examined in dogs, in cats the insulin dose was not different in the presence or absence of antibodies, and the clinical significance therefore seems to be minor.

ORAL HYPOGLYCEMIC AGENTS

Sulfonylureas

HISTORY. During World War II, Janbon and colleagues (1942) found that certain sulfonamide derivatives being used to treat typhoid fever caused hypoglycemia. After the end of the war, derivatives of these antibiotics were first used to treat patients with diabetes. Studies by Loubatieres showed that sulfonylureas did not alter blood glucose concentrations in pancreatectomized dogs and juvenile diabetics (i.e., type I), which suggested that sulfonylureas stimulated the pancreas to secrete insulin (Loubatieres 1946). Indeed, sulfonylureas have become the major therapeutic agent used to treat type 2 diabetes in humans until recently. In type 2 diabetics insulin secretion is still present although insufficient to control blood glucose concentrations. In most diabetic animals the insulin-secretory capacity of the beta cells is lost, and they require insulin for treatment.

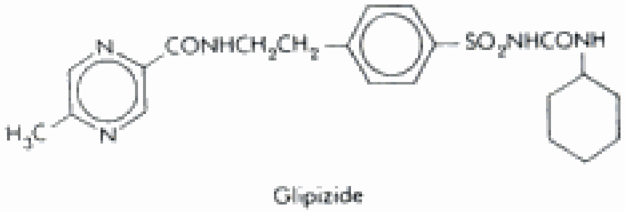

FIG. 34.2—Chemical structure of the sulfonylurea glipizide.

TABLE 34.6—Oral sulfonylurea agents available in the United States

Tolbutamide: Orinase (Upjohn) and generics
Tolazamide: Tolinase (Upjohn) and generics
Chlorpropamide: Diabinese (Pfizer) and generics
Acetohexamide: Dymelor (Lilly) and generics
Glyburide: Micronase (Upjohn) and DiaBeta (Hoechst-Roussel)
Glipizide: Glucotrol (Pfizer)
Glimepiride: Amaryl (Hoechst Marion Roussel)

CHEMISTRY. The chemical structure of the most commonly used sulfonylurea in veterinary medicine, glipizide, is shown in Fig. 34.2. Oral sulfonylurea agents available in the United States are listed in Table 34.6. Sulfonylureas differ in potency, duration of action, metabolism, and side effects.

GLIPIZIDE

MECHANISM OF ACTION. In the pancreatic beta cells, sulfonylureas inhibit ATP-dependent potassium (K^+) channels in the plasma membrane. This results in depolarization and release of insulin (Antomarchi et al. 1987). Because ATP-sensitive K^+ channels also exist in other tissues, sulfonylureas exert tissue-specific responses through the activation of the channels. The extrapancreatic effects of sulfonylureas have been described in detail by Gerich (1989). Sulfonylurea therapy augments the ability of insulin to inhibit hepatic glucose production and to stimulate glucose utilization. It is unclear if these effects are direct effects

SECTION 9

Nutritional Pharmacology

35

FAT-SOLUBLE VITAMINS

MARTIN J. FETTMAN

- **Vitamin A**
- **Vitamin D**
- **Vitamin E**
- **Vitamin K**

The chapters in Section 9 are concerned with quantitatively minor but essential dietary constituents that are required for optimal health, growth, and performance in animals. Included in this list of essential nutrients with prominent metabolic roles are the fat-soluble vitamins, water-soluble vitamins, macroelements, trace elements, and miscellaneous nutrients, including the essential fatty acids derived from linoleic and linolenic acid and the sulfur-containing amino acid, taurine. These substances have diverse biochemical and structural actions which are sometimes buried in the depths of complex physiological functions of the body, but all serve vital roles irrespective of species differences in dietary requirements or reciprocity of functions. Most of these nutrients are provided in adequate amounts by the natural diets of animals living in their usual environments. However, imposition of unusual environmental conditions or performance demands can alter the physiological requirements for many of these substances, and formulation of diets from alternative feed sources can change the bioavailability and interactions of these nutrients. In addition, particular diseases can influence the absorption, metabolism, or excretion of certain dietary constituents so that conditional deficiencies or excesses may develop. It is under these unusual conditions that one must consider, in addition to their nutritional properties, the pharmacological attributes of those nutrients.

Prevention of dietary deficiencies or excesses, rather than the treatment of dietary imbalances, should be a goal of veterinary medical practice. Thus, in this and the following chapters, emphasis will be placed on an understanding of the dietary interactions and biochemical functions of individual nutrients which are integral to their *normal* physiological roles, and on approaches to limit the incidence of imbalances that may impair health or impede performance. Where adequate information regarding the signs of dietary imbalance is available, recognition of those features and the treatment necessary for their correction will be discussed. Finally, information concerning the use of particular nutrients in "supraphysiological" quantities will be presented with due attention to the potential consequences of their injudicious use. Unsubstantiated use of vitamin-mineral supplements in animal dietetics and veterinary therapeutics has the potential to create conditions of dietary imbalance more deleterious than those of the presenting complaints and further emphasizes the necessity of a comprehensive understanding of nutritional pharmacology and its limitations.

Unless specifically stated to the contrary, all daily dietary requirements are based on the current recommendations of the National Academy of Sciences, National Research Council Committee on Animal Nutrition. Individual publications by this body give the nutrient requirements for all major species. They are regularly revised and present usual feed compositions and normal requirements, as well as textual and photographic illustrations of deficiency syndromes. These publications are a valuable addition to the practicing veterinarian's library and for a nominal fee may be acquired from the Printing and Publishing Office, National Academy of Sciences, 2101 Constitution Avenue NW, Washington, DC 20418.

VITAMIN A

Chemical Structure. Vitamin A, or retinol, is a fat-soluble, long-chain, unsaturated alcohol with five (vitamin A$_1$) or six (vitamin A$_2$) double bonds (Fig. 35.1). The former is found predominantly in tissues of mammals and marine fish, and the latter has been isolated from freshwater fish and possesses approximately half the biological activity of vitamin A$_1$. Vitamin A has several isomeric forms, depending on the configuration about its double bonds, including the all-*trans* form, which possesses the greatest biological activity, and several *cis* forms, which are less active. Replacement of the alcohol group on carbon 15 by an aldehyde group produces retinal, and replacement by an acid group produces retinoic acid. Vitamin A does not occur in plants, but its precursor, the carotenoids, do (Fig. 35.1). Of these, β-carotene possesses the greatest provitamin A activity; α-carotene, γ-carotene, and cryptoxanthin are only about one-fourth as potent (McDowell 1989a). Because only one molecule of vitamin A is produced from each molecule of β-carotene, pure vitamin A has twice the potency of β-carotene.

Sources and Chemical Properties. Carotenoids are the main source of vitamin A for herbivores, and many factors affect their availability, their potency as vitamin A precursors, and the efficiency of conversion to active vitamin A following consumption. All green parts of plants contain carotenoids and thus high potential provitamin A activity. Considerable provitamin A activity may be lost during hay-making, ensiling, dehydrating, processing, and storage of crops.

Animal-fat products, particularly fish oils and liver, contain large amounts of vitamin A, largely as retinyl palmitate, the esterified form. Animal by-products such as tankage, meat scraps, and fish meals often have little if any vitamin A activity, by virtue of composition and processing. Because the carotenoid content of legume hay is so high, dehydrated alfalfa remains one of the best natural sources of provitamin A activity. Yellow corn is the only concentrate containing significant amounts, with only about one-eighth that of good roughage (NRC 1982). Commercial sources of supplemental vitamin A are produced primarily from fish oils and from industrial chemical synthesis. Commercial sources are usually all-*trans* retinyl palmitate or acetate. Natural sources may be highly variable in potency owing to differences in conditions during growth, processing, or storage. Oxidation of vitamin A upon exposure to heat and oxygen is a prominent concern.

Several methods are available to determine carotenoid or vitamin A content in biological specimens. Physicochemical methods are quantitative and include colorimetric reactions, thin-layer chromatography, gas chromatography, and high-performance liquid chromatography (HPLC). Vitamin A activity is expressed in international units (IU) or in micrograms (μg) of retinol equivalents. An IU has the biological activity of 0.3 μg of retinol or 0.55 μg of retinyl palmi-

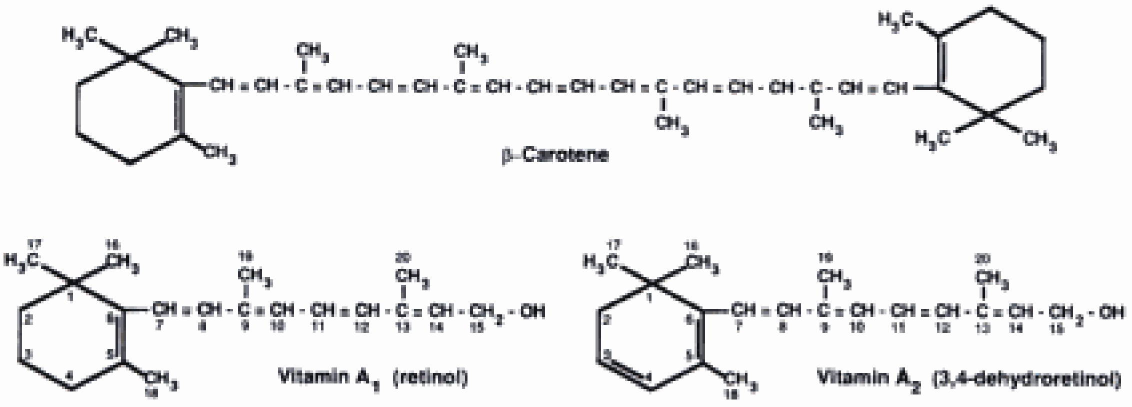

FIG. 35.1

tate. One IU of provitamin A activity is equal to 0.6 μg of β-carotene. One retinol equivalent is equal to 1 μg or 3.33 IU of retinol, and 6 μg or 10 IU of β-carotene.

Biological Characteristics. The conversion of ingested carotenoids into vitamin A occurs in the small-intestinal mucosa and involves two enzymes. The first is β-carotene-15,15′-dioxygenase, which catalyzes the cleavage of β-carotene at the central double bond to produce two molecules of retinaldehyde. The second enzyme is retinaldehyde reductase, which reduces the retinaldehyde to retinol for uptake by the enterocytes. Because the cleavage enzyme is not present in the cat or mink, these species cannot utilize carotenoids, and they must be provided with a dietary source of active vitamin A (McDowell 1989a). There are species differences in the ability to absorb carotenoids; rats, pigs, goats, sheep, rabbits, buffaloes, and dogs cleave virtually all dietary carotenoids in the intestine; whereas, humans, cattle, horses, and carp absorb significant quantities for storage in the liver and adipose tissues. Breed differences in the absorption of carotenoids are also seen; the Guernsey and Jersey breeds of cattle readily absorb carotenoids and have yellow adipose tissue and milk fat, while Holsteins are efficient at cleavage and conversion to vitamin A and have white body fat and milk fat.

Similar to vitamin A derived from carotenoids, vitamin A as the palmitate or acetate ester in animal or industrial sources is absorbed predominantly as retinol, thus requiring its hydrolysis by pancreatic retinyl ester hydrolase. Lipid micelles from the intestinal contents facilitate the uptake of retinol by enterocytes, whereupon the retinol is esterified predominantly to palmitate, incorporated into chylomicrons, and taken up by the lymphatic system for transport to the liver. When vitamin A is released from the liver, the ester is hydrolyzed, retinol is released to the blood, and it is transported by retinol-binding protein (RBP), a specific carrier molecule synthesized by the hepatocytes (Goodman 1980). Nutritional status of the animal influences the synthesis of RBP; protein malnutrition reduces RBP synthesis, and vitamin A deficiency blocks RBP secretion by the liver. The liver contains approximately 90% of total body vitamin A; polar bear livers are so rich in vitamin A that their consumption may result in vitamin A toxicity. Measurement of hepatic vitamin A content may provide more accurate information regarding an animal's vitamin A status than blood levels, which may be maintained through long periods of dietary insufficiency by release from hepatic stores.

METABOLIC FUNCTIONS. Vitamin A is required for at least five distinct physiological processes: normal vision, maintenance of epithelial integrity, reproductive function, bone development, and immune competency (McDowell 1989a). Retinoic acid cannot replace retinol for visual or reproductive function and cannot support rapid epithelial cell division or differentiation, but can otherwise maintain normal growth and health.

VISION. For normal vision, the aldehyde form of vitamin A, 11-*cis*-retinal, combines with the protein opsin to produce rhodopsin, or visual purple, which reacts with light and in the process initiates the activation of the visual neural pathways (Fig. 35.2). Light converts 11-*cis*-retinal to the all-*trans* retinaldehyde, which cannot sustain a stable complex with opsin and is subsequently hydrolyzed from the protein (Fig. 35.2). The energy derived from this reaction is converted to a neural impulse which travels along the optic nerve to the brain, thereby mediating the visual process. Because some of the retinal is lost during this process and must be replaced by vitamin A from the blood, nutritional vitamin A deficiency results in progressive depletion of rhodopsin, which is manifested by slower dark adaptation, progressing to night blindness, and by rod degeneration, leading eventually to complete loss of sight. As part of its function in maintaining epithelial integrity, vitamin A is also required for normal conjunctival and corneal function. Vision may thus become impaired as a result of xerophthalmia, a manifestation of vitamin A deficiency in which the conjunctiva are dehydrated and the cornea becomes cloudy, ulcerated, inflamed, and keratinized. In cows, sheep, horses, and dogs, excessive lacrimation may also result.

EPITHELIAL INTEGRITY. In vitamin A deficiency, the epithelial lining of the respiratory, gastrointestinal, and genitourinary systems may undergo morphologic changes progressing through columnar-to-cuboidal and cuboidal-to-stratified squamous epithelial metaplasia, as well as loss of mucus-secreting capacity. In addition to loss of these systems' normal functions, impairment of the epithelial barriers to microorganisms may significantly reduce an animal's resistance to stress and disease. Vitamin A-responsive dermatoses have been reported in dogs fed commercial diets deficient in vitamin A but otherwise adequate (Ihrke and Goldschmidt 1983). Some of these disorders were histologically compatible with human phrynoderma, a disease thought to be associated with vitamin A deficiency,

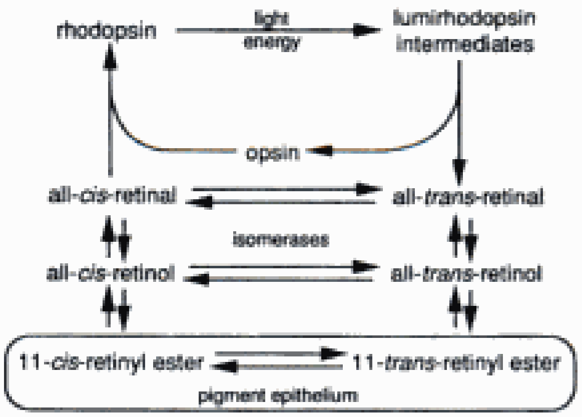

FIG. 35.2—Vitamin A participation in retinal photochemistry. (Adapted from Guyton 1981.)

min A may also act as an anticarcinogen at the level of cell differentiation, thereby preventing loss of control of tissue growth. Studies have shown that vitamin A has no effect on the incidence of cardiovascular disease or cancer in humans (Greenberg et al. 1996; Hennekens et al. 1996; Kushi et al. 1996). Other studies of human smokers and of workers occupationally exposed to asbestos have indicated the possibility that supplemental β-carotene may actually be associated with as much as an 18% increase in the incidence of lung cancer and a 16-26% increase in mortality due to lung cancer or cardiovascular disease (Alpha-Tocopherol, Beta Carotene Cancer Prevention Study Group 1994; Albanes et al. 1996; Omenn et al. 1996). Safe and efficacious levels of dietary carotenoids and/or retinoids for the chemoprevention of cancer remain theoretical and await objective experimental verification.

Signs of Deficiency. In cattle, the signs of vitamin A deficiency include reduced feed intake, slow growth, nyctalopia, xerophthalmia, lacrimation, diarrhea, reproductive abnormalities, and increased susceptibility to infectious diseases. Signs in sheep are similar, with abnormalities in wool fiber structure and strength. In pigs, reproductive performance is impaired, including a variety of developmental abnormalities in term fetuses. In adults, nervous signs predominate, including ataxia, limb trembling, clonic spasms, and paralysis. Vitamin A deficiency in poultry reduces disease resistance, causes neuromuscular incoordination, decreases growth, and reduces egg production and hatchability. Horses develop eye lesions and visual abnormalities similar to those in ruminants, reproductive abnormalities, anorexia, and progressive weakness. In all species, vitamin A deficiency of sufficient severity and/or duration will result in death, either due directly to lesions attributable to retinoid deficiency or due to infectious diseases developed secondarily to impaired immunity.

Assessment of Status. Criteria used to evaluate vitamin A status have included biological response to supplementation, determination of hepatic vitamin A content, and analysis of blood vitamin A concentrations. Because blood vitamin A is maintained by release from the liver, in some species these values may be maintained until hepatic stores are depleted. Thus, low blood levels indicate deficiency, but normal values must be interpreted with caution. For adult dairy cattle, liver vitamin A values less than 1 IU/kg are representative of a deficiency (NRC 1978a). Plasma vitamin A concentrations less than 20 μg/dL in calves and less than 40 μg/dL in adult cattle suggest a deficiency (McDowell 1989a). Vitamin A values below 10 μg/g in the liver or below 10 μg/dL in the plasma indicate a deficiency in pigs (McDowell 1989a).

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. There are significant species differences in the efficiency of conversion of β-carotene to vitamin A, which in turn affects dietary requirements for both carotenoids and retinoids. Rats and poultry possess the greatest ability for conversion, while cats and mink possess no conversion capacity (NRC 1986). Ruminants generally have approximately one-fourth the conversion ability of rats; horses, one-third the capacity of rats; and dogs, one-half the capacity of rats. In any species, the efficiency of β-carotene conversion to vitamin A decreases with increasing dietary intake of β-carotene. Requirements for β-carotene and vitamin A are greatest during pregnancy, lactation, and rapid growth. Deficiency during these phases of life in herbivores can be caused by feeding large quantities of concentrates that are poor sources of provitamin A activity. It has been suggested that dietary requirements for growth in horses may be 1.5-5 times higher than those previously published (Donoghue et al. 1981; NRC 1978b).

EXTRINSIC FACTORS. Stressful environmental conditions and disease have been shown to depress β-carotene conversion ability. Gastrointestinal diseases may impair both β-carotene conversion and absorption of vitamin A. In young calves who are at risk for development of vitamin A deficiency owing to limited reserves at birth, infection with *Cryptosporidium parvum* has resulted in intestinal mucosal pathology sufficient to result in significant impairment of absorption of orally administered vitamin A (Holland et al. 1992). Seasonal effects on vitamin A status have been observed in horses owing to differences in feed carotenoid content, accumulated effects of storage on carotenoid stability, and changes in dietary requirements associated with changes in environment and reproductive status (Maenpaa et al. 1988a,b).

Other dietary constituents may have significant influences on β-carotene or vitamin A stability in feeds, absorption from the gut, or disposition in the body. Because both β-carotene and vitamin A are destroyed by oxidation, the unsaturated fat content of feed may affect their stability, particularly under adverse conditions of storage or handling. Transition elements, including iron, zinc, and copper, may act as catalysts in oxidative chemical reactions and thereby be detrimental to β-carotene and vitamin A stability. Dietary antioxidants such as vitamin E may both protect β-carotene and vitamin A from oxidative breakdown and improve gastrointestinal absorption or utilization. On the other hand, in some studies the combined supplementation of both vitamin A and E provided less protection against bacterial infection than either vitamin alone, implying there may be antagonistic effects at certain dietary levels (Tengerdy and Nockels 1975).

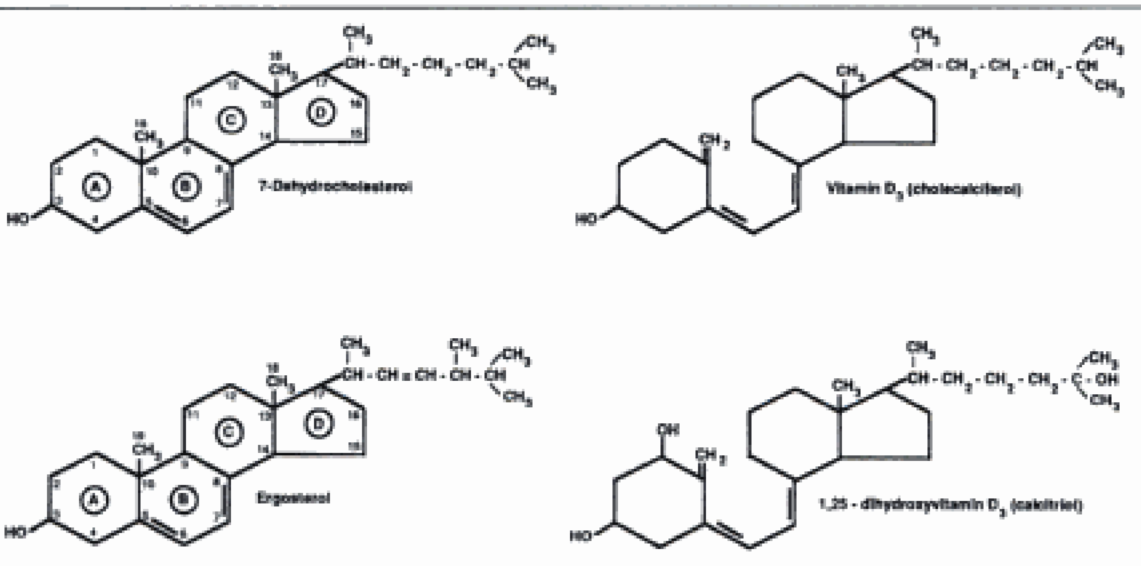
Preparations. Vitamin A is available in natural fish oils and as a synthetic ester of acetate, propionate, or palmitate. Injectable and oral preparations may be obtained singly or as part of a multivitamin preparation. Simple, aqueous solutions are indicated for injection, but because of oxidative instability, chemically stabilized forms of vitamin A are preferred for feed supplementation. Retinyl esters may be stabilized by protective coating with gelatin and antioxidants, included as part of a free-choice mineral mixture, or added with antioxidants to liquids such as oils or molasses that are sprayed onto the feed during processing. Single large doses may be given as intramuscular injections in the prophylaxis or therapy of specific conditions or diseases which increase vitamin A requirements. Large doses may also be included in drinking water or parenteral fluid preparations in the resuscitation of diseased or convalescent animals.

Toxicity. Of all the vitamins, vitamin A is most likely to be supplemented at toxic levels, and signs of toxicity have been demonstrated in most species. Upper safe limits are between 4 and 10 times the nutritional requirements for most nonruminants, and up to 30 times the requirements for ruminants (NRC 1987). Nevertheless, the inappropriate rationale "If a little bit helps, more is better" persists, and toxicity remains a concern. Hypervitaminosis A is characterized by adverse effects caused directly by the retinoids and indirectly by interference with the metabolism of other fat-soluble vitamins, including vitamins D, E, and K. Direct effects may be mediated by changes in cell and organelle membrane integrity caused by excess retinol permeation. Indirect effects may include changes in other fat-soluble vitamin-dependent functions, including bone formation, blood coagulation, and antioxidant functions. Clinical signs of chronic toxicity may include skeletal malformations and fractures, reduced growth and dwarfism, weight loss, dermatoses, anemia, reproductive problems, and enteritis. Acute toxicity, as has been seen in humans consuming polar bear liver or excessive "over-the-counter" supplements, may include drowsiness or insomnia, lethargy or restlessness, headache, and gastrointestinal disturbances. Significant elevations in plasma vitamin A concentrations (often greater than 200 µg/dL) are diagnostic of toxicity.

VITAMIN D

Chemical Structure. Vitamin D activity is derived from a group of sterols of plant or animal origin that undergo transformation by ultraviolet (UV) light and subsequent modification by animal tissues to produce the active vitamin (Fig. 35.3). Hormonal properties of vitamin D are essential to calcium and phosphorus metabolism. Ergocalciferol (vitamin D_2) is derived from ergosterol, a plant sterol, and is the most common dietary source. Cholecalciferol (vitamin D_3) is produced from 7-dehydrocholesterol, an animal sterol, and possesses 2-30 times the biological activity of vitamin D_2, depending on the species studied (McDowell 1989b).

Sources and Chemical Properties. Ergosterol is the main source of provitamin D activity for herbivores, and many factors affect its availability to animals, potency as a vitamin D precursor, and the efficiency of conversion to active vitamin D following consumption. Grains, roots, and oilseeds contain only small amounts of vitamin D activity (NRC 1982). All green parts of plants contain ergosterol and thus high potential provitamin D activity. Fresh green fodder contains little active ergocalciferol until it has been sufficiently exposed to UV light from the sun so that ergosterol becomes activated. Thus, unlike other fat-soluble vitamins, vitamin D activity increases with maturity, owing to an increase in the number of dead, UV-exposed leaves. Artificially dried and barn-cured hay contains less vitamin D than hay that has been cured in the sun. Of the animal sources for vitamin D, meat, unfortified milk and butter, and animal by-products contain little



7-Dehydrocholesterol
Vitamin D3 (cholecalciferol)
Ergosterol
1,25 - dihydroxyvitamin D3 (calcitriol)

FIG. 35.3

Biological Characteristics. Absorption of vitamin E is dependent on fat digestion and is therefore facilitated by biliary and pancreatic secretions. Dietary vitamin E esters are hydrolyzed in the intestinal mucosa, and most vitamin E is absorbed as the free alcohol into the lymphatics for transport to the circulation. The efficiency of vitamin E absorption is less than that for vitamin A, with α-tocopherol being best absorbed and other forms being less well absorbed, in general correspondence with their lesser biological activities. A standardized, oral vitamin E absorption test used widely in humans has been adapted for use in horses to assess gastrointestinal handling of dietary vitamin E (Craig et al. 1991). Vitamin E is stored by all body tissues but predominantly by the liver. However, these stores are less than those for vitamin A and are more rapidly depleted by dietary deficiency.

METABOLIC FUNCTIONS. Vitamin E is required principally for its antioxidant effects, which in turn modulate several physiological processes, including membrane structure and prostaglandin biosynthesis, blood coagulation, reproductive function, and immune competency (McDowell 1989c). Some signs of vitamin E deficiency can be averted by dietary supplementation with other antioxidants, the most important of which is selenium, a cofactor for the free radical-quenching enzyme glutathione peroxidase.

ANTIOXIDANT EFFECTS AND MEMBRANE INTEGRITY. Vitamin E functions as an antioxidant by neutralizing free radicals and preventing membrane lipid peroxidation (Fig. 35.6). At the ultrastructural level, this spares membrane microarchitecture and enzyme activity and prevents the accumulation of oxidative reaction byproducts which may perpetuate the cascade of free radical damage. Gross evidence of these functions includes maintenance of erythrocyte membrane stability and capillary blood vessel integrity, inhibition of platelet aggregation, and prevention of nutritional muscular dystrophy and encephalomalacia. Its effects include promotion of prostaglandin E synthesis, rather than thromboxanes or leukotrienes, from arachidonic acid in a variety of tissues, which may in turn affect many systems' functions. In human subjects, erythrocyte susceptibility to oxidative damage correlates well with erythrocyte vitamin E content (Simon et al. 1997). In rats, free-radical-mediated lipid peroxidation associated with hyperthyroidism is ameliorated by vitamin E supplementation (Seven et al. 1996). However, dietary vitamin E supplementation in horses does not appear to reduce the severity of exercise-induced oxidative damage, as indicated by changes in gluteal muscle thiobarbituric-acid reactive substances and conjugated diene concentrations (Siciliano et al. 1997). Likewise, vitamin E supplementation had no effect on symptoms associated with experimental aflatoxicosis in growing swine (Harvey et al. 1994) or endophyte-infested tall fescue toxicosis in lactating dairy cows (Jackson et al. 1997).

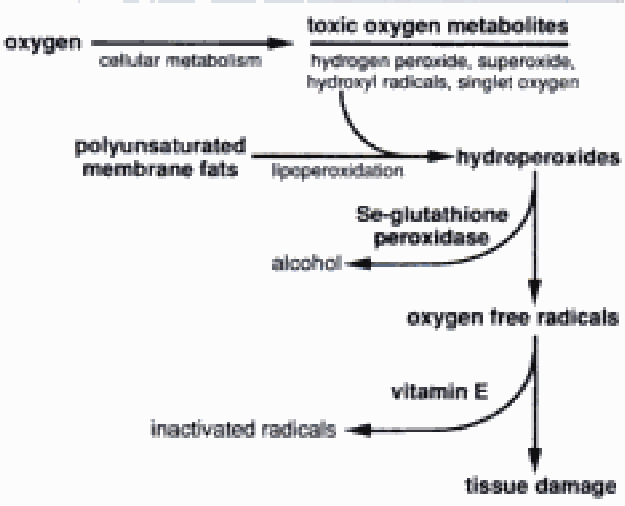


FIG. 35.6—The pathogenesis of lipoperoxidation and the roles of selenium and vitamin E in its control. (From Moore and Kohn 1991.)

REPRODUCTION. Vitamin E and selenium are thought to be required for normal reproductive function, and dietary supplementation has improved fertility and reduced the incidence of some reproductive disorders in several species. In cattle, injection with selenium and oral vitamin E supplementation have been found to reduce the incidence of retained placenta, metritis, and cystic ovaries (Harrison et al. 1984). It has been proposed that the incidence of retained fetal membranes in cows may be related to prepartum oxidative stress, which is responsive to vitamin E supplementation (Brzezinska-Slebodzinska et al. 1994). In sheep, long-term injections with vitamin E and selenium had no effect on fertility or prolificacy but did increase preweaning survival of lambs significantly (Kott et al. 1983).

IMMUNE FUNCTION. Vitamin E deficiency has been associated with an increased frequency and severity of many infectious diseases, because of alterations in immune system responsiveness. Stress alone can depress serum and tissue concentrations of vitamin E, and supplementation of stressed cattle with vitamin E can ameliorate other stress-induced chemical changes (Nockels et al. 1996). Vitamin E deficiency has resulted in reduced lymphocyte transformation and proliferation in response to various mitogens, and impaired neutrophil phagocytic and bactericidal functions (Langweiler et al. 1983; Lessard et al. 1991). Both in vivo and in vitro supplementation with vitamin E have resulted in enhanced mitogen-stimulated lymphocyte proliferation, cell-mediated toxicity, and natural killer cell activity (Reddy et al. 1987). Likewise, concanavalin A-stimulated mononuclear cells from vitamin E-supplemented steers expressed 55% higher interleukin-1 mRNA in vitro than cells from unsupplemented animals (Stabel et al. 1992).

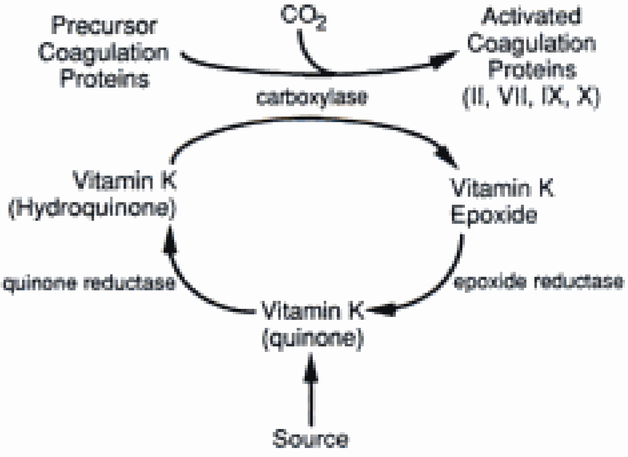

FIG. 35.8—Vitamin K participation in the activation of coagulation proteins. (Adapted from Mount et al. 1982.)

functions to labilize the γ-hydrogen, which is subsequently carboxylated by CO$_2$ (Bell 1978). Vitamin K-deficient animals continue to produce the coagulation factors, but the factors are not active in hemostasis.

CALCIUM METABOLISM. In addition to the vitamin K-dependent coagulation factors, several other proteins with γ-carboxyglutamic acid residues that are presumed to be dependent on vitamin K for their synthesis have been identified, including osteocalcin, which is necessary for normal bone formation (Gallop et al. 1980). Tissues with dystrophic mineralization and calcium-containing kidney stones have also been shown to contain proteins with γ-carboxyglutamic acid residues, leading to the hypothesis that these groups are central to protein interactions with calcium or other divalent cations (McDowell 1989d).

Signs of Deficiency. The predominant clinical sign of vitamin K deficiency in all species is impaired hemostasis, resulting in uncontrolled hemorrhaging and physical signs related to blood loss anemia or blood accumulation in body cavities, which impairs normal function (in the thorax, impeding respiration; in the joints, causing locomotory disturbances; etc.). Deficiency is usually seen only under conditions where enteric microbial synthesis is impaired, such as when oral antibiotics are used, or when metabolic antagonists are consumed, such as dicumarol from moldy sweet clover or warfarin from rodenticides (Osweiler 1978; Mount et al. 1982).

Assessment of Status. Criteria used to evaluate vitamin K status have included biological response to supplementation, determination of activated blood clotting time or prothrombin time (Dodds 1989), and analysis of blood vitamin K concentrations (Mount and Kass 1989). When coagulation times are abnormally prolonged in the absence of liver disease, a vitamin K deficiency should be suspected.

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. As for the other fat-soluble vitamins, the requirements for vitamin K are greatest during pregnancy, lactation, and rapid growth. The potential for deficiency during these phases of life is increased by the superimposition of other conditions which affect vitamin K assimilation and metabolism. Vitamin K deficiency may also result when fat digestion and absorption are abnormal, as in biliary obstruction or inflammatory bowel diseases.

EXTRINSIC FACTORS. Other dietary constituents may have significant influences on vitamin K stability in feeds, absorption from the gut, or disposition in the body. Because vitamin K is destroyed by oxidation, unsaturated fat content of the feed may affect its stability, particularly under adverse conditions of storage or handling. Transition elements, including iron, zinc, and copper, may act as catalysts in oxidative chemical reactions and thereby be detrimental to vitamin K stability. Dietary antioxidants such as vitamin E may protect vitamin K from oxidative breakdown. In coprophagous animals, vitamin K deficiency may result when their access to feces (and hence to microbially derived menaquinones) is blocked. Exposure to vitamin K antagonists must always be considered in the evaluation of potential vitamin K-dependent alterations in hemostasis (Dodds 1989; Byars et al. 1986; Green et al. 1979).

Preparations. If provided with natural dietary sources and/or if enteric microbial synthesis is functional, supplementary vitamin K is not necessary. For animals that are exposed to vitamin K antagonists, receive oral antibiotics, or have impaired gastrointestinal absorption, injectable and oral preparations of menadione may be obtained singly or as part of a multivitamin preparation. Simple, aqueous solutions are indicated for injection, but because of oxidative instability, chemically stabilized forms of vitamin K are preferred for feed supplementation. Water-soluble derivatives or menadione in combination with sodium bisulfite or dimethyl-pyrimidinol bisulfite are more stable and may be further protected by coating with gelatin and antioxidants, included as part of a free-choice mineral mixture, or added with antioxidants to liquids such as oils or molasses that are sprayed onto the feed during processing (McDowell 1989d). Single large doses of menadione may be given as intramuscular injections in the prophylaxis or therapeusis of specific conditions or diseases which increase vitamin K requirements. Large doses may also be included in drinking water or parenteral fluid preparations in the resuscitation of diseased or convalescent animals.

Toxicity. The natural forms of vitamin K, phylloquinone and menaquinone, are relatively nontoxic even at high doses. The toxic dietary level of menadione is approximately 1000 times the nutritional requirement for most animals (NRC 1987). The median lethal dose for a single parenteral injection of menadione in chicks, mice, rats, rabbits, and dogs is in the range of 75-200 mg/kg body weight, and at least 3-4 times that for a single oral dose. Clinical signs of intoxication may include hemolytic anemia and hemoglobinuria, and in horses a single parenteral dose of menadione bisulfite in the range of 2.1-8.3 mg/kg body weight produced acute renal failure (Rebhun et al. 1984). Significant elevations in plasma vitamin K concentrations are diagnostic of toxicity.

WATER-SOLUBLE VITAMINS

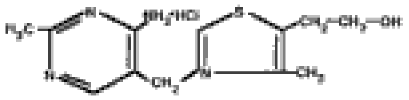
MARTIN J. FETTMAN

Thiamine (Vitamin B$_1$)
Riboflavin (Vitamin B$_2$)
Niacin (Vitamin B$_3$)
Vitamin B$_6$
Pantothenic Acid
Biotin
Folacin
Vitamin B$_{12}$
Choline
Vitamin C

THIAMIN (VITAMIN B$_1$)

Chemical Structure. Thiamin, or vitamin B$_1$, was the first of the B vitamins to be isolated and consists of a pyrimidine and a thiazole moiety joined by a methylene bridge (Fig. 36.1). Most of the thiamin in animal tissues occurs as phosphoric acid esters: approximately 80% as thiamin pyrophosphate (TPP), 10% as thiamin triphosphate (TTP), and 10% as thiamin monophosphate (TMP) and free thiamin (McDowell 1989a).

Sources and Chemical Properties. Brewer's yeast is the richest natural source of thiamin. Cereal grains, their by-products (particularly the germ and seed coats), and oilseed meals are also relatively rich sources, the content dependent on the level of protein (NRC 1982). Thiamin content in forages is related to leafiness, greenness, and protein content and decreases with maturity. Reasonable animal sources include liver, kidney, egg yolk, and dried skim milk. Commercial sources of supplemental thiamin are produced primarily from yeast and from industrial chemical synthesis. They are available as the hydrochloride and mononitrate salts, the latter having lower water solubility and greater stability. Natural sources may be highly variable in potency owing to differences in conditions during growth, processing, or storage, and hydrolysis upon exposure to heat and moisture is a prominent concern.



Thiamin hydrochloride

FIG. 36.1

Heat-labile substances with thiaminase activity occur in certain types of raw fish, shellfish, bacteria, and molds (McDowell 1989a). Thiaminase activity develops with putrefaction and has been attributed in fish to a breakdown product of hemoglobin which splits thiamin at its methylene bridge. Thiamin occurs in many species of fresh- and saltwater fish, where it is found predominantly in the spleen, liver, intestines, and heart, and can be destroyed by cooking. Its production by ruminal bacteria appears to be induced by rapid changes to high-concentrate diets (Haven et al. 1983). Substances with antithiamin activity occur naturally, such as the phenolic acid derivative responsible for bracken fern poisoning in horses (Somogyi 1973), and are synthesized industrially, such as the avian and bovine coccidiostat, amprolium. Thiamin deficiency has been described in cats and dogs fed fresh, minced meat preserved with sulfur dioxide as a sulfiting agent, which is capable of cleaving thiamin into its constituent pyrimidine and thiazole moieties (Studdert and Labuc 1991). Physicochemical methods for the determination of thiamin content in biological specimens are quantitative and include fluorometric spectroscopy, thin-layer chromatography, and high-performance liquid chromatography (HPLC). Thiamin content is expressed as milligrams (mg) per unit dry matter of the substance assayed.

Biological Characteristics. Given adequate hydrochloric acid production in the stomach, thiamin from natural sources is readily digested and absorbed. Phosphoric acid esters are hydrolyzed in the small intestine; free thiamin is absorbed by both passive diffusion and active transport processes and is transported in the blood to the tissues bound to a carrier protein. Organs with higher metabolic activity, such as liver, kidneys, heart, and brain, maintain the highest levels, though little is stored for times of deficiency, with the exception of the pig, in which muscle levels are quite high (Blair and Newsome 1985).

METABOLIC FUNCTIONS. Thiamin functions mainly in its TPP form as the coenzyme cocarboxylase, which is required for oxidative decarboxylations of α-keto acids (McDowell 1989a). Thiamin is therefore necessary for the conversion of pyruvate to acetyl-coenzyme A (CoA), for entry of carbon units into the tricarboxylic acid (TCA) cycle, and for decarboxylation of α-ketoglutaric acid to succinyl-CoA, for progression of the TCA cycle. TPP is also the coenzyme for transketolase reactions in the oxidative pentose phosphate pathway, wherein 2-carbon units are transferred from ribulose-5-phosphate to ribose-5-phosphate, producing sedoheptulose-7-phosphate and glyceraldehyde-3-phosphate. This is essential for ribonucleotide synthesis and nicotinamide adenine dinucleotide phosphate, reduced (NADPH), production for fatty acid synthesis.

NEUROPHYSIOLOGY. Because many of the signs of thiamin deficiency are associated with neural dysfunction, several specific roles have been proposed for thiamin in nervous tissue (Read and Harrington 1986; McDowell 1989a). Through its role as cocarboxylase, it would be required for derivation of energy from oxidative decarboxylation of substrates in this highly metabolically active tissue. Through its role as coenzyme for transketolase, it would be necessary for normal fatty acid and cholesterol production, thereby affecting neuronal membrane synthesis and integrity. In addition, it is also necessary for the synthesis of the principal neurotransmitter, acetylcholine, and for the passive transport of sodium across excitable membranes.

Signs of Deficiency. Thiamin deficiency in animals is principally mediated by thiamin antagonists, or thiaminases, and is thus associated most with feeding of raw fish viscera to carnivores, fern poisoning in nonruminant herbivores, dietary changes to concentrates in ruminants, or coccidiostat overdosage in poultry and cattle. In ruminants, thiamin deficiency is characterized by weakness, ataxia, paresis, anorexia, and diarrhea, followed by signs characteristic of polioencephalomalacia, including blindness, head-pressing, convulsions, paralysis, and opisthotonos (Edwin et al. 1982; Haven et al. 1983). Deficiency in pigs progresses from inappetence and poor growth to sudden death due to myocardial inflammation and necrosis, cardiac arrhythmias, heart failure, and circulatory decompensation (Blair and Newsome 1985). In horses, clinical signs include lethargy, anorexia, weight loss, ataxia, cardiac arrhythmias, muscle tremors, and convulsions (Cunha 1991a). Thiamin deficiency in dogs produces anorexia, emesis, depression, paraparesis, torticollis, circling, and convulsions, progressing to death (Read and Harrington 1982, 1983, 1986). In poultry, neuromuscular effects predominate, including anorexia, paresis, opisthotonos, convulsions, and signs of polyneuritis (Gries and Scott 1972). A syndrome of severe lactic acidosis and circulatory shock in humans maintained with total parenteral nutrition lacking in thiamin has been described, and animals should be monitored for this condition as well (Oriot et al. 1991). Experimental induction of hydrogen sulfide-induced polioencephalomalacia in cattle by feeding high-sulfur, high-concentrate diets has confounded the issue of etiology and thiaminase participation in naturally occurring cases of what was previously thought to be thiamin deficiency in feedlot and range cattle (Sager et al. 1990; Gould et al. 1991).

Assessment of Status. Criteria used to evaluate thiamin status have included biological response to supplementation, determination of products of intermediate metabolism that are dependent on thiamin's function as a coenzyme (such as blood pyruvate or lactate levels), and analysis of enzyme activities for which thiamin is a cofactor (such as erythrocytic transketolase activity). Analysis of blood and urine thiamin concentrations offers a direct indication of status, but techniques have not been widely standardized, and the detection sensitivity for the various thiamin esters varies with the method employed.

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. There are significant species differences in the availability of thiamin synthesized by intestinal microflora, which in turn affects dietary requirements. Animals with functional rumens do not have a dietary requirement for supplemental thiamin, although growing calves and lambs are as susceptible to deficiency as simple-stomached animals. Adult horses are thought to absorb up to 25% of the free thiamin produced in the cecum and probably have no additional dietary requirement. Animals which practice coprophagy likewise are supported by intestinal microbial thiamin synthesis. Thiamin requirements increase with gestation, lactation, growth, or egg production. Increases in thyroid hormone release and metabolic rate induced by environment, disease, or neoplasia increase thiamin requirements, as does increasing age, owing to decreased efficiency of thiamin utilization. The urinary excretion of thiamin increases in polyuric renal diseases, thereby increasing the dietary requirement.

EXTRINSIC FACTORS. Stressful environmental conditions and disease have been shown to depress thiamin utilization. Gastrointestinal diseases may impair both enteric flora thiamin synthesis and subsequent absorption. Gastrointestinal parasites have been shown to compete with the host animal for thiamin, thereby increasing dietary requirements. Other dietary constituents may have significant influences on thiamin stability in feeds, absorption from the gut, or disposition in the body. Because thiamin is destroyed by heat and moisture, environment may affect its stability, particularly under adverse conditions of storage or handling. Spoiled or moldy feeds may contain thiamin antagonists or develop thiaminase activity. The need for thiamin increases dramatically with increasing dietary carbohydrate intake (McDowell 1989a). Conversely, dietary fats and proteins apparently have a "thiamin-sparing" effect. There is some evidence that thiamin may be effective in the treatment of lead toxicity, although its mechanism of action is uncertain (Bratton et al. 1981).

Preparations. Thiamin is available in yeast extracts and as a synthetic ester of hydrochloric or nitric acid. Injectable and oral preparations may be obtained singly or as part of a multivitamin preparation. Single large doses may be given as parenteral injections in the prophylaxis or therapeutics of specific conditions or diseases which increase thiamin requirements, such as for nonaffected ruminants in herd outbreaks of polioencephalomalacia or for carnivores when as little as 10% of their diet is uncooked fish like carp. Large doses may also be included in drinking water or parenteral fluid preparations in the resuscitation of diseased or convalescent animals.

Toxicity. Oral and parenteral thiamin in large doses is usually not toxic. For most animals, upper safe limits are approximately 1000 times their nutritional requirements (NRC 1987). Large intravenous doses in animals have caused vasodilation, bradycardia, hypotension, respiratory depression, and death, but this may have been due to hydrochloride-induced acid-base abnormalities rather than to thiamin itself.

RIBOFLAVIN (VITAMIN B_2)

Chemical Structure. Riboflavin, or vitamin B_2, was the second of the B vitamins to be isolated and consists of a dimethylisoalloxazine core with a ribose side chain (Fig. 36.2). Riboflavin occurs as the free alcohol, as flavin mononucleotide (FMN; riboflavin-5-phosphate), and as flavin adenine dinucleotide (FAD) (McDowell 1989b).

Sources and Chemical Properties. Brewer's yeast is one of the richest natural sources of riboflavin. Cereal grains and their by-products are low in riboflavin, oilseed meals are fair sources, and rapidly growing, green, leafy forages are very good sources (NRC 1982). Commercial sources of supplemental riboflavin are produced primarily from yeast and from industrial bacterial synthesis. They are available as the hydrochloride and mononitrate salts, the latter having lower water solubility and greater stability. Natural sources may be highly variable in potency owing to differences in conditions during growth, processing, or storage, and hydrolysis upon exposure to light and alkalinity is a prominent concern.

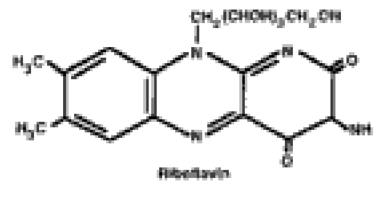


FIG. 36.2

Up to one-fourth of riboflavin present in pet foods may be lost during the extrusion process. Physicochemical methods for the determination of riboflavin in biological specimens are quantitative and include fluorometric spectroscopy, thin-layer chromatography, and HPLC. Riboflavin content is expressed as milligrams (mg) per unit dry matter of the substance assayed.

Biological Characteristics. Following hydrolysis of riboflavin nucleotides by phosphatases in the small intestine, free riboflavin is absorbed by both passive diffusion and active transport processes and is phosphorylated back to FMN in the enterocytes. FMN is transported in the blood to the liver bound to albumin and is converted to FAD in hepatocytes, where about one-third of the body's minimal supplies are stored for release upon demand. Organs with higher metabolic activity, such as liver, kidneys, heart, and brain, maintain the highest levels, though little is stored for times of deficiency.

METABOLIC FUNCTIONS. Riboflavin functions mainly as FMN and FAD, the prosthetic groups for flavoprotein enzymes which participate in the transfer of electrons in biological redox reactions. (McDowell 1989b). Some example flavoproteins are the aerobic dehydrogenases (amino acid oxidases, glucose oxidase), anaerobic dehydrogenases (lipoyl dehydrogenase, succinic dehydrogenase), and oxidases (xanthine oxidase; nicotinamide adenine dinucleotide, reduced [NADH]-cytochrome reductase). Thus, riboflavin plays a key role in the metabolism of carbohydrates, amino acids, and fats and is central to the processes of mitochondrial respiration and oxidative phosphorylation.

Signs of Deficiency. Riboflavin deficiency in animals is characterized by nonspecific signs related to its universal role in cellular metabolism. Because ruminal fermentation produces adequate riboflavin for the adult, its deficiency has only been characterized in young, growing ruminants, in which anorexia, diarrhea, poor growth, loss of hair, circumoral skin lesions, and excessive lacrimation and salivation have been observed. Deficiency in growing pigs produces anorexia, poor growth, dermatitis, alopecia, ataxia, emesis, and visual deficits. In gestating swine, riboflavin deficiency causes abortion, premature parturition, stillbirths, and greater postnatal mortality of piglets (Frank et al. 1984; Blair and Newsome 1985). Intestinal fermentation supplies all that is required for adult horses, but clinical signs produced by experimentally induced deficiency included lethargy, anorexia, severe weight loss, and poor growth (Cunha 1991b). It has been hypothesized that riboflavin deficiency might contribute to the development of periodic ophthalmia, but this has never been confirmed (Cunha 1991b). Riboflavin deficiency in dogs produces anorexia, reduced rates of growth, flaky dermatitis, erythema, muscle weakness, ataxia, and ocular lesions

(NRC 1985; Cline et al. 1996). In cats, riboflavin deficiency may cause hepatic lipidosis and alopecia as well (NRC 1986). In poultry, neuromuscular effects are observed in growing chicks as "curled toe paralysis," and in laying hens as reproductive failure (NRC 1984).

Assessment of Status. Criteria used to evaluate riboflavin status have included biological response to supplementation and analysis of enzyme activities for which riboflavin is a cofactor (such as erythrocytic glutathione reductase activity) (Frank et al. 1984, 1988; Cline et al. 1996). Analysis of blood and urine riboflavin concentrations offers a direct indication of status but first requires hydrolytic treatment to release free riboflavin from its esters.

Dietary Requirements, Indications, and Use

Intrinsic Factors. Animals with functional rumens do not have a dietary requirement for supplemental riboflavin, although growing calves and lambs are as susceptible to deficiency as are simple-stomached animals. Adult horses are thought to absorb adequate riboflavin from that produced in the cecum and probably have no additional dietary requirement. Animals that practice coprophagy likewise are supported by intestinal microbial thiamin synthesis. The riboflavin requirement of adult dogs for maintenance has recently been demonstrated to be higher (~67 µg vs. 50 µg/kg body weight/day) than previously accepted (Cline et al. 1996). Riboflavin requirements increase with gestation, lactation, growth, or egg production. Increases in thyroid hormone release and metabolic rate induced by environment, disease, or neoplasia enhance the rate of riboflavin conversion into its mononucleotide and dinucleotide esters. Pregnant animals produce riboflavin-binding proteins whose synthesis is dependent on estrogen levels, which may facilitate placental transfer of riboflavin to the fetus. The urinary excretion of riboflavin increases in polyuric renal diseases, thereby increasing the dietary requirement.

Extrinsic Factors. Stressful environmental conditions like low temperature and disease have been shown to increase riboflavin requirements (McDowell 1989b). Gastrointestinal diseases may impair both enteric flora riboflavin synthesis and subsequent absorption. Other dietary constituents may have significant influences on riboflavin stability in feeds, absorption from the gut, or disposition in the body. Because riboflavin is destroyed by light and alkali, adverse conditions of storage or handling and alkalinizing feed additives like sodium bicarbonate may affect its stability. High-concentrate feeding increases riboflavin production by ruminal microflora (Miller et al. 1986a), and antibiotic feeding decreases it (Miller et al. 1986b). Supplemental nicotinamide also prevents the decrease in milk protein observed when diets of high-producing cows are supplemented with calcium salts of fatty acids (Cervantes et al. 1996).

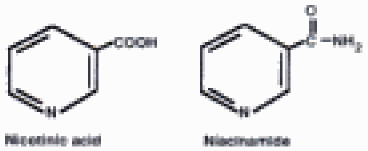
Preparations. Riboflavin is available in yeast extracts, as crystalline riboflavin produced by chemical synthesis or bacterial fermentation, and as the water-soluble phosphate ester. Injectable and oral preparations may be obtained singly or as part of a multivitamin preparation. Single large doses may be given as parenteral injections in the prophylaxis or therapeusis of specific conditions or diseases which increase riboflavin requirements. Large doses may also be included in drinking water or parenteral fluid preparations in the resuscitation of diseased or convalescent animals. Differences exist in the gastrointestinal absorption and subsequent metabolism of nicotinic acid and nicotinamide. Nicotinamide is absorbed more rapidly, but rapid deamidation in the rumen may negate this effect in ruminants (Campbell et al. 1994). However, some source effects on niacin metabolism, such as effects on cellulose digestion, remain to be explained (Campbell et al. 1994; Cervantes et al. 1996).

Toxicity. Oral and parenteral riboflavin in large doses is usually not toxic. For most animals, upper safe limits are approximately 10-20 times, and possibly 100 times, their nutritional requirements (NRC 1987). Very large parenteral doses in laboratory animals have caused reproductive abnormalities and death, but adverse effects have not been reported in domestic species.

NIACIN (VITAMIN B_3)

Chemical Structure. Niacin, or vitamin B_3, is simply a modified pyrimidine synthesized from tryptophan; 3-pyridine carboxylic acid is nicotinic acid, and 3-pyridine amide is nicotinamide, or niacinamide (Fig. 36.3). Most of the niacin in animal tissues occurs as phosphoric acid esters with adenine, nicotinamide adenine dinucleotide (NAD), and nicotinamide adenine dinucleotide phosphate (NADP) (McDowell 1989c).

Sources and Chemical Properties. Niacin is ubiquitous in its distribution among plants and animals, and because of its stability when subjected to many of the usual environmental stresses, much activity is maintained during the pelleting process of feeds by steam and pressure or following cooking. Commercial sources of supplemental niacin are produced primarily from yeast and from industrial chemical synthesis and are available as the acid and the amide. Natural sources may be highly variable in potency owing to differences



Nicotinic acid Niacinamide

FIG. 36.3

Preparations. Niacin is available in yeast extracts, and both injectable and oral preparations may be obtained singly or as part of a multivitamin preparation. Single large doses may be given as parenteral injections in the prophylaxis or therapeusis of specific conditions or diseases which increase niacin requirements. Large doses may also be included in drinking water or parenteral fluid preparations in the resuscitation of diseased or convalescent animals.

Toxicity. High levels of niacin cause vasodilation, itching, heat sensations, nausea, emesis, headaches, and skin lesions in humans (NRC 1987). In laboratory rodents, high niacin intake has been shown to increase the activity of hepatic mixed-function oxidase and other xenobiotic metabolizing enzymes, which can affect the metabolism of a variety of drugs and toxicants. In dogs, 2 g/day of nicotinic acid produced bloody feces, convulsions, and death. Upper safe limits are approximately 350 mg nicotinamide/kg body weight/day, representing 10-1000 times the nutritional requirement, depending on species, and nicotinic acid may be tolerated at up to 4 times this level (NRC 1987).

VITAMIN B_6

Chemical Structure. Vitamin B_6 activity is attributed to three substituted pyridine compounds with equal biological activity in animals: the alcohol form, pyridoxol (pyridoxine); the aldehyde form, pyridoxal; and the amine form, pyridoxamine (Fig. 36.4; McDowell 1989d). Pyridoxol occurs mostly in plants, while the aldehyde and amine predominate in animal tissues. There are, in addition, two coenzyme forms of the vitamin: pyridoxal phosphate and pyridoxamine phosphate.

Sources and Chemical Properties. Vitamin B_6 is ubiquitous in its distribution among plants and animals (NRC 1982). Vitamin B_6 availability is greater from animal sources than from plant sources, perhaps due to differences in tissue protein binding. Because of susceptibility to breakdown upon processing or storage, much activity may be lost during the pelleting process of feeds by steam and pressure or following cooking. Commercial sources of supplemental vitamin B_6 are produced primarily from yeast and from industrial chemical synthesis and are most often available as the hydrochloride salt of pyridoxine. Natural sources may be highly variable in potency owing to differences in conditions during growth, processing, or storage.

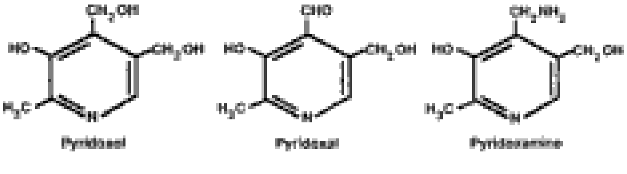


FIG. 36.4

Substances with anti-vitamin B_6 activity have been synthesized, including deoxypyridoxine, the antitubercular drug isonicotinic acid hydrazide (isoniazid), the antihypertensive drug hydralazine, and L-dopa. Physicochemical methods for the determination of vitamin B_6 content in biological specimens are quantitative and include fluorometric spectroscopy, thin-layer chromatography, gas chromatography, and HPLC. Vitamin B_6 content is expressed as milligrams (mg) per unit dry matter of the substance assayed.

Biological Characteristics. Free vitamin B_6 from natural sources is readily digested and absorbed, predominantly from the small intestine. Phosphoric acid esters are hydrolyzed by alkaline phosphatases in the small intestine, absorbed by passive diffusion, and transported in the blood to the liver, where most is converted to pyridoxal phosphate. Both niacin, as NADP, and riboflavin, as flavoprotein pyridoxamine phosphate oxidase, are necessary for phosphorylation of vitamin B_6 to form the active coenzymes. Organs with higher metabolic activity, such as liver, muscle, kidneys, heart, and brain, maintain the highest levels, though little is stored for times of deficiency. Pyridoxal phosphate is transported in the blood primarily in association with albumin and inside erythrocytes.

METABOLIC FUNCTIONS. Vitamin B_6 functions mainly in its coenzyme form of pyridoxal phosphate as a codecarboxylase for reactions involved in transamination, decarboxylation, deamination, desulfhydration, hydrolysis, and synthesis of amino acids (McDowell 1989d). Synthesis of niacin from tryptophan requires a vitamin B_6-dependent enzyme, kynureninase. Vitamin B_6 is required for the first step in porphyrin synthesis, wherein succinyl-CoA and glycine condense to form δ-aminolevulinic acid. Vitamin B_6 also plays a role in the synthesis of arachidonic acid from linoleic acid, hydrolysis of glycogen to glucose-1-phosphate, synthesis of the biogenic amines, and incorporation of iron into hemoglobin.

Signs of Deficiency. Vitamin B_6 deficiency is uncommon in adult ruminants, whose needs are provided by ruminal microorganisms. However, clinical signs of deficiency in growing calves have been documented, including anorexia, diarrhea, poor growth, vomiting, diarrhea, visual impairment, microcytic, hypochromic anemia, and nervous disorders due to demyelinization of peripheral nerves followed by axonal degeneration (Blair and Newsome 1985). Vitamin B_6 deficiency has not been documented in horses, presumably due to adequate endogenous synthesis and production by intestinal microflora (Cunha 1991d). Vitamin B_6 deficiency in dogs and cats causes inappetence, weight loss or growth depression, ataxia, convulsive seizures, cardiomyopathy, and microcytic, hypochromic anemia (NRC 1985, 1986; McDowell 1989d). Experimental pyridoxine deficiency in growing cats also induces renal lesions, characterized by tubular atrophy and

acid, and its deficiency increases linolenic acid production and alters ω-6/ω-3 fatty acid ratios.

Signs of Deficiency. Biotin deficiency in animals most characteristically produces significant changes in the integumentary system. Its deficiency is uncommon in adult ruminants and horses, whose needs are provided by ruminal and large-intestinal microorganisms, respectively (Cunha 1991f). However, resolution of brittle hoof lesions has been reported in some horses supplemented with biotin (Comben et al. 1984). Many practical swine diets, particularly those based on corn or soybean meal, contain marginal levels of available biotin. Deficiency produces anorexia, poor growth, a dermatitis characterized by dryness, roughness, and ulceration, inflammation of the oral mucosa, and cracking of the soles and tops of hooves (McDowell 1989f). The feet become soft and rubbery and are prone to abrasive damage, particularly on rough flooring (Blair and Newsome 1985). Biotin deficiency in dogs and cats is uncommon but is characterized by inappetence, weight loss, dermatitis, and alopecia (NRC 1985, 1986; McDowell 1989f). Biotin deficiency in poultry reduced growth rates and caused dermatitis, hyperkeratosis, brittle and broken feathers, and severe foot disorders, as well as chondrodystrophy and perosis (McDowell 1989f). Signs of biotin deficiency in poults resemble those for pantothenic acid deficiency. In foxes and mink, biotin deficiency occurs whenever diets containing raw egg products are fed and is characterized by lethargy, scaly dermatitis of the paws, exudation from the eyes, and discoloration and loss of hair (Wehr et al. 1980). Experimental biotin deficiency in mice has resulted in skeletal malformations of the developing fetus, including cleft palate, micrognathia, micromelia, syndactyly, and deformities of the cervical vertebral arch (Watanabe and Endo 1991).

Assessment of Status. Criteria used to evaluate biotin status have included biological response to supplementation and measurement of blood or urine concentrations. However, the latter have proved unreliable and have been replaced by measures of pyruvate carboxylase activity (a biotin-dependent enzyme) in the plasma or erythrocytes in poultry and by liver biopsies in mammals (McDowell 1989f).

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. In adult ruminants and horses, biotin synthesis by gastrointestinal microflora is adequate under resting conditions, but as is the case for other species, requirements increase with stress, growth, gestation, or lactation, thereby necessitating supplementation. The urinary excretion of biotin may increase in polyuric renal diseases, thereby increasing the dietary requirement.

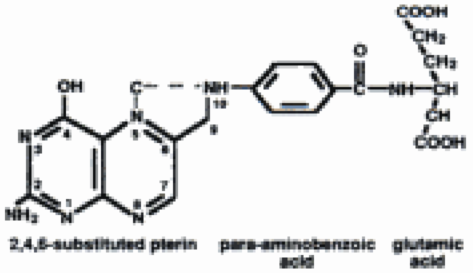
EXTRINSIC FACTORS. Dietary polyunsaturated fat content can increase biotin requirements in poultry and in rats, whereas inclusion of additional antioxidants like ascorbic acid or α-tocopherol protects against oxidative damage and reduces the required dietary level (McDowell 1989f). Stress and other dietary factors may increase biotin requirements, and gastrointestinal diseases may impair enteric flora biotin synthesis and subsequent absorption. Oral antibiotics also increase its dietary requirement, by inhibiting normal enteric microflora production.

Preparations. Biotin is available in yeast extracts and as a synthetic 100% crystalline product. Injectable and oral preparations may be obtained singly or as part of a multivitamin preparation. Single large doses may be given as parenteral injections in the prophylaxis or therapeusis of specific conditions or diseases which increase biotin requirements. Large doses may also be included in drinking water or parenteral fluid preparations in the resuscitation of diseased or convalescent animals.

Toxicity. Biotin is nontoxic even at higher doses. In rats levels of about 4-10 times the nutritional requirement caused reproductive abnormalities in gestating females, but tolerances have not otherwise been adequately evaluated in other species (NRC 1987). Because a high proportion of administered biotin appears rapidly in the urine for excretion, it is thought to be tolerated even at relatively high doses (NRC 1987).

FOLACIN

Chemical Structure. Folacin activity is attributed to a group of compounds based on folic (pteroylglutamic) acid (McDowell 1989g). Pure folic acid is pteroylmonoglutamic acid, which consists of a pteridine nucleus linked to *p*-aminobenzoic acid and one glutamic acid moiety (Fig. 36.7). Most of the folacin in natural sources occurs as pteroyl-γ-L-polyglutamates with from one to nine glutamic acid residues. Changes in the state of reduction of the pteridine group and addition of various 1-carbon substituents can produce modified folacin compounds such as 5,6,7,8-tetrahydrofolic acid, the principal coenzyme form, or



Folic acid (pteroylglutamic acid)

FIG. 36.7

N^5-methyltetrahydrofolic acid, the principal storage form of the vitamin.

Sources and Chemical Properties. Folacin is found widely in both animal and plant sources, mainly as tetrahydrofolic acid and polyglutamate derivatives (NRC 1982). Because of its sensitivity to light and heat, much folacin activity is lost upon cooking or processing of feeds. Folate analogs have been synthesized, predominantly for antimicrobial and anticancer therapy. They may act by binding to dihydrofolate reductase and blocking the conversion of pteroylmonoglutamic acid to tetrahydrofolic acid, or by blocking the transfer of methyl groups from tetrahydrofolic acid to acceptor compounds in metabolism. Sulfonamide antibiotics are analogs of *p*-aminobenzoic acid and competitively inhibit folacin synthesis by microorganisms. Naturally occurring folate antagonists identified in moldy feeds can block intestinal microbial synthesis of folacin. Physicochemical methods for the determination of folacin content in biological specimens are quantitative and include anion exchange, paired-ion reverse phase, conventional reverse phase, and fluorometric HPLC. A nonisotopic, cloned enzyme donor immunoassay system has been developed for the automated assay of folates in serum (van der Weide et al. 1992). Folacin content is expressed as milligrams (mg) per unit dry matter of the substance assayed.

Biological Characteristics. Polyglutamate forms of folacin must be hydrolyzed to pteroylmonoglutamate prior to absorption by the intestinal mucosa (McDowell 1989g). The intestinal conjugase responsible for this reaction is a zinc-dependent enzyme, and its activity is inhibited by acid conditions and drugs that lower intraluminal pH. Pteroylmonoglutamate is absorbed by active transport in the proximal small intestine, and the polyglutamate forms are reconstructed and transported to the tissues for storage, principally in the polyglutamate forms. Folacin-binding proteins facilitate intestinal mucosal uptake, transport in the blood, and uptake and storage by peripheral tissues. Liver contains up to half of body stores, and adult requirements can be met from stored folates for a prolonged period of time. Vitamin B_{12} deficiency can impair both the conversion of pteroylpolyglutamates to pteroylmonoglutamate and the transfer of methyl groups from methyltetrahydrofolate by methionine synthetase, thereby leading to a secondary folacin deficiency.

METABOLIC FUNCTIONS. Folacin, as 5,6,7,8-tetrahydrofolic acid, is essential to the transfer of single-carbon moieties in metabolism (McDowell 1989g). In its role as a methyl-group donor, it is responsible for the synthesis of purines and pyrimidines, the interconversion of serine and glycine, histidine degradation, and the transfer of methyl groups to homocysteine to form methionine, and to ethanolamine to form choline (McDowell 1989g). Because of its central role in nucleic acid synthesis, it is essential for cell division in rapidly growing tissues such as intestinal mucosa and bone marrow. By virtue of its effect on rapidly dividing cell populations, folacin deficiency has been linked to immune system dysfunction as well (Blair and Newsome 1985).

Signs of Deficiency. Folacin deficiency in animals is characterized principally by effects on tissues with rapid rates of cell division. Macrocytic anemia and leukopenia develop because inadequate nucleic acid precursors are available for normal hematopoiesis. Cytoplasmic maturation and hemoglobinization of erythroid precursors continue in the absence of normal cell division, and macrocytic or megaloblastic erythrocytes are produced. Epithelial linings of the gastrointestinal tract and epidermis are also affected. Its deficiency is uncommon in adult ruminants and horses, whose needs are provided by ruminal and large-intestinal microorganisms, respectively (Cunha 1991g). Experimental deficiency in growing lambs fed a semisynthetic diet has been characterized by leukopenia, diarrhea, and pneumonia. In gestating early-lactation dairy cows, large decreases in serum folate levels have been prevented by intramuscular administration of folacin, suggesting that supplementation might increase folacin availability to the fetus and improve neonatal performance (Girard et al. 1989). Studies in growing dairy heifers have documented an increase in weight gain, feed efficiency, hematocrit, and blood hemoglobin concentration following weekly intramuscular injections of 40 mg of folacin from 10 days to 16 weeks of age (Dumoulin et al. 1991). Inadequate folic acid intake in growing pigs and feeding of sulfa drugs to adult swine, thereby inhibiting normal microbial synthesis of folacin in the gut, result in a deficiency characterized by anemia, leukopenia, diarrhea, and a reduced growth rate (Blair and Newsome 1985). Folacin deficiency in dogs and cats has been characterized by inappetence, weight loss, anemia, leukopenia, and glossitis (NRC 1985, 1986; McDowell 1989g). In dogs, decreased antibody responses to infectious canine hepatitis virus and canine distemper virus have been documented (NRC 1985). Folacin deficiency in poultry is characterized by megaloblastic anemia, poor growth, poor feather development, depigmentation of feathers, perosis, reduced egg production and hatchability, and spastic cervical paralysis (McDowell 1989g).

A growing body of literature has associated hyperhomocysteinemia, caused by dietary folate deficiency, with increased risk for occlusive vascular disease in humans (Ueland and Refsum 1989; Clarke et al. 1991; Kang et al. 1992). Homocysteine is a normal constituent of body tissues and fluids and is derived by the cleavage of *S*-adenosylhomocysteine, which is produced from *S*-adenosylmethionine when it donates a methyl group for other synthetic reactions. Hyperhomocysteinemia arises from a deficiency of cystathionine β-synthase activity (which catalyzes the synthesis of cysteine from homocysteine and serine) in the hereditary disease homocystinuria or from a deficiency of folic acid, which is required for the re-methylation of homocysteine by 5-methyltetrahydrofolate-homocysteine methyltransferase (methionine synthase). As little as a 5 μmol/L increase in plasma homocysteine concentration elevates the risk for coronary artery disease by as much as a 20 mg/dL increase in serum cholesterol (Boushey et al. 1995). The risk for atherosclerotic vascular disease in folate deficiency-related hyperhomocysteinemia relative to euhomocysteinemic individuals is estimated to be approximately 2.2 (Graham et al. 1997). Consumption of 5 mg folic acid twice daily for one week, followed by once daily for two weeks, resulted in a decrease in plasma homocysteine levels of approximately 4 μmol/L in mildly hyperhomocysteinemic subjects (Rasmussen et al. 1996). Folic acid supplementation of as little as 400 μg/day has produced similar homocysteine-lowering effects (Boushey et al. 1995). Whether naturally occurring folate-responsive hyperhomocysteinemia or its associated vascular diseases occur in animals is unknown.

Assessment of Status. Criteria used to evaluate folacin status have included biological response to supplementation and measurement of serum and erythrocyte concentrations. Because signs of vitamin B_{12} deficiency may mimic those of folacin deficiency, concentrations of the former should be simultaneously evaluated. In folacin deficiency, the degradation of histidine into glutamic acid is interrupted, producing increased levels of formiminoglutamic acid (FIGLU), an intermediate acid. The amount of FIGLU excreted in the urine following a histidine challenge corresponds well with erythrocytic folate levels and offers a means of assessing functional stores of folacin in the body. In humans, plasma total homocysteine concentrations 6 hours after a standardized methionine loading test (100 mg/kg body weight per os) stress the pathway for irreversible degradation of homocysteine and serve as a marker of folate status (Graham et al. 1997).

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. In adult ruminants and horses, folacin synthesis by gastrointestinal microflora is adequate under resting conditions, but as is the case for other species, requirements increase with stress, growth, gestation, or lactation, thereby necessitating supplementation. Supplementation of sows with folic acid throughout gestation has consistently produced an increased litter size, apparently as a result of improved embryonic or fetal survival in utero (Lindemann 1993). The more rapid the rate of growth in young animals, or the greater the level of production, the greater the need for folacin. Whereas the supply of folates in the diet and by rumen microbial synthesis is adequate to maintain gestation and lactation, the requirement in multiparous or high-producing lactating cows may exceed natural supplies, necessitating supplementation during the first 6-8 weeks of lactation (Girard et al. 1995). The urinary excretion of folacin may increase in polyuric renal diseases, thereby increasing the dietary requirements.

EXTRINSIC FACTORS. Dietary deficiencies of choline, vitamin B_{12}, iron, and ascorbic acid have all been reported to increase folacin requirements (McDowell 1989g). Increased dietary fiber intake as xylan, wheat bran, and beans has increased intestinal microflora synthesis of folacin (Keagy and Oace 1984). Stress may increase folacin requirements, and gastrointestinal diseases may impair both enteric microbial folacin synthesis and subsequent absorption. Oral antibiotics, particularly sulfonamides, also increase its dietary requirement, by inhibiting normal enteric microflora production. Elevated serum folate concentrations are commonly observed in dogs with exocrine pancreatic insufficiency (Williams 1996). This may be explained by secondary small-intestinal overgrowth with bacteria that either synthesize or release folate and/or by enhanced folate absorption as a result of reduced pancreatic bicarbonate secretion and decreased duodenal pH (Rutgers et al. 1995; Williams 1996).

Preparations. Folacin is available in yeast extracts and as a synthetic 100% crystalline product. Injectable and oral preparations may be obtained singly or as part of a multivitamin preparation. Single large doses may be given as parenteral injections in the prophylaxis or therapeusis of specific conditions or diseases which increase folacin requirements. Large doses may also be included in drinking water or parenteral fluid preparations in the resuscitation of diseased or convalescent animals.

Toxicity. Folacin is nontoxic even at higher doses. In rats, single parenteral doses greater than 1000 times the nutritional requirement have induced epileptic seizures, and in rabbits, intraperitoneal injection with 50 mg/kg/day for 10 weeks induced renal lesions, but toxicity has not otherwise been observed in species studied to date (NRC 1987; Campbell 1996).

VITAMIN B_{12}

Chemical Structure. Vitamin B_{12} activity is attributed to a group of compounds whose structure resembles a porphyrin ring consisting of four pyrrole nuclei coupled together so that the inner nitrogen atom of each moiety is coordinated with a central atom of cobalt (McDowell 1989h). The coordinated pyrrole structure is also called a corrin nucleus, and a nucleotide is coupled to the cobalt atom by its nitrogen, and to a propionic acid moiety of the corrin nucleus D ring by a phosphate ester. When cyanide (CN) is attached to the cobalt atom, above the planar ring of the molecule, it is called cyanocobalamin, the most common and most stable form of the vitamin (Fig. 36.8). The CN moiety may be replaced by H_2O (aquacobalamin), OH (hydroxycobalamin), NO_2 (nitrocobalamin), or CH_3

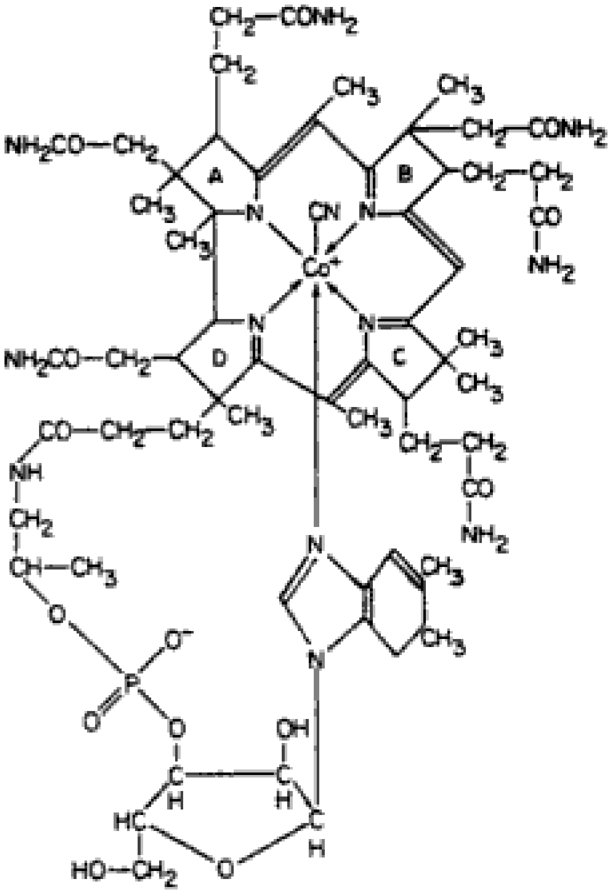


FIG. 36.8—Vitamin B_{12} (cyanocobalamin). (From McDowell 1989h.)

(methylcobalamin), and various nucleotide modifications may produce adenosylcobalamin or deoxyadenosylcobalamin, which along with hydroxy- and methylcobalamin are the predominant forms in animal tissues (McDowell 1989h).

Sources and Chemical Properties. Vitamin B_{12} in nature arises solely from bacterial synthesis and not from yeast or fungi. Vitamin B_{12} is found widely in animal sources, mainly as cyanocobalamin. Plant materials contain virtually no vitamin B_{12} (NRC 1982). Vitamin B_{12} analogs have been identified, predominantly consisting of intermediates in the biosynthesis of cyanocobalamin. They have little or no activity and do not act as vitamin B_{12} antagonists. Physicochemical methods for the determination of vitamin B_{12} content in biological specimens are quantitative and include colorimetric procedures wherein released cyanide is complexed with a chromogen and competitive protein-binding methods wherein cyanocobalamin in test materials displaces radioactively labeled cyanocobalamin in the reaction. A nonisotopic, cloned enzyme donor immunoassay system has been developed for the automated assay of vitamin B_{12} in serum (Kuemmerle et al. 1992). Vitamin B_{12} content is expressed as milligrams (mg) per unit dry matter of the substance assayed.

Biological Characteristics. Vitamin B_{12} in feed is bound to proteins, from which it is released through the action of gastric acidity and peptic digestion, and following which it is bound by a nonintrinsic factor protein until it reaches the proximal small intestine (McDowell 1989h). In the small intestine, trypsin degrades the nonintrinsic factor proteins, facilitating the binding of vitamin B_{12} to intrinsic factor, a glycoprotein which mediates vitamin B_{12} absorption. Vitamin B_{12} is absorbed almost exclusively in the ileum, in a carrier-mediated process with a specific receptor protein located on the microvillus border of the enterocytes. Defective brush border expression of the intrinsic factor-cobalamin receptor has been identified in a heritable syndrome of canine cobalamin malabsorption (Fyfe et al. 1991a,b). Following its transport from the enterocytes to the portal blood, vitamin B_{12} is bound to proteins called transcobalamins, which are synthesized by the liver and facilitate transport and storage of the vitamin. Liver contains much of the body's stores, and half-life has been reported to be as long as 1 month (McDowell 1989h). Vitamin B_{12} is converted to adenosylcobalamin, the coenzyme for mutase, or to methylcobalamin, the coenzyme for methyltransferase, in order to be metabolically active.

METABOLIC FUNCTIONS. As the methylcobalamin coenzyme for methyltransferase, vitamin B_{12} is essential, along with folacin, for the transfer of methyl groups in the synthesis of methionine and choline and for the production of purines and pyrimidines. Vitamin B_{12} deficiency impairs the removal of the methyl group from methyltetrahydrofolic acid, thereby trapping the folate in a nonutilizable form and producing an effective folate deficiency. Vitamin B_{12} is required for the incorporation of serine, methionine, and phenylalanine into proteins, and as the adenosylcobalamin coenzyme for mutase or methylmalonyl-CoA isomerase, it is required for the conversion of propionate to succinyl-CoA. Because methionine synthase activity is also impaired by a methylcobalamin deficiency, hyperhomocysteinemia, as described for folate deficiency, may also be responsive to vitamin B_{12} supplementation (Kang et al. 1992), though the effect is not as marked as for folate supplementation (Rasmussen et al. 1996).

Signs of Deficiency. Vitamin B_{12} deficiency in animals is characterized principally by effects on tissues with rapid rates of cell division and by neurological lesions. Megaloblastic anemia similar to that seen with folacin deficiency develops because inadequate nucleic acid precursors are available for normal hematopoiesis. Its deficiency is uncommon in adult ruminants and horses provided with adequate dietary cobalt, whose needs are provided by ruminal and large-intestinal microorganisms, respectively (Cunha 1991h). Signs attributable to cobalt deficiency are essentially those of vitamin B_{12} deficiency in these species. They include inappetence, anemia, dermatitis, rough hair coat, wasting, and death (McDowell 1989h). Subclinical cobalt (and, hence, vitamin B_{12}) deficiency is thought to have tremendous economic impact on production in areas with cobalt-deficient soils. A report in sheep indicated that reproductive performance and lamb viability in subclinically deficient ewes were significantly affected and could only be completely reversed by cobalt supplementation throughout the period of breeding, gestation, and lactation (Fisher and MacPherson 1991). Cobalt and vitamin B_{12} deficiency was at one time thought to play a role in ketosis and low milk fat syndromes in lactating dairy cows, due to its deleterious effects on propionate metabolism, to reduction in the rate of gluconeogenesis, and to methylmalonate-mediated inhibition of fatty acid synthesis (Elliot et al. 1979; Croom et al. 1981; Peters and Elliot 1983). Although cobalt and/or vitamin B_{12} supplementation of subclinically deficient animals can improve feed efficiency, growth rate, and production, these metabolic diseases have not been linked conclusively to vitamin B_{12} deficiency as yet. Vitamin B_{12} deficiency in pigs is characterized by a normocytic anemia, vomiting, diarrhea, rough hair coat, reduced growth rate, and neurological lesions of increased excitability, unsteady gait, and ataxia (Blair and Newsome 1985). Vitamin B_{12} deficiency has been described in dogs only in a family of Giant Schnauzers with inherited selective intestinal malabsorption of cobalamin. Abnormal findings included inappetence, lethargy, failure to grow, a chronic nonregenerative anemia with anisocytosis and poikilocytosis, and neutropenia with hypersegmentation (Fyfe et al. 1989). Vitamin B_{12} deficiency in kittens has been characterized by slow growth and increased methylmalonic acid excretion (NRC 1985, 1986; McDowell 1989h). A 9-month-old cat with methylmalonic acidemia secondary to a defect in intestinal cobalamin absorption expressed clinical signs including lethargy, fever, anorexia, and poor growth unless fed a restricted protein diet or treated with vitamin B_{12} (Vaden et al. 1992). A congenital disorder of intestinal cobalamin absorption may have been observed in a nine-month-old male cat characterized clinically by lethargy and poor growth, from which serum cobalamin concentrations were virtually nil and hepatic methylmalonyl-CoA-mutase activity was hyperresponsive to cobalamin supplementation in vitro (Vaden et al. 1992). Vitamin B_{12} deficiency in poultry is characterized by poor growth, reduced feed efficiency, perosis, reduced egg production and hatchability, limb weakness, and ataxia (McDowell 1989h).

Assessment of Status. Criteria used to evaluate vitamin B_{12} status have included biological response to supplementation and measurement of serum and tissue concentrations. Because signs of folacin deficiency overlap those of vitamin B_{12} deficiency, concentrations of the former should be simultaneously evaluated (McDowell 1989h). As for folate deficiency, in vitamin B_{12} deficiency, the degradation of histidine into glutamic acid is interrupted, producing increased levels of FIGLU acid, an intermediate, and offers a means of assessing functional stores of vitamin B_{12} in the body. Urinary excretion of methylmalonic acid is also elevated with vitamin B_{12} deficiency and may be used as an index of functional status. Finally, one may evaluate liver cobalt or vitamin B_{12} concentrations in ruminants, wherein concentrations of cobalt less than 0.07 ppm or of cobalamin less than 0.10 μg/g wet weight are diagnostic of deficiency.

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. In adult ruminants and horses, vitamin B_{12} synthesis by gastrointestinal microflora is adequate under resting conditions, but as is the case for other species, requirements increase with stress, growth, gestation, or lactation, thereby necessitating supplementation. The more rapid the rate of growth or the greater the level of production, the greater the need for vitamin B_{12}. The urinary excretion of vitamin B_{12} may increase in polyuric renal diseases, thereby increasing the dietary requirement. In humans, the condition of pernicious anemia occurs when there is a defect in vitamin B_{12} absorption by the gastrointestinal tract, owing to abnormalities in gastric acid production, pancreatic exocrine insufficiency, intrinsic-factor secretion, enterocyte receptor synthesis, or inflammatory bowel disease (McDowell 1989h). Exocrine pancreatic insufficiency (EPI) in dogs is commonly associated with severely subnormal serum cobalamin concentrations, pursuant to defects in intestinal cobalamin absorption (Simpson et al. 1989; Williams 1996). Replacement with exogenous canine pancreatic juice reverses the defect in experimental canine EPI (Simpson et al. 1989). However, it is unclear whether deficiencies of pancreatic proteases or pancreatic intrinsic factor, secondary small-intestinal bacterial overgrowth (SIBO), or some combination of effects is responsible for the cobalamin malabsorption and deficiency (Williams 1996). Serum cobalamin levels are also significantly depressed in some cases of SIBO, whether EPI coexists or not, and this may be due to cobalamin-binding by bacteria or mucosal damage and subsequent malabsorption (Rutgers et al. 1995).

EXTRINSIC FACTORS. Dietary deficiencies of choline, methionine, folacin, and, of course, cobalt have all been reported to increase vitamin B_{12} requirements (McDowell 1989h). Dietary supplementation with propionate increases vitamin B_{12} requirements (Hogue and Elliot 1964), but dietary factors which increase propionic acid production, such as supplementation with ionophores, have had little effect (Daugherty et al. 1986). Stress may increase vitamin B_{12} requirements, and gastrointestinal diseases may impair enteric microbial vitamin B_{12} synthesis and subsequent absorption. Oral antibiotics may also increase its dietary requirement, by inhibiting normal enteric microflora production.

Preparations. Vitamin B_{12} is available commercially as cyanocobalamin, produced by fermentation. Injectable and oral preparations may be obtained singly or as part

concentrations of choline, acetylcholine, or phosphatidylcholine. Deficiency results in reduced acetylcholine levels in the brain and decreased phosphatidylcholine/phosphatidylethanolamine ratios in the liver.

Dietary Requirements, Indications, and Use

Intrinsic Factors. In adult ruminants and horses, choline synthesis by gastrointestinal microflora is adequate under resting conditions, but as is the case for other species, requirements increase with stress, growth, gestation, or lactation, thereby necessitating supplementation. The more rapid the rate of growth or the greater the level of production, the greater the need for choline. Males appear to be more sensitive to choline deficiency than females, glucocorticoids appear to be capable of ameliorating signs of choline deficiency, and growth hormone increases choline requirements independent of its effects on growth (McDowell 1989i).

Extrinsic Factors. Dietary deficiencies of other nutrients affecting methyl-group transfer, such as methionine, folacin, or vitamin B_{12}, can increase choline requirements (McDowell 1989i). Choline, in turn, can spare dietary methionine requirements if adequate sulfate is also provided. Increased dietary fat or protein levels can increase the requirement for choline, while oral antibiotics appear to decrease the requirement, owing to reduced degradation by intestinal microflora. Stress may increase choline requirements, and gastrointestinal diseases may impair lipid digestion and subsequent lecithin or choline absorption.

Preparations. Choline is available commercially as choline chloride, choline bitartrate, or choline dihydrogen citrate, produced by chemical synthesis. Injectable and oral preparations may be obtained singly or as part of a multivitamin preparation. Single large doses may be given as parenteral injections in the prophylaxis or therapeusis of specific conditions or diseases which increase choline requirements. Large doses may also be included in drinking water or parenteral fluid preparations in the resuscitation of diseased or convalescent animals.

Toxicity. The maximum tolerable doses for choline vary with route of administration and among species. In mice, the LD_{50} for a single oral dose of choline chloride is 3900 mg/kg body weight, whereas it is only 53 mg/kg body weight when administered intravenously. The maximum tolerable level for rats is between 3.4 and 6.1 g/kg body weight when administered orally in a single dose. Choline supplementation up to 1000 ppm of the diet appears to improve growth in swine, whereas levels of 2000 or 4000 ppm reduced growth and feed efficiency (Southern et al. 1986). Dogs and poultry appear to be quite sensitive to choline; dogs develop an anemia when fed levels only 3 times the recommended dietary requirement, while growth depression was noted in broilers fed only twice the dietary requirement (NRC 1987).

VITAMIN C

Chemical Structure. Vitamin C activity is attributed to the *l*-isomer of ascorbic acid (reduced) and dehydroascorbic acid (oxidized) (Fig. 36.10). The reversible oxidation and reduction of these two forms is the basis for vitamin C's role as an antioxidant in biological systems (McDowell 1989j).

Sources and Chemical Properties. Fruits and vegetables are the principal natural sources of vitamin C, although some animal by-products, including fish meal and organs like liver and kidney, have activity comparable to some fruits and grains. The sodium salt of ascorbic acid is highly water soluble, and stabilized crystalline forms with ethylcellulose microcoating are available. It is highly susceptible to oxidative damage, which is accelerated by transition metal elements. Physicochemical methods for the determination of vitamin C content in biological specimens are quantitative and include colorimetric spectroscopy, gas chromatography, and HPLC. Vitamin C content is expressed as milligrams (mg) per unit dry matter of the substance assayed.

Biological Characteristics. Vitamin C is absorbed by sodium-dependent active transport processes in the small intestine similar to those for monosaccharides. Vitamin C absorbed from the diet, as well as that produced endogenously in those species capable of synthesis, is distributed widely in tissues. It accumulates in highest concentrations in the pituitary and adrenal glands and increases in concentration in areas of active fibroplasia, such as around wounds undergoing healing. Vitamin C is excreted in the urine as ascorbic acid itself or is metabolized first to oxalic acid when nutritional requirements are exceeded.

Metabolic Functions. Vitamin C is not incorporated into any coenzymes, but is required for many biochemical reactions, particularly those of oxidation. Enzymatic hydroxylation of proline and lysine during the synthesis of collagen requires ascorbic acid, probably to protect the hydroxylase enzymes from oxidative damage by ferrous ions and mixed disulfides. It is

Calcium and Phosphorus
Sodium and Chloride
Potassium
Magnesium
Sulfur

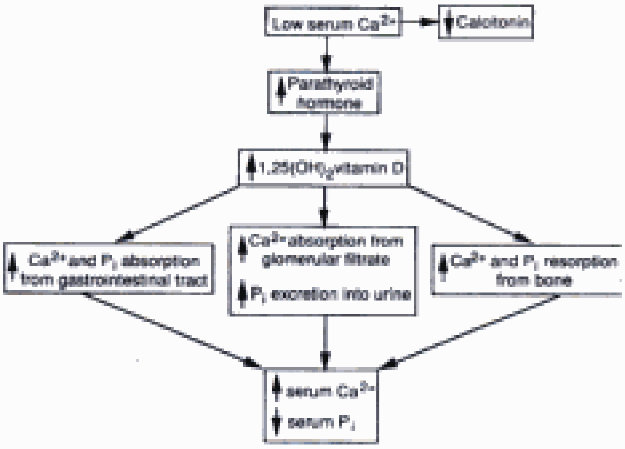
CALCIUM AND PHOSPHORUS

Source and Occurrence. Calcium (Ca) and phosphorus (P) are widely distributed in soil, and in general, hays contain more Ca than grains, and legume hays contain more than grass hays (Minson 1990a,b; NRC 1982). The P content of grains is higher than that of forages, although the same factors affecting forage Ca content seem to affect P concentrations as well. The true availability of Ca and P from plant materials depends on their chemical forms. Much of the P present is often in the form of phytic acid (inositol hexaphosphate), which not only reduces its availability but also binds cations, including Ca, magnesium, and zinc, thereby forming insoluble and unavailable complexes. Commercial sources of Ca and P include a wide variety of salts such as dicalcium phosphate, monocalcium phosphate, calcium carbonate (limestone), and calcium chloride, as well as animal by-products like bonemeal and oyster shell.

Chemical Forms and Distribution. Most of the Ca (approximately 98%) and most of the P (approximately 85%) in the body is present in bone. The remaining small amounts play critical roles in a variety of metabolic functions throughout all tissues of the body. A pH-dependent equilibrium exists between ionized Ca, inorganic phosphate ions, and calcium phosphate salts in the body fluids. In the blood plasma, approximately 45% of the Ca is in the free and ionized form, about 5% exists in salts with phosphate and other anions, and the remaining 50% is bound to anionic sites on plasma proteins. The degree of Ca binding to these proteins is influenced by pH, which likewise affects the disposition of Ca in the gastrointestinal (GI) tract, kidneys, and other organs. Much of the extra-osseous P occurs in the form of phosphate esters of organic acid intermediates in metabolism and as the "high-energy" phosphate bonds of adenosine triphosphate (ATP), guanosine triphosphate (GTP), etc.

Several methods are available for the determination of the Ca and P content in biological specimens. Ashed preparations or acid extracts of tissues may be analyzed by atomic absorption spectroscopy for Ca and by colorimetric reactions for P. Ca in blood and urine may be determined by atomic absorption or flame emission spectroscopy and by fluorescent or visible light spectrophotometry of chromogenic complexes, such as Ca-cresolphthalein (Welch et al. 1990; Farrell 1987a). Non-protein-bound (ultrafiltrable) Ca may be determined by any of these methods following mechanical or centrifugal filtration through an ultrafilter. Because ionized Ca is the physiologically active form and may vary independently of total Ca concentrations in biological fluids like blood, its direct and rapid measurement by ion-specific electrode potentiometry has found increasing clinical utility (Toffaletti 1987). P in blood and urine may be analyzed by ultraviolet or visible light spectrophotometry of chromogenic complexes formed directly, such as phosphomolybdate, or indirectly, following coupled enzymatic reactions with purine nucleoside phosphorylase, xanthine oxidase, and peroxidase (Farrell 1987b).

Biological Characteristics. As described in Chap. 35, one may consider Ca and P metabolism to be controlled by a triad of hormones: parathyroid hormone (PTH), which has both direct effects on bone and kidney and indirect effects through its regulation of vitamin D activation; thyrocalcitonin (TCT), which has direct effects on bone and kidney; and calcitriol (1,25-$(OH)_2$ vitamin D), which has direct effects on bone, kidney, and intestine, as well as indirect effects through its reciprocal regulation of PTH release (Fig. 37.1). Ingested Ca and P are predominantly absorbed in the small intestine by both active and passive processes. Intestinal Ca and P uptake is promoted by calcitriol, which is particularly important for the synthesis of calcium-binding proteins (CaBP) that facilitate Ca absorption and transfer to the blood. In the kidneys, Ca reabsorption from the glomerular filtrate is dependent on positive influences by both PTH and calcitriol. In the proximal nephron, PTH inhibits carbonic anhydrase activity; decreases sodium, bicarbonate, and water absorption; and thereby decreases the concentration gradients necessary for Ca and P reabsorption. Because P is not actively secreted by the nephron, this is the only means of increasing its excretion into



Low serum Ca2+

↑ Ca2+ and Pi resorption from bone
↑ serum Ca2+
↓ serum Pi

FIG. 37.1—Homeostatic response to hypocalcemia. (Adapted from Stewart and Broadus 1987.)

the urine. Proximal tubular loss of Ca is more than compensated for by PTH-stimulated increases in active Ca transport across the loop of Henle in a cyclic AMP-dependent process, and by calcitriol-dependent reuptake of Ca by the distal nephron in CaBP-mediated processes. In the bones, calcitriol facilitates both Ca and P resorption and deposition, the former being stimulated by PTH and the latter by TCT. Ionized Ca levels in the blood determine the release of PTH and TCT; PTH and blood inorganic phosphate concentrations exert reciprocal control over the rate of 25-OH vitamin D activation to calcitriol; and calcitriol, in turn modulates PTH release and affects interorgan Ca and P kinetics.

EFFECTS OF ACID-BASE METABOLISM. Because pH exerts an important influence on Ca binding to proteins and precipitation of salts of Ca and P, alterations in systemic acid-base metabolism can have profound effects on the disposition of these minerals in the body (Fredeen et al. 1988a,b). Changes in acid-base status also may have profound effects on the activity of PTH and calcitriol, which in turn may affect Ca and P balance. In general, acidosis increases the ionization of Ca, thereby increasing the resorption of Ca and P from bone, reducing mineral deposition in eggshells, and augmenting the proportion of ionized Ca in the blood (Peoples 1988). Conversely, alkalosis decreases Ca ionization and promotes bone deposition and eggshell formation. Metabolic acidosis has also been shown to alter bone remodeling through cellular effects. Decreased bicarbonate concentrations reduce osteoblast activity and stimulate osteoclast activity, in addition to the physicochemical effects noted above (Krieger et al. 1992; Bushinsky 1995). There is controversy in the literature regarding the relative "potency" of respiratory versus metabolic acidosis in altering bone mineral deposition (Sprague et al. 1994; Arnett et al. 1994). While acidosis promotes PTH's effects on bone, it apparently inhibits its renal tubular effects and directly suppresses the activity of renal 1α-hydroxylase, thereby inhibiting calcitriol production (Beck et al. 1986; Reddy et al. 1982). The net result is decreased GI absorption of Ca, increased bone mineral resorption, and increased urinary Ca excretion. This has resulted in negative Ca balance in cats (Ching et al. 1989), impaired growth in pigs (Golz and Crenshaw 1991), and bone demineralization in dogs (Burnell and Teubner 1971). The effect of acidification may be employed positively in the prevention of parturient paresis in lactating cows (see below), whereas purposeful alkalinization may be used to reverse demineralization in uremia and to promote eggshell quality in poultry.

It has been hypothesized that the usual daily load of acid produced through metabolism might have similar effects on calcium metabolism and bone turnover, even in the absence of overt disturbances in acid-base balance. In humans, daily oral intake of $KHCO_3$ (but not $NaHCO_3$) to neutralize endogenous acid production significantly improves calcium balance, reduces bone resorption, and increases bone formation in healthy adult males (Lemann et al. 1989) and in postmenopausal females (Sebastian et al. 1994).

METABOLIC FUNCTIONS

BONE DEVELOPMENT. Bone mineralization occurs through the process of calcification of an organic matrix produced by chondroblasts (endochondral ossification) or osteoblasts (intramembranous bone formation), and bone may subsequently be remodeled or serve as a source of Ca and P for the body through the additional actions of osteoclasts and osteocytes. Dietary Ca and P intake must be adequate and in the appropriate relative ratio to support bone mineralization. A deficiency of Ca or P or an otherwise adequate Ca intake in conjunction with an excess of dietary P can result in nutritional secondary hyperparathyroidism with the development of rickets in deficient growing animals and of osteomalacia in deficient adult animals. Conversely, excessive Ca intake over prolonged periods of time can lead to the development of hypercalcitoninism and osteopetrosis (NRC 1980).

NEUROMUSCULAR FUNCTION. Ca has two opposing effects on neural function. It blocks sodium channels in the neuronal membrane, making it less excitable, and it is required for the normal secretion of neurotransmitters like acetylcholine. Thus, hypocalcemia makes membranes more excitable but decreases neurotransmitter secretory capacity. In most species, enough neurotransmitter is released under conditions of hypocalcemia so that because of their enhanced excitability, muscles exhibit increased activity. Signs of hypocalcemia in most species thus include muscle fasciculations, seizures, and tetany, as seen in lactation tetany of horses and in puerperal tetany of dogs. It has been hypothesized that ruminants normally secrete much less neurotransmitter at the myoneural junction, so with hypocalcemia, not enough is released to elicit a response, and flaccid paralysis results. Signs of hypocalcemia in early-lactation cows with "milk fever" thus progress from an early stage of hypersensitivity and tetany to one of weakness and paresis and ultimately paralysis.

Muscle contractions are regulated by the concentration of ionized calcium in the sarcoplasm. Sarcoplasmic reticulum membranes contain an ATP-dependent Ca pump that maintains low concentrations in resting myocytes. Upon stimulation, Ca is rapidly released from the terminal cisternae of the sarcoplasmic reticulum and binds to the troponin component of the actin filaments. Troponin undergoes a conformational change that moves tropomyosin, which in turn uncovers myosin-binding sites on F-actin. This binding promotes the formation of cross-links between the actin and myosin filaments, which causes them to be drawn toward the center of the sarcomere, resulting in shortening of the myocyte and muscular contraction. This basic process is central to contraction of all smooth and striated muscle, including that of the heart. Hypocalcemia can produce significant electrocardiographic changes, arrhythmias, and even cardiac arrest. At a lesser order of magnitude, ciliary and flagellar contractions and movement of intracellular contractile elements such as microtubules and microfilaments similarly require Ca to function. Secretion of peptide hormones is dependent on mobilization and exocytosis of intracellular secretory granules in calcium-dependent processes. Peptide hormone action is also influenced by target cell Ca levels, which in conjunction with cyclic AMP, acts as a second messenger in the regulation of postreceptor functional responses.

Because of its central role in the intermediary metabolism of nutrients required for energy-yielding and synthetic processes, P is also necessary for all of the above actions attributed to Ca in the control of neuromuscular and other bodily functions.

HEMOSTASIS. Both the intrinsic and extrinsic systems of blood coagulation are dependent on Ca as a cofactor for activation of coagulation factors (Dodds 1989). The conversions of vitamin K-dependent factors II, VII, IX, and X to their active forms require ionic Ca. In addition to the procoagulant factors, other regulators of hemostasis depend on Ca, including protein C, which inactivates factors Va and VIIIa, and factor XIII, the fibrin-stabilizing factor which facilitates polymerization of fibrin monomers activated by the common pathway of coagulation.

PRODUCTION. Ca and P are the principal mineral components of milk and obviously account for the structure of eggshells. The dietary Ca and P requirements for lactation and egg production are the greatest of any period of life, and a deficiency of either, or otherwise adequate Ca intake in conjunction with an excess of dietary P, can result in marked decreases in milk production or eggshell quality and production. The concentrations of Ca and P in milk will remain relatively constant through periods of significant dietary deficiency or imbalance, which result rather in decreases in production corresponding to the degree of deficiency.

Signs of Deficiency. The signs of chronic Ca deficiency, or adequate Ca but excessive P intake, relate mostly to skeletal abnormalities associated with the clinical condition of rickets (Call et al. 1986; McDowell 1989; Cunha 1991a). Failure of mineralization leads to abnormal proliferation and degeneration of the cartilage, weak and deformed bones, stiff and enlarged joints, pathologic fractures, and locomotory abnormalities. Accessory signs may include lethargy, anorexia, weight loss, hypogalactia, and neuromuscular dysfunction (Call et al. 1986, 1987; Shupe et al. 1988). In poultry, Ca or P deficiency can lead to decreased eggshell thickness, increased fragility, and reduced hatchability (McDowell 1989). In cattle, dietary P deficiency can produce a periparturient syndrome characterized by hypophosphatemia, intravascular hemolysis, hemoglobinemia, and hemoglobinuria, apparently as a result of impaired ATP production and subsequent effects on erythrocyte viability (Ogawa et al. 1989a,b). There is little evidence that dairy cows exhibit a specific appetite for Ca- or P-containing mineral supplements even after 9-12 weeks of deficient intake (Coppock et al. 1976). It has been suggested that dietary Ca and/or P imbalances may be contributory factors in developmental orthopedic diseases of growing horses (Thatcher 1991). While their association with lesions characteristic of rickets is clear, their relationship to physitis and limb deformities is less so. In one study, mild to moderate physitis and flexure limb deformities were observed in 37 of 42 light horse weanlings studied for over 30 weeks and fed high-forage or high-concentrate rations, irrespective of low (~0.30% dry matter [DM]), medium (~0.70% DM), or high (~1.10%) P content; all lesions resolved before the end of the study (Cymbaluk and Christison 1989). Signs of acute Ca deficiency relate predominantly to neuromuscular and cardiovascular abnormalities, most notable among which are the syndromes of parturient paresis in lactating cows and of puerperal tetany, lactation tetany, or eclampsia in other species, as described earlier.

Assessment of Status. Criteria used to evaluate Ca and P status have included biological response to supplementation, analysis of blood Ca and P concentrations, measurement of urinary and/or fecal excretion of Ca and P (Ching et al. 1989), assessment of bone mineral density by noninvasive densitometric methods (Ching et al. 1990; Cummings et al. 1990), histomorphometric analysis of fluorescent-labeled bone turnover (Ching et al. 1990), and evaluation of indirect indices of bone turnover, including serum alkaline phosphatase activity, serum or urine osteocalcin concentrations, and urinary hydroxyproline excretion (Taylor et al. 1990; Ching et al. 1989; Maenpaa et al. 1988). Because blood Ca and P are maintained by release from bone stores, as well as by GI absorption and urinary excretion, these values may be maintained through long periods of imbalance. Thus, low blood levels may indicate deficiency, but normal values must be interpreted with caution. Because approximately one-half of blood Ca circulates bound to plasma proteins like albumin, hypoproteinemia can result in significant decreases in total serum Ca values, which must then be evaluated by correcting for hypoalbuminemia and/or by directly measuring ionized Ca levels. The former is used routinely in dogs but has not proved useful in cats (Meuten et al. 1982; Flanders et al. 1989). In addition, because blood pH influences the Ca-protein binding relationship, alterations in acid-base status may have profound, sometimes unpredictable effects on measured Ca levels (Kohn and Brooks 1990; Ching et al. 1989; Chew et al. 1989). Reference values for each species should be consulted in the interpretation of each parameter of Ca and P metabolism.

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. There are significant individual differences in the utilization of Ca and P from different dietary sources, in tolerance to discrepancies from the ideal Ca:P ratio, and in the utilization of Ca and P for nonmaintenance purposes, which in turn affects the requirement for both minerals. Requirements for Ca and P are greatest during pregnancy, lactation, and rapid growth. The potential for deficiency or imbalance during these phases of life is increased in herbivores fed large quantities of concentrates that are poor sources of Ca but very high in P. Growing horses fed such diets and not supplemented with Ca may develop the disorder known as "big head" or "miller's disease," wherein not only is Ca intake low, but excess dietary P depresses Ca availability, resulting in nutritional secondary hyperparathyroidism (Cunha 1991a). Young pigs and calves are likewise sensitive to wide Ca:P ratios (Mahan 1982; Miller et al. 1987). Conversely, older swine, mature horses, and lactating cows appear to be more tolerant to discrepant dietary Ca:P ratios, as long as minimum dietary requirements are met and vitamin D supply is adequate, although high dietary Ca or P fed during the dry period may predispose the latter to parturient paresis (Minson 1990a,b; Barton et al. 1987; Reinhart and Mahan 1986; Belyea et al. 1976).

Other intrinsic factors may affect Ca and P metabolism, including GI diseases, in which absorption is depressed. In chronic renal disease, excessive P is retained owing to decreased rates of glomerular filtration, insufficient 25-OH vitamin D is hydroxylated to calcitriol by the diseased kidneys, and GI and renal handling of Ca is impaired, resulting in renal secondary hyperparathyroidism. Although studies in partially nephrectomized dogs have not conclusively demonstrated a specific renoprotective effect of lower dietary P intake, survival was definitely enhanced, and the effects of restricted P intake were greater than those of restricted dietary protein (Finco et al. 1992).

EXTRINSIC FACTORS. In addition to the adverse effects of dietary P as phytic acid on Ca availability from feeds, oxalic acid may also chelate Ca and make it unavailable for GI absorption (Emanuele and Staples 1990; Ward et al. 1979). In horses, wheat bran phytate phosphorus availability is only about 30%, as opposed to 58% availability from inorganic mineral supplements (Cunha 1991a). Because ruminal microflora produce phytases which are capable of releasing P from phytic acid, natural feed sources of P, including those of phytic acid, are generally better utilized by ruminants than horses, whose large-intestinal flora produce only some phytases, or than simple-stomached animals who cannot utilize such chelated P at all (Morse et al. 1992a). Both a microbial-derived phytase and a recombinant phytase are now commercially available. When these products are fed to growing-finishing pigs, 15-30% of the unavailable P in a corn-soybean meal diet is made available (Cromwell et al. 1995a,b). In other studies, an equation was derived to predict the amount of dietary P released per unit of supplemented phytase (Yi et al. 1996). Phytase supplementation has also been shown to increase bone mineral content and density in a dose-related fashion in pigs fed a pearl millet-soybean meal-based diet (Murry et al. 1997). Some minerals, including magnesium, zinc, and iron, may depress Ca uptake, and high dietary aluminum markedly inhibits dietary P uptake by calves, resulting in reduced feed intake and weight gain and abnormal bone formation (Crowe et al. 1990). On the other hand, certain dietary constituents, like lactose, have been shown to enhance Ca uptake, even when lactose-induced maldigestion adversely affects protein or fat assimilation (Schuette et al. 1991). For cats, the mineral form (acid vs. alkaline salt) of dietary P affects its digestibility and subsequent excretory routes (Fettman et al. 1992), whereas for lactating cows, dietary P concentration has affected the amount and route (urine vs. feces vs. milk) of excretion (Morse et al. 1992b).

Preparations and Therapy. Ca and P are available in combination mineral products, including mono and dibasic calcium phosphate, as well as individually in Ca salts like calcium chloride, calcium carbonate, or calcium hydroxide and in P salts like magnesium, sodium, or potassium phosphates, defluorinated rock phosphates, and as phosphoric acid. Injectable and oral preparations may be obtained singly or as part of a multimineral preparation. Simple, aqueous solutions are indicated for injection, but because of acid-base interactions, large quantities should be used with caution. Likewise, Ca and bicarbonate salts cannot be combined in aqueous solution, where they will precipitate as calcium carbonate. Single large doses of calcium gluconate or calcium borogluconate may be given as intravenous, intramuscular, or subcutaneous injections in the prophylaxis or therapeusis of specific conditions or diseases which increase Ca requirements. A 20-33% calcium borogluconate solution is recommended for the treatment of parturient paresis in cattle

the glomerular filtrate. The osmotic gradient established by this process governs water reabsorption and the subsequent absorption of solutes like Ca and P along their concentration gradients. In the thick ascending limb of the loop of Henle, active transport of Cl creates an electrogenic gradient necessary for coupled absorption of Na and other cations. In the distal nephron, active Na absorption is coupled to proton or K secretion by mineralocorticoid-regulated processes that are central to normal fluid, electrolyte, and acid-base homeostasis. A deficiency of Cl in the glomerular filtrate leads to preferential absorption of bicarbonate by the proximal tubules along the Na-generated electrical gradient, impairs normal ion transport by the loop of Henle, and increases the delivery of Na to the distal nephron (Fettman et al. 1984a,b). This activates the renin-angiotensin-aldosterone axis and can lead to excessive urinary K excretion or paradoxic urinary acidification in the face of metabolic alkalosis. Nephrogenic diabetes insipidus may also result, owing to depletion of the NaCl-dependent renal medullary concentration gradient necessary for water reclamation from the collecting tubules. Thus, either dietary Cl depletion, third-space retention, or pathologic losses in the sweat or excreta may lead to tertiary disorders of renal function and a vicious cycle of propagated fluid and electrolyte abnormalities.

CELL MEMBRANE ELECTRICAL POTENTIALS. The cell membranes of all cells have an ATP-dependent Na,K pump which pumps three Na ions to the exterior for every two K ions pumped to the interior of the cell. The handling of Na and K by this pump not only helps to maintain osmotic equilibrium across the cell membrane but also plays a central role in the propagation of electrical impulses across the membranes of "excitable" cells, including those of the nerves, heart, skeletal muscle, and numerous endocrine tissues. Because the resting cell membrane is many times more permeable to K than to Na, the resting electrical potential described by the Nernst equation (approximately –90 mV) is predominantly attributable to K. When an action potential is elicited, the membrane becomes much more permeable to Na, Na rapidly enters the cell, and the membrane potential rises to that described by the Nernst equation for Na (approximately +45 mV). This depolarization is responsible for transmission of nerve impulses, elicitation of muscle contraction, and stimulation of endocrine cell secretion. Repolarization is initiated via an increase in membrane permeability to K and its extracellular diffusion and is maintained by the subsequent return to normal membrane permeability for Na and K and reactivation of the Na,K-ATPase pump. Changes in Na balance are evidenced clinically by alterations in neuromuscular, cardiovascular, and endocrine functions similar to those described for K (see below).

LACTATION. As is the case for most nutrients, dietary requirements for Na and Cl increase significantly during lactation. Even during times of significant dietary deficiency, lactating cows seem unable to decrease milk Na concentrations appreciably (Smith and Aines 1959), although Cl levels may decrease by up to about 50% (Fettman et al. 1984a,b). Burkhalter et al. (1979) estimated the maintenance requirement for Cl to be quite low (approximately 0.04% DM). Coppock (1986) has estimated that a 600 kg cow producing 30 kg milk/day would secrete 33 g/day of Cl in the milk; for a production level of 40 kg/day, this would increase to 44 g/day lost in the milk. This would require an increased intake to a level of approximately 0.20-0.25% of the diet dry matter. The corresponding dietary requirement for Na would be approximately 0.15-0.20% DM (Minson 1990c). Dietary deficiencies of either Na or Cl have been reported to result in substantial decreases in feed intake, body weight, and milk production (Aines and Smith 1957; Fettman et al. 1984b,c).

SALT AND HYPERTENSION. Most studies in human subjects have definitively demonstrated a significant association between dietary salt consumption and hypertension. The "Intersalt" study of over 10,000 individuals demonstrated that a 24-hour urinary Na excretion higher by 100 mmol was associated with systolic blood pressure higher by 3-6 mm Hg (Elliott et al. 1996). A meta-analysis of 56 trials that had randomized allocation to control and dietary sodium intervention groups demonstrated a mean reduction of –3.7 mm Hg in systolic pressure and –0.9 mm Hg in diastolic pressure for a 100 mmol/day reduction in daily Na excretion in hypertensive patients (Midgley et al. 1996). In contrast, decreases in blood pressure in response to dietary sodium restriction were negligible in individuals who were normotensive (Midgley et al. 1996).

Studies of the prevalence of hypertension in dogs are few, and the associated risk factors, including dietary salt, have not been well studied. Approximately 10% of 102 apparently healthy dogs observed in one study were found to be hypertensive: systolic pressure > 202 mm Hg, and diastolic pressure > 116 mm Hg (Remillard et al. 1991). In a study of over 1900 pet dogs, hypertension was not defined, but increased systemic blood pressure was associated with specific breeds, advancing age, diabetes, obesity, hyperadrenocorticism, and hepatic disease (Bodey and Michell 1996). A modest increase in mean blood pressure was associated with chronic renal disease only in those dogs with substantial reductions in glomerular filtration rate. Although dietary sodium intake was not assessed, it appeared that consumption of home-made diets was associated with lower systolic pressure than was eating commercial food.

In another report, spontaneous systemic hypertension was identified in five dogs but was diagnosed as essential hypertension (no apparent causative disorder) in only one subject (Littman et al. 1988). None responded to dietary Na restriction alone. In healthy dogs, increasing dietary Na intake from 5 to 245

during lactation. The potential for deficiency or imbalance during these phases of life is increased in herbivores fed large quantities of concentrates during these phases that are poor sources of Na and Cl. Other intrinsic factors may affect Na and Cl metabolism, including GI diseases, in which absorption is depressed, and in secretory diarrhea, where losses are increased. In acute renal disease, excessive Na and Cl may be lost owing to tubular damage and mineralocorticoid nonresponsiveness. In hypoadrenocorticism (Addison's disease), a deficiency in aldosterone secretion results in excessive urinary Na loss, K retention, metabolic acidosis, nephrogenic diabetes insipidus, and dehydration (Tyler et al. 1987).

EXTRINSIC FACTORS. The Na and Cl content of drinking water may significantly affect the necessity for dietary supplementation (Coppock et al. 1988). The temperature and humidity of the environment have important effects. In horses, heat and humidity affect Na and Cl excretion in the sweat. In all animals potential increases in water consumption may increase urinary losses. Lactating cows maintained in a hot, humid environment respond adversely to acidogenic Cl-containing salts like calcium chloride and appear to benefit from alkalinizing Na-containing salts like sodium bicarbonate (Coppock et al. 1982a,b; West et al. 1991; Shalit et al. 1991).

Preparations and Therapy. Na and Cl are available in a variety of mineral products, including common salt (NaCl), sodium phosphates, sodium bicarbonate, calcium chloride, and magnesium chloride. Injectable and oral preparations may be obtained singly or as part of a multimineral preparation. Simple, aqueous solutions are indicated for injection, and isotonic saline (0.9% NaCl) serves as the base for most extracellular fluid replacement solutions used in clinical practice. Single large doses of NaCl may be given as intravenous, intramuscular, or subcutaneous injections in the treatment of depletion disorders. Single large doses of sodium bicarbonate may be administered parenterally in the treatment of metabolic acidosis, but rapid administration of such solutions should be avoided, because paradoxic cerebrospinal fluid acidosis, impaired hemoglobin-oxygen dissociation, cranial hemorrhage, and other unwanted effects may result. Adverse effects on central nervous system function have been observed in hyponatremic human patients treated with Na-containing solutions either at too high a dose or at too great a rate of replenishment (Berl 1990). Frequent monitoring of blood and urine Na concentrations, coupled with a reasonable rate of replenishment, can prevent these potential problems (Berl 1990).

Toxicity. Animals appear to tolerate fairly high dietary levels of Na and Cl, because homeostatic mechanisms tend to protect them against excessive absorption. However, the addition of excessive NaCl to a diet can produce adverse effects, including polydipsia, polyuria, anorexia, weight loss, edema, nervousness, paresis, paralysis, and death (NRC 1980). In cattle, levels of salt below approximately 5% of the diet dry matter have little effect on general health, feed intake, weight gain, or milk production (NRC 1980). Fattening steers have tolerated as much as 9.33% DM without effect, but swine experience neuromuscular signs characteristic of salt poisoning with diets containing 6-8% DM as NaCl, and lactating ewes exhibit increased weight loss and decreased lamb survivability when fed 13.1% DM (NRC 1980). Poultry may tolerate NaCl up to 2% DM, and horses and rabbits up to 3% DM (NRC 1980). The major factor affecting NaCl toxicity is the availability of nonsaline drinking water during the consumption of excess salt. Although oral administration of water is effective in alleviating signs of acute toxicity, its rate of administration must be carefully regulated to avoid unwanted effects associated with reestablishment of osmotic equilibria, particularly across the blood-brain interface.

POTASSIUM

Source and Occurrence. Potassium (K) is widely distributed in the soil and found in high concentrations in most plant species (NRC 1982). Because the K content of feeds usually parallels that of protein, the substitution of purified protein or nonprotein nitrogen sources for natural protein sources may increase the potential for inadequate K intake in high-concentrate diets for producing, growing, or lactating animals (Ward 1978). Commercial sources of K include potassium chloride, carbonate, bicarbonate, sulfate, and phosphate salts.

Chemical Forms and Distribution. K is the principal cation of the intracellular fluid compartment and, after Ca and P, the third most abundant mineral in the body. Some K is located in bone as phosphate and carbonate salts, but the majority is found as the free ion in extraosseous tissues, where it plays a central role in osmotic and acid-base homeostasis and in maintaining cell membrane electrical potentials, in concert with Na. Despite its high body levels and critical role in metabolism, body reserves are limited and some excretory losses are obligatory, so dietary deficiency may become evident in as little as 1-2 weeks.

Several methods are available for the determination of K in biological specimens. Blood, urine, and ashed preparations or acid extracts or tissues may be analyzed by atomic absorption or flame emission spectroscopy. Fluid samples may also be analyzed by ion-specific electrode potentiometry. Chromogenic dye-binding methods have also been implemented for K determination by colorimetric spectrophotometry (Wong et al. 1985).

Biological Characteristics. As was described for Na, the renin-angiotensin-aldosterone system plays an important role in maintaining K homeostasis.

33 randomized, controlled trials of K supplementation as the sole difference between intervention and control conditions, K was associated with a significant mean reduction in systolic and diastolic blood pressure of −3.11 mm Hg and −1.97 mm Hg, respectively (Whelton et al. 1997). In individual studies, systolic pressure was reduced by as much as −41.0 mm Hg (Obel 1989). These effects were achieved following daily supplementation with 60 mmol K/day or more in all but two of the trials and appeared to be enhanced when subjects concurrently consumed a diet high in Na.

Although not as well studied in veterinary patients, hypertension has been identified in cats with naturally occurring, chronic renal disease (Jensen et al. 1997). Although only 3 of 12 hypertensive subjects were hypokalemic, 10 of 12 were hyperaldosteronemic, which would contribute to impaired K balance. Given the association between kaliopenia and chronic renal disease in cats (Fettman 1989; Dow et al. 1990), it is possible that the occurrence of hypertension in feline chronic renal failure may be responsive to dietary K supplementation.

SKELETAL MUSCLE FUNCTION. The K gradient across muscle cell membranes influences cell volume, protein synthesis, enzyme activity, electrical conductivity, and changes in blood flow during exercise (Fettman 1989). K depletion can result in impaired myocytic carbohydrate metabolism, muscular paresis, followed by paralysis, myocytic swelling and rhabdomyolysis, and exercise-associated ischemic myonecrosis (Fettman 1989). Animals affected with so-called kaliopenic myopathy have generalized appendicular muscle weakness, an abnormal gait, and are reluctant to move. Cats so affected demonstrate a characteristic, persistent ventroflexion of the neck (Fettman 1989).

ACID-BASE METABOLISM. K ions and protons in the body are integrally related, owing to their ability to undergo exchange across interfaces between the intra- and extracellular fluid compartments (Fettman 1989). Acute alkalosis is often associated with hypokalemia, owing to exchange of intracellular protons for extracellular K ions and the relative replacement of K ion secretion by that of protons during the process of Na reabsorption by the distal renal tubules. The resulting redistribution allows intracellular acid reserves to buffer the extracellular proton deficiency, while altered renal excretion limits unwanted acid loss in the urine. Conversely, acidosis is often associated with hyperkalemia, in which intracellular uptake of extracellular protons for buffering is electrically counterbalanced by release of intracellular K ions. Urinary excretion of K ions is likewise decreased to facilitate coupling of distal renal tubular Na absorption to proton secretion. Paradoxically, chronic metabolic acidosis may result in K depletion, predominantly through stimulation of adrenal cortical aldosterone release by protons and subsequent stimulation of K excretion by the GI tract and kidneys. Chronic K depletion can likewise result in metabolic acidosis through an acquired syndrome of hypoadrenocorticism secondary to the chronic understimulation of mineralocorticoid release by low circulating K levels (Fettman 1989).

EFFECTS OF GROWTH AND LACTATION AND SIGNS OF DEFICIENCY. Because of the high K content of muscle tissue and the large amounts present in milk, growth and lactation are associated with the highest dietary requirements for K. Maintenance requirements for K range from as little as 0.20% of the diet dry matter for rodents and chickens to 0.40% DM in horses; requirements for growth or lactation may double or triple these values (Ward 1978). Growing pigs and calves require as much as approximately 0.60% DM (Golz and Crenshaw 1990; Weil et al. 1988). However, Leibholz et al. (1966) showed that increasing the dietary protein content for growing pigs increased the K requirement from 0.60% to approximately 1.20% DM. Likewise, although maintenance requirements for cats are approximately 0.35% DM, growth and increasing dietary protein intake can increase this to as much as 0.50% with 68% protein in the diet of growing kittens (Hills et al. 1982). Feeding trials have indicated that as much as 0.80% DM may be required to maximize feed efficiency and rate of gain in steers; 100% DM is required for horses (Devlin et al. 1969; Stowe 1971). A dietary K content of 0.70% DM appears to be adequate for cows in mid- to late lactation, and high-producing cows in early lactation may require 0.80-1.00% DM (Dennis and Hemken 1978).

The signs of chronic K deficiency include anorexia, depressed growth, dull and coarse hair or wool, pica, hypogalactia, lethargy, muscular weakness, stiffness or paralysis, and neurologic dysfunction. Because of changes in pancreatic β-cell electrical potential, insulin secretory responsiveness to glucose challenge may be impaired, resulting in carbohydrate intolerance. In pigs and in chickens, dietary basic amino acid requirements may increase during K deficiency, because their intracellular concentrations increase to maintain cation balance (Ward 1978).

Assessment of Status. Criteria used to evaluate K status have included biological response to supplementation, analysis of plasma and erythrocytic K concentrations, and measurement of urinary and/or fecal excretion of K (Dow et al. 1987a,b, 1990; Pradham and Hemken 1968). Because K is located principally within the intracellular fluid compartment, measurement of extracellular fluid K levels, as in blood plasma, can often be misleading as to the actual status of K in the whole body. One alternative is to measure K content in erythrocytes in those species where these levels parallel those of other tissues, which is not the case in dogs or cats (Harvey 1989). Urinary K excretion may also be indexed to urinary creatinine and plasma K and creatinine concentrations as the fractional excretion value (FE_K) for a gross indication of urinary loss. This value may be affected by dietary intake, by renal tubular dysfunction, and by creatinine clearance rate and should be interpreted with caution. Reference values for each species should be consulted in the interpretation of each parameter of K metabolism.

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. As discussed above, requirements for K are greatest during pregnancy, growth, and lactation. The potential for imbalance during these phases of life is increased in animals fed large quantities of concentrates during these phases that are poor sources of K. K availability from most feeds is relatively high, and its absorption may increase with increasing dietary content, although actual retention may be unaffected (Combs and Miller 1985a,b; Grings and Males 1987). GI disease may both depress absorption of K and increase its secretion, thereby rapidly depleting the animal of K. In acute renal disease, excessive K may be lost in the urine owing to tubular damage and impaired reabsorption from the glomerular filtrate. In disorders causing relative hyperadrenocorticism—including third-space syndromes, dietary NaCl depletion, and chronic metabolic acidosis—increased aldosterone secretion may result in excessive K excretion (Fettman 1989). Cats with underlying chronic renal dysfunction fed an acidified diet marginally sufficient in K have developed a clinically significant polymyopathy/nephropathy syndrome (Dow et al. 1987a,b, 1988, 1989).

EXTRINSIC FACTORS. Other dietary minerals have little effect on K availability from feeds (Erdman et al. 1980). Transport stress may increase dietary K requirements, and in feeder calves, blood parameters indicative of stress and weight gains following shipping were improved by increasing dietary K by 20% more than that required by nonstressed animals (Hutcheson et al. 1984). Milk yields in lactating cows exposed to heat stress have been increased significantly by increasing dietary K intake. In one study, a change from 0.66% to 1.08% DM increased milk yield by 7.4% (Mallonee et al. 1985), while in another a change from 1.3% to 1.8% DM increased milk production by 4.5% (Schneider et al. 1986). Dietary acidification in cats has reduced GI K absorption, increased urinary K excretion, and resulted in negative K balance (Ching et al. 1989; Dow et al. 1990). Primary K deficiency in cats appears to result in secondary taurine depletion, and earlier work in rats and dogs indicates that supplemental dietary taurine may ameliorate the cardiotoxic effects of K deficiency (Dow et al. 1992).

Preparations and Therapy. K is available in a variety of mineral products, including potassium chloride (lite salt), potassium carbonate, potassium bicarbonate, potassium citrate, potassium gluconate, and potassium monohydrogen or dihydrogen phosphate. Injectable and oral preparations may be obtained singly or as part of a multimineral preparation. Simple, aqueous solutions are indicated for injection, and lactated Ringer's solution (4 mmol/L K) serves as a base for many extracellular replacement solutions used in clinical practice. Single large doses of K salts in solution should be administered parenterally with a great deal of caution, because the rapid increase in blood K concentrations can be cardiotoxic. Single large oral doses of K salts in solution are much safer, as their absorption is regulated by the animal and takes place over a longer period of time. K concentration in intravenous solutions should be adjusted according to the estimated deficit of K in the patient, but because these calculations rely on blood plasma levels, they should be used conservatively. Generally speaking, K concentrations in intravenous solutions should not exceed 80 mmol/L or be administered in excess of 0.5 mmol/kg body weight/hour. Exceptions to this include cows with severe third-space syndromes following GI obstruction and cats with severe kaliopenic polymyopathy/nephropathy syndrome. For the latter, up to 10 mmol may be required to restore K levels, although most cats respond with oral supplementation of 2-4 mmol/day (Fettman 1989). Frequent monitoring of blood and urine K concentrations, coupled with reasonable rates of replenishment, should prevent unwanted effects.

Toxicity. K toxicosis is unlikely under most conditions, resulting only when supplemented dietary or parenteral levels of K-containing salts are excessive (NRC 1980). Lower levels of increased dietary K (2-4% DM) decrease diet palatability, feed intake, and rate of gain in growing animals (NRC 1980; Neathery et al. 1980). Higher levels of K (greater than 0.58 g/kg body weight) administered orally to young calves produced excess salivation, muscular tremors of the limbs, excitability, metabolic acidosis, and hemoconcentration (Neathery et al. 1979). Intravenous administration of large amounts of K results, in all species, in cardiotoxicity characterized by such electrocardiographic changes as increased T-wave amplitude, decreased P-wave amplitude, prolonged QT interval, and ventricular fibrillation or asystole (Bolton 1975). Chronic consumption of high dietary K can depress GI magnesium absorption significantly. Feeding 0.68 g K per 100 g body weight resulted in clinical signs of magnesium deficiency in rats, while in sheep 2-3% DM is tolerated before magnesium depletion results (NRC 1980; Grings and Males 1987; Greene et al. 1983). Contrary to previous reports (NRC 1980), the addition of Na to high-K diets in sheep did not improve magnesium homeostasis (Poe et al. 1985). Maximum tolerable dietary levels are assumed to be approximately 3% DM for most species (NRC 1980).

MAGNESIUM

Source and Occurrence. The magnesium (Mg) concentration of plants is affected by soil type, climate, light intensity, temperature, and stage of growth, as

neuromuscular function have been observed in patients treated too rapidly with Mg-containing solutions, so caution should be exercised during rapid intravenous Mg replenishment.

Toxicity. Mg toxicosis has not been reported following consumption of natural feedstuffs and has been associated with excessive supplementation only from commercial sources. Chronic ingestion of low toxic levels of Mg has been associated with diarrhea, depressed nutrient utilization, and lower rates of growth in chicks, guinea pigs, calves, and sheep (NRC 1980; Chester-Jones et al. 1990a). Higher levels can cause anorexia, weight loss, severe diarrhea, impaired bone mineralization, lethargy, and progressive degeneration of the stratified squamous epithelium of the rumen papillae (NRC 1980; Chester-Jones et al. 1990b). Acute overdosage with Mg results in impaired motor function in horses, cattle, and dogs. In sheep and horses, respiratory paralysis, cyanosis, and cardiac arrest have also been observed (NRC 1980). Maximum tolerable dietary levels for Mg are approximately 0.50% in cattle and sheep and 0.30% in poultry and swine (NRC 1980). Intravenous administration of 0.028 g/kg body weight in horses, dogs, cattle, and sheep has produced clinical signs, recumbency, and death (NRC 1980). Oral administration of 1.5-2 times the recommended laxative dose of magnesium sulfate to horses with suspected intestinal impactions resulted in Mg toxicosis and may have been predisposed by renal insufficiency, hypocalcemia, and/or damaged intestinal integrity caused by vascular compromise or concurrent administration of dioctyl sodium sulfosuccinate (Henninger and Horst 1997). Minerals and other factors which depress GI Mg absorption will increase the tolerable limit of dietary Mg, and acute Mg intoxication can be alleviated by treatment with Ca salts such as calcium borogluconate.

Until recently a strong association was presumed between dietary Mg intake and the occurrence of feline lower urinary tract diseases (FLUTD), heretofore known under the catchall term of "feline urologic syndrome," or FUS. Experimental studies indicated a direct dose relationship between dietary Mg level and formation of magnesium ammonium phosphate (struvite) crystals, uroliths, and lower urinary tract obstruction (Lewis et al. 1978). Reassessment of this work revealed that the salt form of Mg used to supplement the experimental diets was magnesium oxide, a potent dietary alkalinizer. Subsequent studies have shown that dietary effects on urinary pH are substantially more important than the dietary intake and ensuing urinary excretion of Mg in predisposing cats to lower urinary tract disorders (Buffington et al. 1985). While the predominant form of crystal observed in naturally occurring cases of FLUTD is struvite, not all cases of FLUTD are associated with crystalluria or with any abnormalities of routine urinalysis (Buffington et al. 1997). Although dietary Mg and effects on acid-base metabolism are significant risk factors for FLUTD, other risk factors have included age, gender, season, weather, activity levels, and consumption of dry foods, and important findings have included mucus plug formation, urethral spasm, and viral or bacterial infections, none of which may be responsive to dietary manipulation, but all of which may interact to increase the relative risk for development of FLUTD (Buffington et al. 1997; Jones et al. 1997).

SULFUR

Source and Occurrence. Sulfur (S) in plants varies widely. Because sulfur-containing amino acids (SAA) are important, although minimal, components of all proteins, organic S levels tend to vary with nitrogen or crude protein content (NRC 1982). Thus, legumes contain more S than grasses, the leaf fraction contains more S than the stem, and total concentration decreases with plant maturity (Minson 1990e). SAA are produced by plants from inorganic sources of S absorbed from the soil. Plant S is found as SAA, elemental S, and sulfate salts of various cations. Commercial sources of S include those used for soil fertilization, food and pharmaceutical preservatives, dietary mineral supplements, fungicides, paper bleaches, fumigants, and sulfuric acids for industrial manufacture (NRC 1980).

Chemical Forms, Distribution, and Biological Characteristics. S is required for the synthesis of many S-containing compounds found in the body, including SAA (methionine, cysteine, cystine, taurine), some B vitamins (biotin, thiamine), structural compounds (chondroitin sulfate, proteins, glycosaminoglycans), and antioxidants (glutathione, cystathionine, cysteinylglycine). Disulfide bonds in some proteins play an important role in maintaining tertiary structure necessary for structural protein integrity or enzymatic activity. Conversely, oxidation of key sulfhydryl groups in other proteins produces mixed disulfide bridges, denaturation, and loss of function, as is seen in Heinz body formation from hemoglobin and membrane destabilization following oxidative free radical damage.

By virtue of microbial incorporation of inorganic S into amino acids, ruminants are capable of using a wide variety of dietary sources of S. Elemental sulfur, sodium sulfate, and DL-methionine were shown to result in similar increases in S retention in heifers fed a tall-fescue-based diet, although predominant routes of S excretion differed among treatments (Front et al. 1990). In sheep, dietary supplementation with sodium sulfate to approximately 2 g S/day resulted in approximately 50% absorbed and recycled through plasma sulfate (Kandylis and Bray 1987). In fact, it has been suggested that during dietary S deprivation, plasma sulfate recycled to the rumen via the saliva can significantly affect S balance in ruminants (Kandylis 1983). Monogastrics, on the other hand, must obtain all of their organic S in the form of exogenous SAA. However, all

CHROMIUM

Source and Occurrence. Chromium (Cr) occurs in three valency states as Cr(II), Cr(III), and Cr(VI). The trivalent and hexavalent forms are most stable, while Cr(II) is rapidly oxidized to Cr(III). Meats, grains, and brewer's yeast contain chromium, principally as Cr(III) (NRC 1982). Cr bioavailability appears to be greater from natural sources or supplemental $CrCl_3$ than from other salt forms such as chromium acetate but is nevertheless poorly absorbed from the gastrointestinal(GI) tract regardless of nutritional status or dosage. Recent work indicates that GI Cr absorption may be enhanced significantly by pretreatment with nonsteroidal anti-inflammatory drugs like indomethacin or aspirin (Kamath et al. 1997). This effect may be mediated by an increase in mucosal permeability, by inhibition of GI prostaglandin synthesis, or by the presence of a more acidic luminal environment and is reversed by replacement with an exogenous prostaglandin E_2 analog. Concurrent treatment of pigs with porcine pituitary somatotropin does not appear to affect assimilation of, or physiological response to, supplemental dietary Cr picolinate (Anderson et al. 1997).

Biological Characteristics and Signs of Deficiency. In animal tissues, Cr(III) is bound to plasma proteins and distributed predominantly in liver, kidney, and spleen. Cr(III) is the biologically active form, incorporated into a low molecular weight ligand consisting of nicotinic acid, glutamic acid, glycine, and cysteine (NRC 1980; Offenbacher and Pi-Sunyer 1988). This compound is known as "glucose tolerance factor" (GTF) and is required, together with insulin, for normal glucose utilization by peripheral tissues (Sargent et al. 1979). The GTF enhances the reactions between insulin and its cell membrane receptors via sulfhydryl groups, thereby facilitating insulin's actions. Rats consuming a Cr-free diet develop a syndrome indistinguishable from diabetes mellitus (Schroeder 1966; Wooliscroft and Barbosa 1977). Because of this biological function for Cr and declining tissue Cr levels with age in humans, it has been proposed that some forms of adult onset or non-insulin-dependent diabetes mellitus may be associated with nutritional Cr deficiency. In growing Holstein calves fed corn-cottonseed hull diets containing 370 mg Cr/kg dry matter (DM), glucose clearance during an intravenous glucose tolerance test (IVGTT) was improved by about 27%, and serum cholesterol decreased by about 10% (Bunting et al. 1994). Other studies have found that dietary Cr supplementation in humans may increase serum HDL (high-density lipoprotein) cholesterol concentrations, which may in turn reduce the risk for coronary heart disease (Roeback et al. 1991). Likewise, dietary supplementation of growing-finishing pigs with 200 mg/kg DM Cr as Cr picolinate or Cr tripicolinate has decreased serum cholesterol significantly (Page et al. 1993), as well as improved glucose disappearance by about 30% during an IVGTT (Amoikon et al. 1995). Fat thickness over the ribs was decreased, and nitrogen absorption, dry-matter digestibility, daily gain, longissimus muscle area, and percentage of muscling were increased in pigs (Page et al. 1993; Kornegay et al. 1997), while fat thickness over the ribs and serum cholesterol were each decreased by almost 20% in growing lambs (Kitchalong et al. 1995).

Studies have indicated that steer calves fed a corn silage diet may be Cr deficient, based on an increase in average daily gain and feed efficiency following dietary supplementation with 0.4 ppm Cr as a high-Cr yeast product (Chang and Mowat 1992). Following supplementation with 0.2 ppm Cr as high-Cr yeast, transport-stressed feeder calves experienced not only an increase in dry-matter intake, feed efficiency, and gain but also significant decreases in serum cortisol and increases in serum immunoglobulin concentrations and hemagglutinating antibody titers to human red blood cells (Moonsie-Shageer and Mowat 1993; Chang and

Mowat 1992). Dietary Cr supplementation with 0.5 ppm improved the peak antibody response to an infectious bovine rhinotracheitis (IBR) vaccine challenge in 8-month-old calves (Burton et al. 1994) and increased both the humoral response to ovalbumin and mitogen-stimulated blastogenic response of peripheral blood mononuclear cells in early-lactation dairy cows (Burton et al. 1993). When neonatal calves were fed a milk replacer diet containing 0.4 ppm supplemental Cr from $CrCl_3$ or a Cr-nicotinic acid complex, both in vitro and in vivo indices of cell-mediated immune function were enhanced, as was the response to an intranasal challenge with IBR (Kegley et al. 1996). However, in another study, supplemental dietary Cr (0.14 ppm) from yeast had no effect on antibody titers following vaccination in stressed feeder calves against IBR, parainfluenza-3 (PI_3), bovine respiratory syncitial virus (BRSV), or bovine viral diarrhea (BVD), and Cr from an amino acid-chelated source improved the response to BVD vaccination only (Chang et al. 1996). Likewise, 6- to 8-week-old calves supplemented with a high-Cr yeast product (3 mg Cr/day) exhibited no changes in the secretion of adrenocorticotropic hormone (ACTH), cortisol, and plasma tumor necrosis factor-α or in lymphocyte proliferative response to mitogen stimulation following challenge with bovine herpesvirus-1 (BHV-1) (Arthington et al. 1997). Although supplementation of weanling pigs with 0.2 ppm Cr as $CrCl_3$, Cr-picolinate, or Cr-nicotinic acid complex improved rate of gain, feed intake, and in vitro cellular immune response, it had no effect on in vivo immune challenge with lipopolysaccharide (van Heugten and Spears 1997). In another study, 0.3 ppm supplemental dietary Cr as Cr-picolinate did significantly decrease the plasma tumor necrosis factor-α response to lipopolysaccharide challenge in growing pigs (Myers et al. 1997).

Dietary Requirements, Indications, Use, and Toxicity. Few specific indications for Cr supplementation have been identified for domestic animals. It has been suggested that Cr, like iron and zinc, may be sequestered during infections, thereby increasing its requirements, but this has not been thoroughly studied. Newer studies cited above on growing calves and pigs and lactating cows indicate that typical feeds may not be adequate in Cr and that supplemental Cr, up to 0.4-0.5 ppm, may have beneficial effects on growth and immune function.

Some Cr salts (trioxide, chromates, and dichromates) are potent cytotoxins by virtue of their protein-precipitating and oxidizing properties. Signs of acute oral Cr toxicity have been infrequently observed. In young calves, gastric congestion and inflammation and ruminal and abomasal ulceration were seen following a single dose of 30-40 mg Cr(VI)/kg body weight (NRC 1980). Signs of chronic oral Cr toxicosis have included skin contact dermatitis, respiratory passage irritation, ulceration of the nasal septum, and lung cancer. Maximal tolerable dietary levels for Cr are approximately 3000 ppm in the oxide form and 1000 ppm as the chloride salt (NRC 1980).

COBALT

Source and Occurrence. Cobalt (Co) content of plants varies with soil content and pH, as well as with rate of plant growth. Australia, New Zealand, Great Britain, and portions of Africa have Co-deficient areas. In North America, low-Co soils are found around the Great Lakes and in New England and Florida. Uptake of Co is low by forages grown in alkaline soils or following the use of lime fertilizers (NRC 1982). Co content is also lower during periods of rapid plant growth.

Biological Characteristics and Signs of Deficiency. The principal function of Co is as a component of vitamin B_{12} (cyanocobalamin). Thus, nonruminants have not been shown to require elemental Co in their diets, since they receive vitamin B_{12} preformed. In ruminants, and possibly other herbivores, dietary Co is required to support enteric microbial synthesis of vitamin B_{12}. Supplemental sources of Co include cobalt oxide, cobalt chloride, and cobalt sulfate; however, much of an orally administered dose of elemental Co is not absorbed—in rats, 80% is excreted in the feces (NRC 1980).

As a vital component of biologically active vitamin B_{12}, Co is required for those metabolic functions described for cyanocobalamin. These include erythropoiesis (as a cofactor for purine and pyrimidine synthesis); histidine, methionine, and choline metabolism (as a cofactor for methyl group transfers); and propionic acid conversion to succinyl CoA (as a cofactor for methylmalonyl CoA isomerase). Marginal Co deficiency in ruminants may be associated with impaired reproductive function, reduced appetite, decreased growth rate, and reduced milk production. More obvious signs of chronic Co deficiency may include frank inappetence, progressive weight loss, emaciation, anemia, and death (NRC 1980).

Dietary Requirements, Indications, and Use. In areas of endemic deficiency, top dressing of soil with 100-150 g Co per acre is sufficient to prevent deficiency. Cobalt iron oxide pellets or cobalt oxide/ferruginous clay "bullets" may be administered intraruminally to provide for slow release. Problems associated with these pellets include regurgitation by the animal and coating with calcium phosphate, which reduces the bioavailability. Co salts may be included in trace mineral premixes and salt blocks or can be added to loose salt at a ratio of 15 g/100 kg for sheep and 50 g/100 kg for cattle. Evaluation of cobalt glucoheptonate to enhance in vitro fiber digestion in ruminal fluid obtained from steers fed a Co-sufficient diet indicates that increasing dietary Co above the minimum requirement recommended by the NRC (1989) has no additional effect (Hussein et al. 1994).

anomalies (thin cortices, broadened epiphyses, cartilage erosions, and osteoporosis).

IMMUNOLOGIC FUNCTION AND FREE RADICAL METABOLISM. Cu deficiency has been associated with impaired mitogen-stimulated T and B lymphocyte blastogenesis, reduced antibody production following challenge with certain antigens, and impaired cell-mediated immunity (Prohaska and Lukasewycz 1981; Koller et al. 1987; Failla et al. 1988; Bala et al. 1992). Cu deficiency has also been shown to impair respiratory burst activity (owing to loss of cytochrome c oxidase activity) and to suppress candidacidal activity (owing to loss of Cu, Zn-superoxide dismutase activity) in isolated rat peritoneal macrophages (Babu and Failla 1990a). Moreover, the respiratory burst and microbicidal activity of rodent and bovine neutrophils were likewise significantly impaired by Cu deficiency (Babu and Failla 1990b; Boyne and Arthur 1981 1986). Dietary Cu depletion of Holstein steers resulted in significant depressions in neutrophil superoxide dismutase activity and killing capacity for *Staphylococcus aureus* even when no other signs of Cu deficiency were apparent (Xin et al. 1991a). Copper deficiency in Holstein steers also impaired the immune responses generated against *Pasteurella hemolytica* and IBR virus challenge (Stabel et al. 1993). Abnormalities in Cu, Zn-superoxide dismutase activity in Cu-deficient laboratory rodents may have also resulted in increased free radical-mediated lipid peroxidation (Prohaska 1991; Lawrence and Jenkinson 1987; Balevska et al. 1981). In addition, simultaneous Cu deficiency-induced decreases in hepatic activities of Se-dependent glutathione peroxidase and non-Se-dependent glutathione transferase may have impaired alternative mechanisms for free radical quenching (Prohaska 1991; Allen et al. 1988). Thus, host defenses against both microbial and chemical insults may be impaired by Cu deficiency.

Signs of Deficiency. As indicated by its metabolic functions, Cu deficiency may result in dysfunction of several body systems. Clinical manifestations include a hypochromic, microcytic anemia similar to that seen with dietary iron deficiency, bone disorders, neonatal ataxia, hair or wool depigmentation, impaired keratinization (resulting in uncrimped, "steely" wool), infertility, cardiovascular disorders, diarrhea ("peat scours" in New Zealand due to dietary Mo excess), and immunosuppression (Lofstedt et al. 1988; Sanders 1983; Mills et al. 1976). In human patients maintained for longer than 1 year with enteral or parenteral feeding, Cu deficiency was associated with anemia, neutropenia, or pancytopenia, which were responsive to Cu supplementation (Tamura et al. 1994; Wasa et al. 1994). In the absence of other obvious signs of deficiency, a Cu-deficient, high-Mo diet fed to feedlot cattle has resulted in depressed feed intake, feed efficiency, and growth (Irwin et al. 1979). Other studies have shown that neonatal ataxia in calves may appear without other signs of Cu deficiency in the dams (Sanders and Koestner 1980). Likewise, lower plasma Cu levels in lactating cows have been associated with lower milk production, lower hematocrits, and impaired fertility without other, more obvious signs of Cu deficiency (Kappel et al. 1984). In another study, only combined supplementation with both Cu and Mg salts improved fertility in Holstein cows, while individual mineral supplementation alone had no effect (Ingraham et al. 1987).

In an epidemiologic study of osteochondrosis in Thoroughbred foals, 7 of 8 animals had subnormal serum Cu and ceruloplasmin concentrations, and pathologic lesions in the zones of endochondral ossification were similar to those observed in experimental Cu deficiency-induced lysyl oxidase dysfunction (Bridges et al. 1984). Three of those foals may have been exposed to excessive Zn, thereby suppressing dietary Cu availability. Foals fed 1000 ppm or more of dietary Zn developed a secondary Cu deficiency and cartilaginous disease characteristic of osteochondritis dissecans (Bridges and Moffitt 1990). Foals fed an experimental, low-Cu (1.7 ppm) liquid milk replacer diet also developed cartilaginous lesions, including focal fragmentation of articular cartilage, metaphyseal physis separation, and widespread chondrocytic hypoplasia and necrosis (Bridges and Harris 1988).

Assessment of Status. Plasma Cu levels may be determined by atomic absorption spectroscopy; lower-than-normal levels may indicate Cu deficiency. Conversely, increased plasma Cu levels may occur with inflammation (due to IL-1 effects) or with Cu toxicosis. Unfortunately, plasma Cu concentrations do not necessarily reflect storage levels in organs like liver or kidney. Thus, plasma Cu levels may be normal in the face of impending deficiency or toxicosis. Ashed preparations or acid extracts of biopsies of these storage tissues may also be analyzed by atomic absorption spectroscopy. Owing to wide variability among animals in a given herd, the minimal sample size for determination of blood Cu status in cattle has ranged from 1 to 22% of the herd (3-55 cattle sampled/herd) (Tanner et al. 1988). In horses, significant breed and age effects have been identified with respect to both plasma Cu and ceruloplasmin levels (Cymbaluk et al. 1986). The use of serum ceruloplasmin levels as an indicator of Cu status in cattle and sheep has been limited, as it appears to correlate better with plasma Cu concentrations than with corresponding liver Cu content (Blakeley and Hamilton 1985). Finally, as a result of Cu and cuproprotein consumption during the process of blood coagulation, Cu and ceruloplasmin levels in serum are lower than in plasma, and following storage of blood samples on ice for extended periods (Kincaid et al. 1986b).

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. Dietary Cu requirements are integrally related to the dietary intakes of competing elements, including Zn, Mo, and inorganic S. Under otherwise optimal dietary conditions, swine and poultry require approximately 4-5 ppm Cu in the diet, while ruminants require 8-10 ppm. Physiologic states of growth, pregnancy, and lactation increase the Cu requirement accordingly. GI disease, which may affect Cu absorption, and renal disease, which may affect Cu loss in the urine, are examples of disorders affecting the dietary Cu requirement.

EXTRINSIC FACTORS. Factors affecting Cu absorption include dietary levels, presence in the diet of minerals that may compete for transport (Fe, Zn, Ca, and Cd), and interfering substances that may bind Cu (phytate, fiber, chelating agents) (Fischer et al. 1981; Prince et al. 1984). The actual mechanisms responsible for the inhibitory effects of Mo and S on Cu absorption and metabolism have not been completely elucidated but may include GI precipitation of Cu as insoluble thiomolybdates, antagonism of Cu transport by enterocytes, and, if sufficient thiomolybdates are absorbed, chelation of Cu from plasma albumin and tissue metallothioneins, resulting in increased fecal and urinary Cu excretion (Kincaid and White 1988; Suttle 1991). Nomograms and equations describing the effects of dietary Mo and S on Cu absorption have been published to predict their effects on dietary Cu requirements (Minson 1990a). In addition, Cu availability may be affected by curing or storage of plant materials; Cu in fresh forage is generally less available than that in the same dried forage, owing to greater ruminal sulfide generation by fresh forages. Likewise, low-roughage, high-concentrate diets, which promote ruminal sulfide production, may interfere with Cu availability. Although interactions have been observed between dietary Cu source (CuO vs. $CuSO_4$) and acid-base metabolism, dietary cation-anion balance has not been shown to have any effect on dietary Cu availability (Xin et al. 1991b).

Preparations and Therapy. In deficient areas, Cu in the form of cupric sulfate can be added to salt at a rate of 0.5%. Soil fertilization with Cu has been used in Australia and New Zealand but may be ineffective in areas of the western United States where soil Mo levels are high. Oxidized copper wire, broken into small rods of 10 mm or less in length and referred to as copper oxide needles (CuO_n), may be administered to ruminants in gelatin capsules. Following their intraruminal deposition, they slowly pass to the abomasum for long-term release following the action by gastric acidity to solubilize the Cu (Cameron et al. 1989). A single oral dose of copper oxide needles at the start of the grazing season has been shown to provide adequate Cu supplementation for sheep and cattle for several months (Cameron et al. 1989; Suttle 1987). In sheep, a dose of 0.1 g/kg body weight (approximately 5.0 g/animal) appears to be adequate to maintain liver and serum Cu levels for at least 2 months (Suttle 1987). In cattle, as little as 5.0 g of copper oxide needles can maintain liver Cu stores for 240 days, and a dose-related increase in liver Cu is observed following administration of up to 20 g (Suttle 1987). Copper oxide wire also appears to have an anthelmintic action in sheep, with a 5.0 g bolus reducing parasite burdens by as much as 96% for *Haemonchus contortus* burdens and 56% for *Ostertagia cincta* (Bang et al. 1990). Another approach is the use of controlled-release copper oxide-impregnated glass boluses—17 g boluses for sheep and 75 g boluses for cattle, containing approximately 18% by weight of Cu (Allen et al. 1984). Sustained-release methods of Cu administration provide longer-term protection against Cu deficiency and a greater margin of safety against Cu toxicity, which is otherwise a concern with mineral salt supplementation.

Toxicity. Cu toxicosis may be either acute or chronic in chronology, but the signs of chronic Cu poisoning are usually evoked peracutely, thereby confusing its interpretation. Acute Cu toxicosis may occur following accidental overdosage or consumption of Cu-containing anthelmintics, foot baths, fungicides, or feed additives (NRC 1980). Clinical signs include nausea, vomiting, salivation, abdominal discomfort, convulsions, paralysis, collapse, and death (NRC 1980). Pathologic lesions include widespread organ congestion, extravascular fluid exudation, and hepatic and renal degeneration and necrosis. Chronic Cu toxicosis progresses through two phases. The first is the long-term accumulation phase, during which abnormally high levels of Cu are accumulated by the liver (Soli 1980). This results in a subclinical period of organ damage due to excessive Cu accumulation, which may be characterized by hepatocellular degeneration, elevations in serum levels of hepatic enzymes, and spongy degeneration of parts of the brain. The second phase may represent an acute culmination of this subclinical period or may be precipitated by some acute stress that results in lysosomal degeneration, Cu release, and a hemolytic crisis (Ishmael et al. 1971; Gopinath et al. 1974; Soli 1980). Three basic mechanisms have been identified for hepatic Cu accumulation: simple chronic Cu poisoning in response to excessive dietary intake; hepatogenous chronic Cu poisoning following injury by toxic plant alkaloids (such as from *Heliotropium europaeum* or *Senecia* spp.) and Cu accumulation by damaged hepatocytes; and phytogenous chronic Cu poisoning following consumption of plants grown under high-sulfate and/or excess-Mo conditions, which facilitate Cu accumulation to toxic levels (Bostwick 1982). Sheep are particularly sensitive to chronic Cu toxicosis, accumulating excessive hepatic levels following consumption of otherwise moderate levels of Cu in their feed. The hemolytic crisis may be caused by direct oxidative effects by Cu or lysosomally derived free radicals on hemoglobin, leading to Heinz body formation, and on erythrocyte membranes, leading to membrane instability (NRC 1980). In either case, red blood cell membrane rigidity increases their fragility and precipitates in hemolysis. Sheep appear to be the most sensitive species to chronic Cu toxicosis. Other species are affected only at much higher dietary intakes.

have an unthrifty appearance (Niyo et al. 1980; Weiss et al. 1983; Moore and Kohn 1991). Se deficiency has been associated with significant derangements of both humoral and cell-mediated immunity in weanling pigs, beef calves, and lambs (Kott et al. 1983; Reffet et al. 1988; Swecker et al. 1989; Lessard et al. 1991). Prepartum treatment of sows with Se or vitamin E has resulted in higher colostral IgM levels and improved immune transfer to their offspring (Hayek et al. 1989). Dairy cows treated at 3 and 1.5 weeks before calving with Se as sodium selenite (5 mg/100 kg body weight) and *d,l*-α-tocopheryl acetate (25 IU/100 kg of body weight) produced 22% more colostrum during the first 36 hours postpartum and 10% more milk during the first 12 weeks of lactation than nonsupplemented cows (Lacetera et al. 1996). While blood glutathione peroxidase activities at birth and 28 days of age were higher in their calves, there was no effect on plasma immunoglobulin concentration or body weight.

Dietary Requirements, Indications, and Use

INTRINSIC FACTORS. Requirements for Se are greatest during pregnancy, growth, and lactation. Other intrinsic factors which may affect the Se requirement include systemic diseases which increase oxidative stress due to inflammatory, neoplastic, or other toxic effects, thereby increasing the need for free radical quenching and xenobiotic biotransformation (Fettman 1991; Pence 1991). Significant reductions in plasma Se concentrations of hospitalized human patients with euthyroid sick syndrome have been attributed to their hypercatabolic state (Van Lente and Daher 1992).

EXTRINSIC FACTORS. The considerable site- and species-specific differences in plant Se content can have significant effects on supplemental dietary Se requirements in ruminants. Likewise, variation in vitamin E content of both plant- and animal-source dietary components can affect supplemental dietary Se requirements. Regardless of the source of Se supplementation used, dietary Se appears to be more available to sheep fed a predominantly concentrate versus a predominantly forage diet (Koenig et al. 1997). Although dietary levels of transition elements may influence oxidative changes in feeds, neither Cu, Fe, or Zn have been shown to affect GI Se absorption (Minson 1990b; Dove and Ewan 1990). Diets for growing and finishing heifers and steers should probably contain at least 0.10 mg Se/kg DM, and those for breeding bulls and pregnant or lactating cows should contain 0.05-0.10 mg/kg DM (Minson 1990b). For dairy cows, GI Se absorption is linear over a range of approximately 0.4-3.1 mg/day, and the daily requirement is estimated at 2-2.5 mg/day (Harrison and Conrad 1984; Stowe et al. 1988). Reference values for serum Se (ng/mL) are 70-100 for cattle, 120-150 for sheep, 130-160 for horses, and 180-220 for swine (Stowe and Herdt 1992). Hepatic Se concentrations are normally between 1.2 and 2.0 μg/g DW, for all species and ages (Stowe and Herdt 1992).

Preparations and Therapy. Se fertilization of marginal soils is effective in raising plant Se content. Selenate salts appear to be more available than selenite salts, and in New Zealand, sodium selenate-containing granules with 1% Se have been used to apply approximately 10 g Se/hectare each year as a means of increasing forage Se levels (Minson 1990b). In the United States, the Food and Drug Administration allows up to 0.3 ppm Se in complete feeds for cattle, sheep, swine, chickens, turkeys, and ducks. Salt and mineral mixtures for free-choice feeding may contain up to 120 ppm for beef cattle and 90 ppm for sheep. Total daily intake should not exceed 3 mg for beef cattle and 0.7 mg for sheep. In breeding ewes, it is reported that oral doses of 5 mg Se one month before mating and one month before lambing may improve reproductive performance. Sustained-release pellets containing elemental Se in an iron matrix, as well as Se-containing osmotic pump boluses, are available for intraruminal administration (Maas et al. 1994). An alternative intraruminal slow-release device is a glass bolus impregnated with elemental Se. Injectable combination products of vitamin E and selenium contain approximately 50 IU of vitamin E and 5 mg of selenium per milliliter and are dosed at about 1 mL per 100 kg of body weight. Parenteral doses of approximately 5 mg/100 kg of body weight have been recommended to treat Se deficiency in domestic animals (Maas 1983; Van Vleet 1989; Moore and Kohn 1991). However, some more work indicates that a single label dose of injectable Se does not result in prolonged blood Se concentrations or glutathione peroxidase activity which is normally considered to be adequate (Maas et al. 1993). Blood Se was shown to peak at 5 hours postinjection and to decrease below normal levels thereafter, while blood glutathione peroxidase activity peaked at 28 days and never attained normal values. More work may be indicated to determine the optimal dose of this parenteral product, and/or alternative methods of Se supplementation may be required for long-term prevention of dietary deficiency.

Toxicity. Acute, high-level Se toxicosis may occur under pasture conditions, following consumption of sufficient quantities of Se-accumulator plants, and following overdosage with a Se supplement to prevent or treat deficiency. In pigs, as little as 3 mg Se/kg body weight produced fatal Se toxicosis manifested by vomiting, respiratory distress, weakness, central nervous system (CNS) depression, coma, and death (Hatch et al. 1979b; NRC 1980). Dietary levels of greater than 20 ppm have also induced toxicity in feeder pigs (Casteel et al. 1985). In young lambs, 10 mg sodium selenite administered orally resulted in depression, ataxia, dyspnea, pollakiuria, cyanosis, dilated pupils, tympany, and death. Pathologic lesions included edema, hyperemia, hemorrhages, and necrosis in several body systems (Morrow 1968). Selenium intakes as sodium selenite of up to 50 mg/day for 90 days or 100 mg/day for 28 days by adult Holstein cows had no adverse effects (Ellis et al. 1997). The minimum lethal dose for Se administered by intramuscular injection to dogs is approximately 2.0 mg/kg (Janke 1989). The minimum, single lethal doses of oral sodium selenite for horses, cattle, and pigs are 3.3, 10, and 17 mg/kg body weight, respectively (Traub-Dargatz and Hamar 1986).

Chronic Se poisoning resulting from prolonged intake of lower toxic levels of Se results in the clinical syndromes of "blind staggers" or "alkali disease" (NRC 1980). Blind staggers is a chronic clinical syndrome that has been linked to the consumption of Se-accumulator plants and has been characterized with the paradoxically acute onset of blindness, head pressing, circling, dysphagia, and paralysis (NRC 1980; O'Toole et al. 1996). However, it has been suggested that many field cases of "blind staggers" may have actually been sulfate intoxication-related polioencephalomalacia, and that others may have actually been malignant catarrhal fever, swainsonine intoxication (from the Se-accumulator *Astragalus* spp.), or pyrrolizidine alkaloid intoxication (*Senecio* spp.) (O'Toole et al. 1996). Alkali disease has been observed following the consumption of feeds containing 5-40 ppm Se over several weeks or months. Signs include lameness, hoof malformations, loss of hair (especially from the mane and tail), depression, anorexia, emaciation, and recumbency followed by death (NRC 1980; Traub-Dargatz and Hamar 1986). Approximately 2 ppm Se in the diet is considered the maximum tolerable level for all species.

VANADIUM

Source and Occurrence. Vanadium (V) occurs in four valency states as V(II), V(III), V(IV), and V(V). The pentavalent salts are vanadates, and the quadrivalent forms are vanadites. Vanadium is widely distributed in nature at low levels but on occasion may occur at toxic levels in rock phosphates which are used as phosphorus sources for animal diets (NRC 1980). Although less than 1% of ingested elemental V is actually absorbed from the GI tract, it is considered a nutritionally essential trace element, and definitive biological effects can be demonstrated following repletion of deficient animals.

Biological Characteristics and Signs of Deficiency. The exact metabolic pathways for V transport and incorporation into tissues have not been extensively studied. Absorbed V is taken up by most tissues of the body but is principally directed to growing bone, as well as liver, kidneys, and spleen. Supplementation of rat diets with 0.1 ppm V as sodium orthovanadate (Na_3VO_4) enhances growth significantly (NRC 1980). Diets containing less than 10 ppb retard feather growth in chicks (NRC 1980). Feeding 0.1 mg sodium metavanadate per kilogram body weight to calves increases growth rate and erythrocyte production (NRC 1980). Interest in V has increased in recent years because of the insulin-like actions it can exert on a variety of tissues. Following the first demonstration of insulin-like stimulation of glucose oxidation in isolated rat adipocytes by Na_3VO_4 (Schecter and Karlish 1980), further studies were initiated to determine whether vanadate might ameliorate some of the abnormalities observed in diabetes mellitus. When fed 70-100 mg Na_3VO_4 per kilogram body weight per day for 4 weeks, rats with streptozotocin-induced diabetes mellitus experienced significant improvements in blood glucose concentrations and dynamic cardiac performance compared to controls (Heyliger et al. 1985). Neither peroxyvanadate nor vanadate exerts any effects on insulin binding or insulin sensitivity in isolated human adipocytes, yet peroxyvanadate was as effective as insulin in inhibiting isoproterenol-mediated lipolysis (Lonnroth et al. 1993). In human patients with non-insulin-dependent diabetes mellitus (NIDDM), twice daily oral treatment with 50 mg vanadyl sulfate for 3 weeks significantly improved glycemic control during both oral glucose tolerance tests and euglycemic hyperinsulinemic clamps (Cohen et al. 1995). Adverse side effects of vanadyl sulfate (50 mg twice daily per os) in humans have included diarrhea, flatulence, nausea, and abdominal cramps, all of which disappeared after 1-2 weeks of treatment (Boden et al. 1996). Increased insulin-stimulated hepatic glycogen synthesis accounted for most of the nearly 90% increase in systemic glucose disposal, while hepatic glucose output was nearly completely suppressed by vanadium treatment. In another study, oral treatment with sodium metavanadate (125 mg/day) for 2 weeks improved glucose utilization by approximately 30-40% in human NIDDM patients, reduced exogenous insulin requirements by approximately 14% in insulin-dependent diabetics, and decreased serum cholesterol significantly in both groups (Goldfine et al. 1995).

Dietary Requirements, Indications, Use, and Toxicity. No specific indications for V supplementation have been identified for healthy domestic animals. It has been suggested that V, like iron and zinc, may be sequestered during infections, thereby increasing its requirements, but this has not been thoroughly studied. Vanadium exerts its toxic effects through inhibition of cell enzymes, including Na,K-ATPase (NRC 1980). In vitro ruminal fluid dry-matter digestibility is reduced by as little as 5-7 ppm in the inoculum (NRC 1980). However, sheep have tolerated up to 200 ppm in the diet, and cattle have been fed up to 7.5 mg/kg body weight without adverse effects (NRC 1980). Rats fed up to 20 ppm V in the diet exhibit no adverse effects, but progressively higher amounts can reduce growth, induce diarrhea, and ultimately cause death (NRC 1980). Supplemental dietary Cr has been shown to alleviate V toxicity, perhaps by antagonizing V-induced uncoupling of oxidative phosphorylation (NRC 1980). No specific recommendations may be made regarding a safe and efficacious dose for the treatment of NIDDM in animals.

ZINC

Source and Occurrence. Zinc (Zn) concentrations are generally higher in plant leaves than stems, so that legumes contain more than grasses, and immature plants contain more than mature ones (Minson 1990c; NRC 1982). Zn concentrations in fish and meat meals are higher than in plants, particularly because of higher Zn levels in certain organ tissues (liver, kidney).

Chemical Forms, Distribution, and Biological Characteristics. Zinc is relatively available from a variety of sources, including elemental zinc and insoluble salt forms, which are solubilized by gastric acids for absorption by the small-intestinal mucosa. Inorganic salts of Zn, including the oxide, carbonate, acetate, chloride, and sulfate, are readily available following oral administration (Neathery et al. 1975; NRC 1980; Wedekind and Baker 1990). Chelated dietary forms of Zn, complexed with methionine or lysine, have been purported to enhance bioavailability, and in one study improved immune responsiveness noticeably (Chirase et al. 1991). Most studies have found little difference in Zn bioavailability between $ZnSO_4$ and Zn-methionine or Zn-lysine complexes, although they both have greater availability than ZnO in pigs, cattle, and sheep (Swinkels et al. 1996; Schell and Kornegay 1996; Rojas et al. 1995; Wedekind et al. 1994). Oral administration of diiodohydroxyquinolein, a Zn-chelating compound, has been shown to enhance Zn bioavailability in rats and in hypozincemic human patients with chronic renal failure (Paniagua et al. 1995). Endogenous factors that play a role in Zn absorption include prostaglandin E_2, which may facilitate its mucosal transport, and metallothioneins, which are induced during inflammation and mediate changes in interorgan distribution of Zn (Sobocinski et al. 1978; Starcher et al. 1980). IL-1, released during inflammatory disorders and particularly during bacterial infections or endotoxemia, induces hepatic and renal metallothionein synthesis, leading to sequestration of Zn in these tissues and induction of hypozincemia (Etzel et al. 1982; Klasing 1984). While this response may deprive proliferating bacteria of Zn, thereby suppressing their growth, it is also possible that lower Zn levels may adversely affect host metabolic and immune responses as well.

METABOLIC FUNCTIONS

APOENZYME AND MEMBRANE INTERACTIONS. Zn functions as a necessary cofactor for many metalloenzymes, including alcohol, lactic acid, malic acid, and glutamic acid dehydrogenases, alkaline phosphatases, pancreatic carboxypeptidases A and B, carbonic anhydrase, deoxythymidine kinase, DNA- and RNA-polymerases, and superoxide dismutase. Zn binds to many organic molecular moieties, including sulfhydryl, amino, imidazole, and phosphate groups, thereby facilitating its interactions with a plethora of biologically important compounds. Zn has a direct stabilizing effect on cellular membranes and may alter membrane fluidity, thereby affecting ion gating, hormone-receptor interactions, cytoskeletal activity, membrane-bound enzyme activation, and membrane lipid participation in free radical reactions. In addition, the expression of several genes for the synthesis of hepatic proteins, including transthyretin and retinol-binding protein, is regulated by Zn and results in up-regulation of expression during Zn deficiency (Kimball et al. 1995).

IMMUNOLOGIC MODULATION. Zn-deficient mice demonstrate impaired cell-mediated immune responses to allogeneic tumor cell inoculations and reduced delayed-type hypersensitivity reactions to dinitrofluorobenzene, both of which are corrected following Zn supplementation (Frost et al. 1981; Fraker et al. 1982). Similarly, the humoral immune response to sheep red blood cells is reduced in Zn-deficient mice, predominantly through interference with T-helper cell proliferation and function, leading to reduced B-cell and plasmacyte development (Fraker et al. 1977; Luecke et al. 1978; Luecke and Fraker 1979). Zn deficiency in laboratory rodents increases their susceptibility to infection by bacteria (Sobocinski et al. 1977), as well as to yeast like *Candida albicans* (Salvin and Rabin 1984). Pretreatment with Zn increases survival following intravenous administration of *Salmonella typhimurium* in rats, through effects on host immunity and on developing endotoxemia (Tocco-Bradley and Kluger 1984). In fact, lethality in endotoxin-treated mice has been reduced significantly by pretreatment with Zn, through effects that appear to include stabilization of lysosomal membranes and moderation of cellular proteolytic reactions (Snyder and Walker 1976). In rhesus monkeys, Zn deficiency induces an intrinsic neutrophil defect that specifically affects chemotaxis, although phagocytosis of opsonized yeast was not affected (Vruwink et al. 1991).

Zn deficiency has likewise been linked to immune dysfunction in humans, including impaired T-cell mitogenic responses and decreased natural killer cell activity and monocyte cytotoxicity (Pekarek et al. 1979; Allen et al. 1981; Allen et al. 1983; Duchateau et al. 1981a). Oral Zn supplementation in humans over 70 years of age has resulted in increased circulating levels of T lymphocytes, improvement in the delayed cutaneous hypersensitivity reaction to Candidin and streptokinase-streptodornase, and increased IgG antibody response to tetanus vaccination (Duchateau et al. 1981b). Zn supplementation of human peripheral blood lymphocytes in vitro stimulates B-lymphocyte mitogenic responses (Cunningham-Rundles et al. 1980). Human patients who consumed Zn-gluconate-containing throat lozenges regularly throughout a cold experienced a significant reduction in duration of symptoms from 7.6 to 4.4 days and had fewer days with coughing, headache, hoarseness, nasal congestion and drainage, or sore throat (Mossad et al. 1996). In a study of stressed feeder calves, dietary Zn supplementation with either zinc oxide or zinc methionine increased feed

is now known that this enzyme does not exist, and that docosahexaenoic acid is derived by the sequential chain elongation of 20:5;ω-3 to 22:5;ω-3 and 24:5;ω-3, followed by Δ6-desaturation to 24:6;ω-3 and β-oxidation to 22:6;ω-3 (Sprecher et al, 1995; Figure 38.2).

Interest in the potential health benefits of the ω-3 family has increased in recent years, in large part due to epidemiological studies of societies consuming large amounts of marine fish. This led to the identification of marine fish oils as major sources of ω-3 fatty acids, which are synthesized de novo by phytoplankton at the base of the aquatic food chain and subsequently accumulated by the fish at the peak of that chain (Logas et al. 1991; McDowell 1989; Neuringer et al. 1988).

Biological Characteristics. The EFAs are absorbed along with other dietary lipids in the small intestine by a process dependent on biliary and pancreatic secretions. The preliminary hydrolysis by pancreatic lipase of ω-3 fatty acids from dietary triglycerides may not be as efficient as for other fats (Nestel 1990). In addition, pancreatic lipase preferentially splits the fatty acids in the 1-C and 3-C positions of dietary triglycerides. Because most of the ω-3 fatty acids in marine fish oil are in the C-2 position of the triglycerides, these would be absorbed predominantly as monoglycerides, which may influence their subsequent metabolism. The ω-3 fatty acids are more readily absorbed when specific synthetic triacylglycerols are administered with eicosapentaenoic acid (20:5;ω-3) or docosahexaenoic acid (22:6;ω-3) predominantly in the C-2 position and a medium-chain fatty acid, decaenoic acid, in the C-1 and C-3 positions (Christensen et al. 1995). Fatty acyl-binding proteins in the small-intestinal epithelial cells appear to facilitate intracellular transport and distribution of EFA either to local cellular organelles or to chylomicra for transport via the lymphatics to distant sites. In humans, chronic ingestion of oils containing high concentrations of ω-3 fatty acids results in incorporation of long-chain ω-3 fatty acids, in a dose-dependent manner, in adipose tissue (Leaf et al. 1995) and in plasma phospholipids (Andersen et al. 1996).

METABOLIC FUNCTIONS. Absorbed EFAs are interconverted to other fatty acids of the same ω series. Arachidonic acid (20:4;ω-6) derived from dietary linoleic acid (18:2;ω-6) and docosahexaenoic acid (22:6;ω-3) derived from dietary α-linolenic acid (18:3;ω-3) serve an important role in cell membrane structure and are the principal precursors for the biologically active ω-6 (bienoic, or 2-series) and ω-3 (trienoic, or 3-series) eicosanoids, respectively (Fig. 38.4). Arachidonic acid accounts for 5-15% of total fatty acids in most tissue phospholipids, while docosahexaenoic acid is present predominantly in the retina, cerebral cortex, testes, and sperm (Neuringer et al. 1988). In the cerebral gray matter, docosahexaenoic acid composes up to one-third of the fatty acids of phosphatidyl ethanolamine and phosphatidyl serine.

A deficiency of one series may lead to a complementary increase in tissue levels of another series. When completely deprived of ω-6 fatty acids, tissue levels of all ω-6 derivatives are lower than normal, whereas levels of ω-9 fatty acids like oleic (18:1;ω-9) and eicosatrienoic (20:3;ω-9) and of ω-7 fatty acids like palmitoleic (16:1;ω-7) are increased (McDowell 1989). Docosapentaenoic acid (22:5;ω-6) is normally very low in most tissues but replaces docosahexaenoic acid (22:6;ω-3) when there is an ω-3 EFA deficiency. Conversely, because the enzymes responsible for chain elongation and desaturation interact with all series of

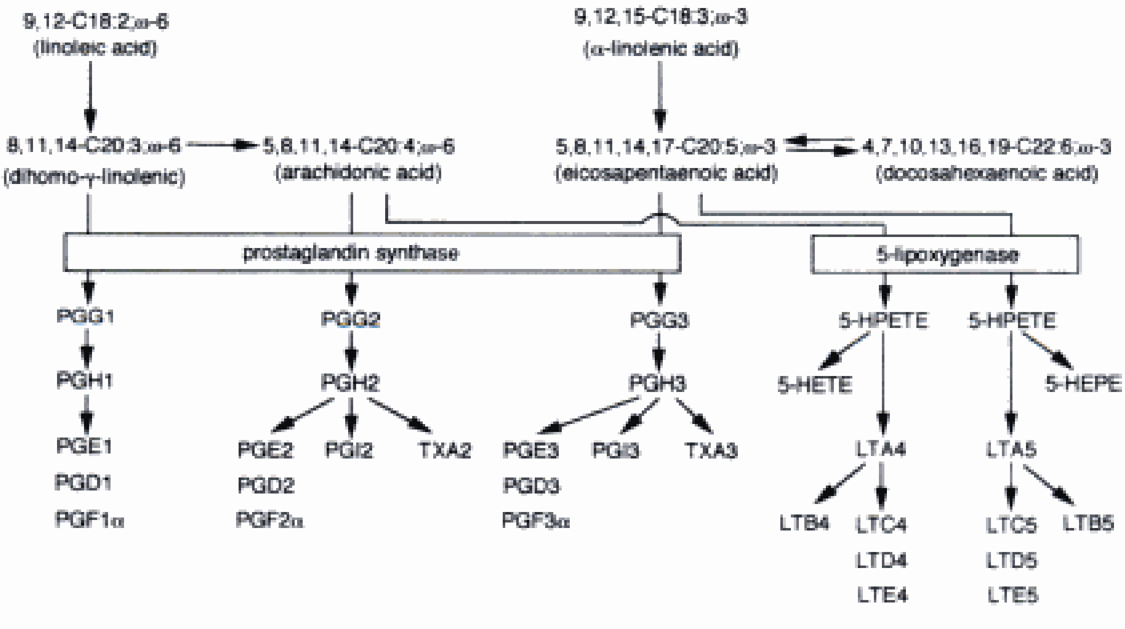

FIG. 38.4—Derivation of eicosanoids from ω-6 and ω-3 fatty acids. (Adapted from Barcelli 1991.)

differ in their effects on the activities of hepatic lipid metabolic pathways and circulating lipid levels (Ikeda et al. 1994).

MEMBRANE FUNCTION. Polyunsaturated acids generally increase membrane fluidity, compliance, and permeability, but specific properties may be attributed to different ω-3 fatty acids owing to particular molecular configurations (Neuringer et al. 1988). For instance, substitution of arachidonic acid (20:4;ω-6) or docosahexaenoic acid (22:6;ω-3) for linoleic acid (18:2;ω-6) in artificial phosphatidylcholine membranes did not additively increase fluidity as expected but may have promoted tighter phospholipid packing and reduced deformability. In the retina, where docosahexaenoic acid predominates, this may afford a better configuration for interaction with the visual pigment rhodopsin (Neuringer et al. 1988). Studies in ω-3 EFA-deficient rats which have shown impaired exploratory behavior, maze-learning, and brightness discrimination may indicate some effects on central nervous function as well, which may be attributed to changes in neural membrane function. Reductions in vessel wall-induced blood coagulation and platelet aggregation in individuals fed higher levels of ω-3 EFAs may reflect changes in cell membrane reactivity and membrane-bound mediators like thromboplastin and platelet-activating factor, as well as alterations in thromboregulatory eicosanoid metabolism (Henry et al. 1991).

EICOSANOID METABOLISM. Cyclooxygenase and lipoxygenase-derived metabolites of the ω-3 fatty acids have different biologic activities from those of metabolites derived from the ω-6 family (Lefer 1989). Bienoic eicosanoids of the 2-series derived from ω-6 EFAs have counterregulatory effects on blood coagulation and vasoreactivity. Prostaglandins E_2 and I_2 tend to inhibit platelet aggregation and to promote vasodilation, whereas thromboxane A_2 promotes aggregation and vasoconstriction. In contrast, the trienoic products, prostaglandin E_3 and thromboxane A_3, may both have vasodilatory properties (Lefer 1989). The 5-series of leukotrienes and lipoxins derived from eicosapentaenoic acid is less active than the 4-series produced from arachidonic acid and competes against the 4-series metabolites for receptor sites in target organs. While leukotrienes B_4 and D_4, and lipoxin A_4, may increase microvascular permeability and enhance leakiness, their 5-series counterparts have little such activity (Lefer 1989). Dietary enrichment with ω-3 EFAs increases their levels in the tissues and reduces the production of ω-6 EFA-derived eicosanoids under inflammatory, vasoreactive, or procoagulant conditions, thereby effecting numerous changes in metabolism as described below (Lefer 1989; Barcelli 1991). Subsequent modulation of the production of cytokines, including interleukin-1, interleukin-6, and tumor necrosis factor-α, may contribute further to clinical improvements in inflammatory conditions as diverse as rheumatoid arthritis, psoriasis, atopic dermatitis, colitis, systemic lupus erythematosus, and endotoxemia (Blok et al. 1996; Meydani 1996).

HEMOSTASIS AND CARDIOVASCULAR DISEASE. Epidemiological studies of Greenland Eskimos first indicated a relationship between dietary ω-3 EFA consumption and reduced risk for cardiovascular disease (Fisher et al. 1986; Herold and Kinsella 1986). Compared to those living in Denmark and consuming a diet lower in ω-3 EFAs, these Eskimos had lower blood triglyceride, cholesterol, LDL, and VLDL levels; higher HDL levels; decreased ability of platelets to aggregate; and a much lower incidence of cardiac disease. Other studies have shown that Europeans consuming as little as 30 g of marine fish daily had a 50% lower rate of mortality due to coronary artery disease than non-fish-consuming cohorts. Experimental studies in rats, rabbits, pigs, dogs, and horses have demonstrated effects of supplementary ω-3 EFAs, including changes in tissue lipid composition, lipid metabolism, platelet aggregability, monocyte-derived procoagulant activity, and platelet survival, all of which may reduce the occurrence of arterial lesions (Herold and Kinsella 1986; Levine et al. 1989). Dietary fish oil supplementation attenuates the myocardial dysfunction caused by ischemia-reperfusion injury in the rat (Yang et al. 1993) and reduces the vulnerability of normal or ischemic myocardium to induced arrhythmias in nonhuman primates (McLennan et al. 1993). Studies in humans have, in addition, demonstrated a significant blood pressure-lowering effect of dietary ω-3 EFA supplementation in both middle-aged and elderly hypertensive patients (Radack et al 1991; Margolin et al. 1991), without adverse effects on glucose metabolism (Toft et al. 1995). Effects have been observed with as little as 2 g ω-3 EFA per day.

CHRONIC RENAL DISEASE. Studies of the effects of dietary modification on the progression of chronic renal disease have turned to the particular role of dietary lipids on renal function (Barcelli 1991). Early studies indicated that rats fed a diet high in linoleic acid experienced lesser degrees of azotemia and proteinuria following partial renal ablation than those fed a low-linoleic acid diet (Heifets et al. 1987). Feeding a high-linoleic acid diet resulted in increased renal cortical and medullary linoleic and arachidonic acid content and apparently reduced the degree of systemic hypertension, the loss of glomerular permselectivity, and the development of glomerular lesions. Conversely, dietary supplementation of partially nephrectomized rats with ω-3 EFA-rich menhaden fish oil produced more rapid progression of remnant renal dysfunction, characterized by lower glomerular filtration rates, higher degrees of proteinuria, and accelerated death rates due to renal failure (Scharschmidt et al. 1987). In contrast, studies of renal dysfunction in a uninephrectomized, obese Zucker rat model found that dietary ω-3 supplementation reduced the degrees of hypercholesterolemia, proteinuria, and focal glomerulosclerosis (Kasiske et al.

IMMUNE FUNCTION. Taurine represents over 60% of the free amino acid pool of human lymphocytes in vivo and in culture (Wright et al. 1986). Human lymphocytes grown in taurine-deficient media continue to multiply, but with decreased cell viability, which is reversible following resupplementation with taurine. Taurine's role as an antioxidant may help regulate phagocytic cell oxidative pathways, and both lymphocyte and neutrophil function are impaired in taurine-deficient animals (Pion and Kittleson 1990). Because oligotaurinemia in human trauma patients persists longer than other hypoaminoacidemias and is not fully corrected even after 7 days of supplementation, it is possible that taurine depletion plays a critical role in immune suppression following injury (Paauw and Davis 1994).

RETINAL FUNCTION. Taurine occurs in exceptionally high concentrations in the photoreceptor cells of the outer nuclear layer of the retina (Wright et al. 1986; Pion and Kittleson 1990). The retinas of some animals can synthesize significant quantities of taurine in situ, but most is accumulated by a sodium-dependent, energy-consuming, high-affinity transport system located in the retinal pigmented epithelium (Wright et al. 1986). Taurine thus accumulated is transferred to the neural layer by a passive process that is facilitated by taurine-specific binding proteins located in the inner retina. Taurine may (1) act as an inhibitory neurotransmitter, (2) regulate osmotic pressure in the rods, (3) regulate retinal ionic calcium concentrations, and (4) control phosphorylation-dependent functions of the neural retina. Taurine has also been shown to affect retinal phagocytic function and to scavenge free radicals, thereby playing an important role as an antioxidant to prevent lipid peroxidation in this light-sensitive region (Wright et al. 1986).

BRAIN FUNCTION. Taurine is actively accumulated by brain cells and appears to play important roles in CNS development and as a neuromodulatory agent (Pion and Kittleson 1990). Taurine-deficient kittens display numerous neurological abnormalities, including cerebellar dysfunction which has been linked to abnormal division and migration of cells into the external granular cell layer. Likewise, neuroblasts in the ventricular and pial zones undergo incomplete differentiation and migration into the molecular layer (Wright et al. 1986). As a poorly diffusible, zwitterionic molecule, its presence in high concentrations in the CNS may assist in osmotic regulation, ionic balance, and membrane depolarization (Pion and Kittleson 1990). Taurine has anticonvulsant properties and has been shown to protect the brain against osmotic stress during hypernatremia and diabetic hyperglycemia (Pion and Kittleson 1990).

MYOCARDIAL FUNCTION. Pion et al. (1987) reported that low plasma taurine concentrations in cats are associated with echocardiographic evidence of myocardial failure that is reversible following oral supplementation of taurine to restore plasma levels to normal. Dietary taurine supplementation (500-1000 mg/day) of cats with moderate-to-severe dilatative cardiomyopathy has resulted in marked improvements in clinical response to standard pharmaceutical treatment, as well as significant increases in survival rate (Pion et al. 1992). Because myocardial taurine content is directly related to plasma taurine concentrations, a direct link between taurine deficiency and myocardial failure is proposed. Subsequent studies have shown that compared to normal cats, taurine-deficient cats with cardiomyopathy also have 20% lower plasma tocopherol levels, 40% higher retinol concentrations, 36% lower cholesterol, and 100% higher triglyceride concentrations (Fox et al. 1993). Thus, nutrients other than taurine may affect the expression of dilated cardiomyopathy. The mechanisms whereby taurine affects cardiac function remain unclear. Taurine is present in high concentrations in mammalian myocardium (100-200 times that found in plasma), which are additionally maintained by active transport processes. Zwitterionic taurine may retard cardiocytic potassium (K) efflux associated with body K depletion, catecholamine-induced arrhythmias, or digoxin toxicity. Taurine addition to rat cardiac tissue slices in vitro, and taurine administered to rats and dogs in vivo, has been shown to restore cardiac K content and to reverse drug-induced arrhythmias. Dietary K depletion was hypothesized to adversely affect taurine efflux across the cell membranes or to affect its metabolism (Dow et al. 1992). Thus, there appears to be a reciprocal relationship between cellular K and taurine content, which may explain the induction of taurine deficiency secondary to K depletion and the concurrence of epidemiological findings in cats with taurine-responsive congestive cardiomyopathy and those with kaliopenic nephropathy-polymyopathy syndrome (Dow et al. 1987 1992).

Signs of Deficiency. The effects of naturally occurring taurine deficiency have almost exclusively been noted in domestic cats, although some studies in humans have documented taurine depletion in preterm infants (who have low cysteine sulfinic acid decarboxylase activity) fed low-taurine milk replacement formulas (Rassin et al. 1983; Watkins et al. 1983), in patients with chronic renal failure (Bergstrom et al. 1989), and in critically injured patients inadequately maintained by total parenteral nutrition (Paauw and Davis 1990).

The earliest reports of the effects of dietary taurine deficiency in cats related specifically to the occurrence of the syndrome of "feline central retinal degeneration" (Hayes et al. 1975). Degenerative changes begin as small foci in the area centralis, followed by band-shaped horizontal lesions which progressively enlarge to involve the entire retina and are characterized histologically by vesiculation and disintegration of the photoreceptor cells and degeneration of the underlying tapetum (Morris et al. 1990; da Costa and Hoskins 1990).

Taurine deficiency has important effects on reproduction, including abortion, reduced live births,

GLUTAMINE

Chemical Structure and Properties. Glutamine (α-aminoglutaramic acid) is the amide derivative of glutamic acid, existing as a colorless needle-shaped crystal in pure form. It is insoluble in most alcohols, has limited solubility in water (~3 g/100 mL at 20° C), and is unstable during heat sterilization and storage (Tremel et al. 1994). Synthetic dipeptides of glutamine, made with alanine (alanyl-glutamine) and glycine (glycyl-glutamine), exhibit greater water solubility and chemical stability and have received attention as supplements for parenteral solutions (Tremel et al. 1994; Petersson et al. 1994).

Source and Occurrence. Glutamine is synthesized from glutamic acid by all animals predominantly in the skeletal muscle, lungs, and adipose tissue, and is found in highest concentrations in these tissues, as well as liver, kidney, small intestine, and lymphocytes (Curthoys and Watford 1995). Glutamine comprises more than 60% of free α-amino acids in the body and has traditionally been considered a nonessential amino acid because it is readily derived from glutamic acid in healthy animals. Glutamic acid is derived from ammonium (NH_4^+) and α-ketoglutaric acid, a tricarboxylic acid (TCA) cycle intermediate, in a reaction catalyzed by glutamic acid dehydrogenase. An additional ammonium ion is incorporated into glutamic acid by the action of glutamine synthetase, to form glutamine in an amidation reaction driven by ATP hydrolysis. Glutamine is present in concentrations of 0.5-0.8 mM in plasma and up to 20 mM in the intracellular water of tissues like skeletal muscle. The plasma glutamine pool turns over very rapidly, and although some dietary glutamine is absorbed intact from the GI tract, the abdominal viscera usually exhibit net uptake, so that the majority of circulating glutamine is derived from de novo synthesis in extraspanchnic tissues.

Biological Characteristics. Glutamine synthetase is found in most tissues, but as a result of its large mass, skeletal muscle is the major site of glutamine production in the body. The lungs are the next most important site of glutamine production, and more recent studies indicate that adipose tissue is capable of significant rates of glutamine synthesis as well (Curthoys and Watford 1995). Glutamine has many unique metabolic functions in the body, which are met in healthy animals by its de novo endogenous synthesis. In critically ill, "hypercatabolic states," glutamine is released from muscle and lung tissue, intracellular glutamine levels decrease markedly, and plasma glutamine concentrations increase. However, glutamine turnover increases significantly as well, due to increased uptake for metabolism by liver, intestines, and kidneys. Elevated rates of glutamine synthesis may not be sufficient to meet the body's disease requirements, and so glutamine is now considered a "conditionally essential" amino acid in disorders as diverse as metabolic acidosis, starvation, cancer, sepsis, trauma, and diarrhea.

METABOLIC FUNCTIONS

GASTROINTESTINAL FUNCTION. The GI tract is the principal organ of glutamine utilization, accounting for extraction of up to 25% of circulating glutamine (Souba 1991). Although the small-intestinal epithelial cells require large amounts for synthetic purposes (e.g., purines and pyrimidines for nucleic acid synthesis), owing to their high rate of turnover, the majority of extracted glutamine serves as the principal respiratory fuel in these cells (Curthoys and Watford 1995). Glutamine undergoes oxidative deamidation to glutamate, and glutamate undergoes oxidative deamination to α-ketoglutarate for entry into the TCA cycle. Alternatively, glutamate undergoes transamination with pyruvate to produce alanine and α-ketoglutarate, or with oxaloacetate to produce aspartate and α-ketoglutarate. Much of the glutamine undergoes only partial oxidation to 3-carbon intermediates, including pyruvate, lactate, and alanine. These are utilized by other tissues, and the ammonia released during glutamine's catabolism contributes to urea synthesis in the liver.

During starvation, intestinal disease, as well as systemic diseases associated with hypercatabolism, intestinal glutaminase activity increases significantly, and glutamine extraction may more than double. Glucocounterregulatory "stress" hormones, including glucocorticoids and glucagon, have been demonstrated to increase the specific activity of glutaminase in the small-intestinal mucosa while simultaneously diminishing glucose uptake and oxidation (Souba 1991; Colomb et al. 1997). Supplementation of parenteral feeding formulas with glutamine or glutamyl dipeptides (25-30% of amino acid nitrogen) has repeatedly been shown to spare villous morphology and ameliorate intestinal mucosal atrophy associated with deprivation of enteral nutrition (Schroder et al. 1995; Wiren et al. 1995; Burrin et al. 1994). Parenteral nutrition-associated increases in intestinal permeability, which may result in gut bacterial translocation and sepsis, are also prevented by supplementation of parenteral formulas with glutamine (2-4% w/w) (Gianotti et al. 1995; Li et al. 1994; Barber et al. 1990). A high-calorie oral rehydration solution supplemented with glutamine (30 mmol/L) was recently shown more effective in correcting plasma and extracellular fluid volumes in neonatal calves with enterotoxigenic *Escherichia coli* diarrhea than similar glutamine-free solutions (Brooks et al. 1997).

LIVER FUNCTION. The liver principally uses glutamine for gluconeogenesis and ureagenesis. Ammonia released by hepatic deamidation of glutamine is preferentially routed to urea synthesis, while the carbon skeleton (α-ketoglutarate) serves as a precursor to oxaloacetate, the key metabolic intermediate in new glucose synthesis (Fig. 38.5). Following deamidation, glutamine also serves as a precursor for the synthesis of ornithine, the rate-limiting substrate in the urea cycle.

caution should be exercised in individuals for which dietary protein restriction may be indicated, including certain forms of renal failure, hepatic dysfunction, or behavioral disorders.

  - **Special Considerations in Specific Applications**

Long before the ability to view microorganisms with a microscope and three centuries before Koch and Pasteur, Fracastoro postulated that germs caused infections. In the 1840s, Ignaz Semmelweis, a Hungarian obstetrician, demonstrated the beneficial effects of hand washing between patients as well as the antiseptic effect of chlorine in the form of chlorinated lime. Following Pasteur's identification of infective agents as the cause of disease, Joseph Lister suggested the use of antiseptics in the field of surgery. His treatment of the hands with 1:20 carbolic lotion and his initiation of methods for chemical sterilization of bandages, dressings, and surgical instruments and for antisepsis of wounds began aseptic surgery. Although originally targeted toward the surgeon, general cleanliness and the use of antiseptics and disinfectants have spread to all fields of the medical, dental, and veterinary professions.

Cleansers, antiseptics, and disinfectants are differentiated by their intended use and characteristic properties and not by their chemical content. A cleanser aids in physical removal of foreign material and is not a germicide. An antiseptic is a germicide applied to living tissue, and a disinfectant is a germicide applied to inanimate objects. Because certain antiseptics may be inactivated on inanimate surfaces and because certain disinfectants are hazardous to living tissue, the two should not be used interchangeably. Even products with the identical active chemical moiety may be formulated in such a way to prevent their interchangeable use. Products to be used on inanimate surfaces, objects, or instruments are regulated by the Environmental Protection Agency (EPA), whereas chemicals in antiseptics for use on the human body must be registered with the Food and Drug Administration (FDA).

CLEANSERS. Cleansers (surfactants, detergents) remove dirt and contaminating organisms by solubilization and physical means. Cleaning an area to remove gross contamination prior to disinfection or antisepsis treatment maximizes their efficacy. Cleansers can be classified into three types based on the position of the hydrophobic portion of the molecule: anionic, cationic, and nonionic.

Soaps are anionic surfactants of the general structure $R\text{-}COO^-Na^+$. Dissociation in water to $R\text{-}COO^-$ liberates a molecule with both a hydrophilic and a hydrophobic portion that can emulsify and solubilize hydrophobic dirt, fat, and protoplasmic membranes. Once solubilized, this contamination can be rinsed away with water. The ability to solubilize membranes renders soaps antibacterial against gram-positive and acid-fast bacteria. The anionic nature of soaps, however, causes them to be inactivated in the presence of certain positive ions such as free Ca^+ in hard water and in the presence of cationic detergents. The mixture of soaps and quaternary ammonium compounds (QACs) forms a precipitate that terminates the activity of both compounds. Inclusion of antiseptic compounds in soap preparations has given them a wider antibacterial spectrum.

The QACs are examples of cationic surfactants with germicidal activity. These compounds have been widely used as disinfectants. Cationic surfactants combine readily with proteins, fats, and phosphates and are thus of limited value in the presence of serum, blood, and other tissue debris (Huber 1988). In addition, use with materials such as gauze pads and cotton balls makes them less microbicidal owing to adsorption of the active ingredients. For these reasons, and because several outbreaks of infections have been associated with use of contaminated solutions, the Centers for Disease Control (CDC) no longer recommend cationic surfactants for antisepsis.

Second- and third-generation QACs are less affected by hard water and other anions. These quaternaries are fungicidal, bactericidal, and virucidal against lipophilic viruses but are not sporicidal, tuberculocidal, or active against hydrophilic viruses. Benzalkonium chloride, the first commercially available quaternary compound, has been shown to cause chemical burns when used undiluted (Bilbrey et al. 1989).

ANTISEPTICS AND DISINFECTANTS. An antiseptic is a chemical agent that reduces the microbial population on skin and other living tissues. Because, in most cases, its mechanism of action involves nonspecific disruption of cellular membranes or enzymes, caution must be taken not to harm host tissue. An ideal antiseptic would have a broad spectrum of activity, low toxicity, and high penetrability, would maintain activity in the presence of pus and necrotic tissue, and would cause little skin irritation or interference with the normal healing process.

The use of antiseptics has been suggested in situations that require maximal reduction of bacterial contamination (Larson 1987), such as when defense mechanisms are compromised after surgery, during catheterization or insertion of other invasive implants, and in immunocompromised states due to immune defects, cytotoxic drug therapy, extreme old or young age, or extensive skin damage (burns and wounds).

Disinfection is the elimination of many or all pathogenic organisms, excluding spore forms, from an inanimate object. The treatment of objects that are too large to soak in disinfectant, such as cabinets, exam tables, chairs, lights, and cages, is considered surface disinfection. Immersion disinfection, sometimes wrongly referred to as cold sterilization, is the immersion of smaller objects in disinfectant for sufficient time to kill the majority of contaminating organisms. True chemical sterilization necessitates the use of an EPA-registered agent capable of killing all infective organisms, including fungal and bacterial spores, usually within 10 hours. Chemical sterilization should not replace heat-pressure sterilization.

The ideal characteristics of a disinfectant include a broad spectrum, fast action, activity in the presence of organic material (including blood, sputum, and feces), compatibility with detergents, low toxicity, and residual surface activity. Disinfectants should not corrode instruments or metallic surfaces or disintegrate rubber, plastic, or other materials, and they should be odorless and economical (Molinari et al. 1982).

Microorganisms can be ranked from least to most resistant to disinfectant killing as follows: vegetative bacteria, medium-size lipid-coated viruses, fungi, small nonlipid enveloped viruses, *Mycobacterium tuberculosis*, and bacterial endospores. Using these different resistances, disinfection can be further divided into three levels. Low-level disinfection kills most bacteria, some viruses, and some fungi, but not tubercle bacilli or bacterial spores. Intermediate-level disinfection inactivates *M. tuberculosis*, most viruses and fungi, but not necessarily bacterial spores. High-level disinfection destroys all microorganisms except high numbers of bacterial spores.

A second classification system divides instruments and patient-care items into three categories based on risk of infection involved in their use (Spaulding 1968). In this system, items are classified as (1) critical—those that enter or penetrate skin or mucous membranes (e.g., needles, scalpels); (2) semicritical—those that touch intact mucous membranes (e.g., anesthesia equipment, endoscopes); and (3) noncritical—those that do not touch mucous membranes but may contact intact skin (e.g., cages, tables, food bowls). In general, items classified as critical should be sterilized, semicritical items require high-level disinfection, and noncritical items require low- to intermediate-level disinfection.

The following is a discussion of local anti-infective agents categorized by the active chemical entity. Where appropriate, considerations and recommendations for their use as cleansers, disinfectants, or antiseptics are noted.

Alcohol. Although many alcohols are germicidal, the two most commonly used are ethyl and isopropyl alcohol. These compounds are both lipid solvents and protein denaturants. They kill organisms by solubilizing the lipid cell membrane and by denaturing membrane cellular proteins. Alcohols are most effective when diluted with water to a final concentration of 70% ethyl or 50% isopropyl alcohol by weight. It is thought that at greater concentrations, initial dehydration of cellular proteins makes them resistant to the denaturing effect (Molinari and Runnel 1991). The alcohols have excellent antibacterial activity against most vegetative gram-positive, gram-negative, and tubercle bacillus organisms but do not inactivate bacterial spores. They are active against many fungi and viruses, principally enveloped viruses due to alcohol's lipid-solubilizing action. They are active against cytomegalovirus and herpes simplex and human immunodeficiency viruses.

Both isopropyl and ethyl alcohols are commonly used, effective antiseptics, with only subtle differences in their action. Because their effectiveness is drastically reduced by organic matter such as excreta, mucus, and blood, they are most effective on "clean" skin. Of all agents, they produce the most rapid and largest reduction in bacterial counts (Lowbury et al. 1974), with contact times of 1–3 minutes resulting in elimination of almost 80% of organisms. Rapid evaporation limits contact time; however, residual decreases in bacterial counts are seen to occur after the alcohol has evaporated from the skin. Although alcohols are among the safest antiseptics, toxic reactions have been reported in children. Alcohol is very drying to the skin and can cause local irritation. In efforts to minimize this drying effect, emollients such as glycerine have been added with good results (Larson et al. 1986).

The alcohols are not recommended for high-level disinfection or chemical sterilization due to their inactivity against bacterial spores and reduced efficacy in the presence of protein or other bioburden. Blood proteins are denatured by alcohol and will adhere to instruments being disinfected. Fatal *Clostridium* spp. infections have occurred postoperatively that were the result of contaminated surgical instruments that had been disinfected with alcohol containing bacterial spores (Nye and Mallory 1923). After repeated and prolonged use, alcohols can damage the shellac mounting of lensed instruments, can swell or harden rubber and certain plastic tubing (Rutala 1990), and can be corrosive to metal surfaces. Alcohols are flammable; thus caution must be taken in their storage and when used prior to electrocautery or laser surgery. In deciding between ethyl and isopropyl alcohol, it is important to consider isopropyl's inactivity against hydrophilic viruses, its less corrosive nature, and the abuse potential for ethyl alcohol (grain alcohol).

Halogens. Elemental iodine has activity against gram-positive and gram-negative bacteria, bacterial spores, fungi, and most viruses. It exerts these lethal effects by diffusing into the cell and interfering with metabolic reactions and by disrupting protein and nucleic acid structure and synthesis. Iodine has a characteristic odor and is corrosive to metals. It is insoluble in water and thus is prepared in alcohol (tincture) or with solubilizing surfactants ("tamed" iodines). Tincture of iodine, used as early as 1839, in the French Civil War, is most effectively formulated as a 1–2% iodine solution in 70% ethyl alcohol. In this form, most (~90%) bacteria are killed within 3 minutes of application. The antibacterial activity of this combination is greater than that of the alcohol alone. Tincture of iodine, however, is irritating and allergenic, corrodes metals, and stains skin and clothing. It is also painful when applied to open wounds and is harmful to host tissue; therefore, it can delay healing and thereby increase the chance of infection. For these reasons, this preparation has fallen out of favor as an antiseptic or disinfectant. Strong tinctures of iodine have been used as blistering agents in the equine industry.

Efforts to reduce the undesirable aspects of tinctures while retaining the powerful killing action of iodine have led to the introduction of tamed iodines known as iodophors. In this preparation, iodine is solubilized by surfactants, which allow it to remain in a dissociable form. Application of this product allows for slow continual release of free iodine to exert its germicidal effects. The iodophors have a similar spectrum of activity to aqueous solution; are less irritating, allergenic, corrosive, and staining; and have prolonged activity after application (4–6 hours). Common solubilizing carriers include polyvinylpyrrolidone (called PVP-iodine or povidone-iodine [PI]) as well as other nonionic surfactants, making iodophors excellent cleansing agents as well as antiseptics and disinfectants. Iodophor solutions retain their activity in the presence of organic matter at pH < 4 (Huber 1988). The water-soluble carriers have been postulated to interact with epithelial surfaces to increase tissue permeability, thereby enhancing iodine's killing efficacy.

Free iodine released by the iodophor complex is apparently responsible for its germicidal activity. Proper dilution to 1% iodine is necessary for maximum killing effect and minimal toxicity. More-concentrated solutions are actually less efficacious, presumably due to stronger complexation preventing free iodine release. It takes approximately 2 minutes of contact time for release of free iodine (Lavelle et al. 1975). Literature reports indicate that iodophors are quickly bactericidal, virucidal, and mycobactericidal but may require prolonged contact times to kill certain fungi and bacterial spores. Iodophors formulated as antiseptics are not suitable as hard-surface disinfectants, due to insufficient concentrations of iodine.

Consideration must be taken of iodine's ability to be systemically absorbed through the skin and especially mucous membranes. The extent of absorption is related to the concentration used, frequency of application, and status of renal function (the principal excretory route) (Swaim and Lee 1987). Complications of systemic iodophor absorption include increased serum enzyme levels, renal failure, metabolic acidosis (Pretsch and Meakins 1976), and increased serum free iodide. If renal function is normal, serum iodine concentrations quickly return to normal. Clinical hyperthyroidism and thyroid hyperplasia have been reported after treatment with PI (Scheider et al. 1976; Altemeier 1976). Chap. 53 should be consulted for further details.

Chlorine-containing solutions were first introduced by Dakin in the early 1900s in the chemical form of sodium hypochlorite. They are effective antibacterial, fungicidal, virucidal, and protozoacidal agents. The chemical forms most commonly used today include the hypochlorites (sodium and calcium) and organic chlorides (chloramine-T). In either form, the germicidal activity is due to release of free chlorine and formation of hypochlorous acid (HOCl) from water. The mechanisms of action of these compounds include inhibition of cellular enzymatic reactions, protein denaturation, and inactivation of nucleic acids (Dychdala 1983). Dissociation of HOCl to the less microbicidal hypochlorite ion (OCl^-) increases as pH increases, and thus the solution may be rendered ineffective above pH 8.0 (Weber 1950). Mixing NaOCl with acid liberates toxic chlorine gas, and NaOCl decomposes when exposed to light.

Low concentrations of free chlorine are active against *M. tuberculosis* (50 ppm) and vegetative bacteria (<1 ppm) within seconds. Concentrations of 100 ppm destroy fungi in less than 1 hour, and many viruses are inactivated in 10 minutes at 200 ppm. Household bleach is 5.25% (52,500 ppm); thus dilutions of 1:100–1:250 should result in effective germicidal concentrations, although more-concentrated solutions are often recommended (1:10–1:100).

The use of the hypochlorites as disinfectants is limited by several characteristics. Chlorine solutions are corrosive to metals and destroy many fabrics. Because chlorine solutions are unstable to light, they must be prepared fresh daily. Hypochlorites are inactivated by the presence of blood more so than are the organic chlorides (Bloomfield and Miller 1989). They have a strong odor and are not suitable for enclosed spaces. Despite these shortcomings, chlorine solutions are commonly used as low-level disinfectants to sanitize dairy equipment, animal housing quarters, hospital floors, and other noncritical items. Of 12 disinfectant solutions evaluated for their ability to kill the dermatophyte *Microsporum canis,* those containing hypochlorite were most effective. Also found effective were benzalkonium chloride- and glutaraldehyde-based products; phenolics and anionic detergents were considered inadequate (Rycroft and McLay 1991). The hypochlorites are not recommended for use as antiseptics because they are very irritating to skin and other tissues and they delay healing.

Several compounds from a class called N-halamines (oxazolidinones and imidazolidinones) have been developed that are water-soluble solids and have been shown to be bactericidal, fungicidal, virucidal, and protozoacidal in water disinfection at low total halogen concentrations (1–10 mg/L). They are noncorrosive and tasteless and odorless in water. They are extremely stable in water even in the presence of organic loads. Their potential use in poultry processing to control *Salmonella* organisms has been evaluated (Smith et al. 1990).

Chlorhexidine. Chlorhexidine (Chx) is a synthetic cationic compound (1-1′-hexamethylenebis[5-(*p*-chlorophenyl)biguanide]) with better activity against gram-positive organisms than against gram-negative ones. It was found to be superior to PI against *Staphylococcus aureus* infection in dogs (Amber et al. 1983), but some gram-negative bacteria were found to be resistant (Russel 1986). Chlorhexidine kills bacteria by disrupting the cell membrane and precipitating cell contents. It has also been suggested that membrane bound adenosine triphosphatases, specifically inhibition of the F1 ATPase, may be a primary target for Chx (Gayle et al. 1981). It is active against fungi, fairly active against *M. tuberculosis,* but poorly active against viruses. The antibacterial activity of Chx is not as rapid as that of the alcohols; however, as a 0.1% aqueous solution, significant killing action is evident after only 15 seconds. Additionally, Chx solutions have the longest residual activity, remaining chemically active for 5–6 hours and retaining their activity in the presence of blood and other organic material. Being cationic, it is inactivated by hard water, nonionic surfactants, inorganic anions, and soaps. Dilution with saline causes precipitation, and its activity is pH dependent. It has extremely low toxicity even when used on intact skin of newborns (O'Neill et al. 1982).

Chlorhexidine is available in a detergent base as a 4% solution or as a 2% liquid foam. It is widely used as a presurgical antiseptic, wound flush, and teat dip. Its use as a disinfectant has not been described.

Aldehydes. Two related aldehyde disinfectants are formaldehyde and glutaraldehyde (GLT). Formaldehyde has antimicrobial activity both as a gas (see below) and in liquid form. Formalin, the aqueous form, is 37% formaldehyde by weight. It inactivates microorganisms by alkylating the amino and sulfhydryl groups of proteins and ring nitrogen atoms of purine bases (Favero 1983). Formaldehyde is an effective but slow bactericide, virucide, and fungicide, requiring 6–12 hours' contact time. It is effective against *M. tuberculosis,* bacterial spores, and most animal viruses, including foot-and-mouth disease virus. Its action is not affected by organic matter, and it is relatively noncorrosive to metals, paint, and fabric. Formaldehyde alone is considered a high-level disinfectant and in combination with alcohol can be used as a chemical sterilant for surgical instruments. However, due to irritating fumes and pungent odor at low concentrations (~1 ppm), and because the National Institute for Occupational Safety and Health requires it to be handled as a potential carcinogen, thereby limiting worker exposure time, formaldehyde's use as a disinfectant has been limited to certain veterinary applications (see below).

GLT, a saturated dialdehyde, is similar to formaldehyde but without some of its shortcomings. GLT has better bactericidal, virucidal, and sporicidal activity than formaldehyde. Its biocidal activity is related to its ability to alkylate sulfhydryl, hydroxyl, carboxyl, and amino groups affecting RNA, DNA, and protein synthesis (Scott and Gorman 1983). Acidic GLT solutions are not sporicidal; thus, they must be "activated" by alkalinizing agents to a pH between 7.5 and 8.5. Once activated, these solutions have a limited shelf life (14 days) due to polymerization of the GLT molecules (Rutala 1990). Newer formulations (stabilized alkaline GLT, potentiated acid GLT, GLT-phenate) have increased shelf life (28–30 days) and excellent germicidal activity (Pepper 1980).

GLT has gained wide acceptance in high-level disinfection and chemical sterilization due to several favorable properties, including wide spectrum of activity. Low surface tension allows GLT to penetrate blood and exudate without coagulating proteins. It retains its biocidal activity in the presence of organic matter. It is noncorrosive to metal, rubber, and plastic and does not damage lensed instruments. GLT solutions must be used in well-ventilated areas, since air concentrations of 0.2 ppm are irritating to the eyes and nasal passages (CDC 1987).

Contact times of less than 2 minutes for vegetative bacteria, 10 minutes for fungi, and 3 hours for bacterial spores were necessary using a 2% aqueous alkaline GLT solution (Stonehill et al. 1963). Activity against the tubercle bacillus was found to be somewhat variable; at least 20 minutes at room temperature is needed to reliably kill these organisms with 2% GLT. When used as a high-level disinfectant, a minimum of 1% GLT should be used. GLT-phenate formulations should be used with caution since they were shown to be less effective than other aldehyde solutions in decreasing bacterial counts from some medical instruments (Ayliffe et al. 1986). GLT disinfectants were found to more effectively reduce duck hepatitis B virus infectivity when they contained additives such as alcohol, an ammonium chloride derivative, and a surfactant (Murray et al. 1991).

The caustic nature of both formaldehyde and GLT makes them inappropriate as antiseptics, and in fact, protective gloves should be worn when using the aldehyde disinfectants.

Hydrogen Peroxide. Conflicting reports concerning hydrogen peroxide's efficacy as a germicide make evaluating its utility in disinfection and antisepsis difficult. Although it has been reported to have bactericidal (Schaeffer et al. 1980), virucidal (Mentel and Schmidt 1973), and fungicidal (Turner 1983) activity, others believe it to be more effective against bacterial spores (Reybrouk 1985; Baldry 1983) than against vegetative bacteria. For this reason, one author suggests that hydrogen peroxide antiseptic use be restricted to initial treatment of recently contaminated wounds suspected of containing clostridial spores (Reybrouk 1985). Because 3% hydrogen peroxide has been shown to be damaging to tissues including fibroblasts (Lineweaver et al. 1982), it is not considered suitable for routine wound care. It is, however, considered a stable and effective disinfectant and is used in the disinfection of soft contact lenses.

Phenols. Carbolic acid, a phenol, is the oldest example of an antiseptic compound. However, due to severe local and systemic toxicity, it is no longer appropriate for use as an antiseptic. These agents act as cytoplasmic poisons by penetrating and disrupting microbial cell walls. Most commercially available phenolic products contain two or more compounds that act synergistically, resulting in a wider spectrum of activity, including against *M. tuberculosis*. Sodium o-phenylphenol is effective against staphylococci, pseudomonads, mycobacteria, fungi, and lipophilic viruses and against ascarids, strongyles, and tichurids. Cresols are substituted phenols and are more bactericidal and less toxic and caustic than phenols. Phenolics are not recommended for disinfection of anything other than noncritical items, because residual disinfectant on porous materials can cause tissue irritation even when the items have been thoroughly rinsed, because of strong odors, and because of absorption into feed.

Gases. Gases are used primarily as disinfectants for large spaces and for sterilization of sensitive surgical equipment. Ethylene oxide (C_2H_4O) is a water-soluble flammable gas used for gas sterilization. Mixing ethylene oxide with carbon dioxide or fluorocarbons reduces its flammability. Ethylene oxide kills bacteria, fungi, yeasts, viruses, and spores. Bacterial spores are only 2–10 times more resistant to the killing activity than are vegetative cells. It has been shown that the relative humidity of the microenvironment is critical to microbial susceptibility to ethylene oxide. Activity is decreased in the presence of organic matter due to interaction with proteins and nucleic acids. Care must be used to contain the gas, as it has an irritant effect on the skin and eyes and may cause headaches and nausea.

Formaldehyde gas inactivates viruses, fungi, bacteria, and bacterial spores. Its activity is dependent on relative humidity, and its efficacy is thought to peak at less than 50% relative humidity. Formaldehyde has been used for disinfection of hospital linen and for terminal disinfection in certain food-producing industries (see below).

Popriolactone, methyl bromide, and propylene oxide have also been used as gas disinfectants.

of the disinfectant molecule to get to the organism). Certain compounds (hypochlorites and iodines) are more susceptible to this type of interference than others. GLT is less affected by organic contamination than other compounds and is therefore useful for instruments whose surface or design makes them impossible to thoroughly clean. Soil contamination can make large-animal facilities difficult to disinfect and may require removal of surface layers of soil and bedding for complete treatment. The presence of inorganic ions (Ca^{+2}, Mg^{+2}, Na^{+}, and Cl^{-}) may be physically incompatible with certain antiseptics/disinfectants, and therefore dilution with either hard water or saline solutions may render these formulations ineffective.

Organism Type. The sensitivity of different classes (bacteria, fungus, virus, etc.) of organisms has been previously discussed. Within each group, however, differences in sensitivities to the various chemical compounds exist that may render a particular disinfection process ineffective against certain microbes while effective against others. Gram-positive bacteria are in general less resistant to disinfectant/antiseptic compounds than are gram-negative organisms due to a less complex and less lipid-rich outer membrane. Staphylococci are less susceptible to alcohols, glycols, and ethylene oxide than are other cocci. Of the gram-negative bacteria, *Pseudomonas aeruginosa, Escherichia coli,* and *Klebsiella* spp. seem to be more resistant to antimicrobial agents, especially QACs and Chx, than other species. Mycobacteria, due to the hydrophobic nature of their cell walls, are highly resistant to many compounds. *Mycobacterium tuberculosis* is resistant to Chx, acids, and alkalis, while QACs are tuberculostatic. The tuberculosis organism is killed by alcohols, formaldehyde (GLT, but slower killing), and ethylene oxide. Bacterial sporicides include the aldehydes, hydrogen peroxide, hypochlorites, iodine, acid alcohol, and ethylene oxide. By inhibiting germination or spore outgrowth, phenols, QACs, biguanides, and alcohols are sporostatic. The efficacy of most germicides against bacterial spores increases with temperature; however, the most effective method against bacterial spores is moist heat (115° C autoclaving). Fungi are sensitive to chlorine, phenols, iodine compounds, ethylene oxide, and the aldehydes, whereas QACs are fungistatic. Fungal spores are resistant to most disinfectants. The sensitivity of viruses to disinfectant compounds relates to the composition of the viral envelope. The lipid-enveloped viruses are readily inactivated by lipophilic agents such as ether, chloroform, phenols, QACs, and even detergents. The nonenveloped viruses are resistant to these agents but are sensitive to chlorine and the aldehydes. Formaldehyde and β-propriolactone are used to inactivate viruses in the production of viral vaccines utilized in veterinary medicine.

MICROBIAL RESISTANCE TO DISINFECTANTS AND ANTISEPTICS. Bacterial resistance to antibiotics is a well-researched phenomenon. Recent evidence suggests a similar emergence of microbial resistance to actions of certain antiseptics and disinfectants, termed "acquired resistance." This type of resistance is the result of acquisition of either a plasmid or a chromosomal mutation and usually involves previous exposure to the chemical agent. A second type, termed "intrinsic resistance," is most frequently due to the biochemical makeup of the organism or cellular components making them inherently resistant to certain molecules. As an example, the cell walls of gram-negative bacteria and mycobacteria may act as absorption barriers to certain agents, thereby protecting deeper sensitive cellular targets. Bacterial spores similarly exhibit intrinsic resistance to many disinfectants. Table 39.2 illustrates examples of, and suspected mechanisms responsible for, resistance to disinfectant agents. The significance of such resistance in clinical practice is uncertain because unlike with systemic antibiotics, very high concentrations of compound are easily and safely achievable.

ANTISEPTIC USAGE IN VETERINARY MEDICINE. The role of antiseptics in veterinary medicine includes their use in skin cleansers, wound scrubs, and teat dips.

TABLE 39.2—Examples of intrinsic and acquired resistance to certain germicidal agents and suspected mechanisms for each (when known)

Agent	Intrinsic resistance	Mechanism	Acquired resistance	Mechanism
Alcohol	Mycobacteria		*E. coli* K12 mutants	Increase in acidic phopholipids
Phenols			*Staphylococcus aureus*	Lipid enhanced
Quaternary ammonium compounds	Most gram-negative organisms, especially *Pseudomonas aeruginosa;* mycobacteria	Outer membrane	Methycillin-resistant *Staphylococcus aureus*	Plasmid mediated
			Serratia marcescens	Increase in cellular lipid content
Chlorhexidine			*Serratia marcescens*	Alteration of inner cytoplasmic membrane
Hexachlorophane	Gram-negative organisms		*Pseudomonas aeruginosa*	Plasmid conferred

wounds irrigated with 0.05–0.1% Chx diacetate solution had fewer infections than those treated with 0.1–0.5% PI. Concentrations of Chx gluconate 0.5% or greater were effective against *S. aureus* in vitro; however, concentrations above 0.05% were lethal to equine fibroblasts (Redding and Booth 1991) and in a wound model in pigs. Unfortunately, it also delayed healing to a greater extent than other solutions tested, including PI (Archer et al. 1990).

Chlorine solution, such as sodium hypochlorite, was used as an effective wound flush in World War I. Full-strength Dakin's solution (0.5% NaOCl) kills bacteria and fibroblasts, as well as retarding epithelialization in vivo in rats (Lineweaver et al. 1985). Other studies have shown low concentrations (0.025–0.0025%) to be toxic to neutrophils, fibroblasts, and endothelial cells, prompting one author to recommend abandoning the use of NaOCl as an irrigant (Kozol et al. 1988). In contrast, a concentration of 0.025% NaOCl was shown to be bactericidal while having no in vitro and in vivo tissue toxicity, suggesting a modified Dakin's solution may be a safe and effective fluid dressing (Heggers et al. 1991). Chloramine-T (Chlorazene) was shown to reduce in vitro *P. aeruginosa* growth and the ability of the bacteria to colonize experimentally created wounds in guinea pigs. Additionally, Chlorazene did not delay the healing of these wounds at a concentration of 0.03% (Henderson et al. 1989). Thus, it was concluded that this preparation should have no effect on healing of wounds when used to sanitize hydrotherapy units.

Teat Antisepsis. Postmilking teat antisepsis is one of the most effective procedures for reducing clinical and subclinical mastitis during lactation (Bramley and Dodd 1984). An ideal teat dip kills bacteria left on the skin after milking, prevents colonization of the teat orifice by pathogens, and cleans teat lesions without irritating the skin (Pankey et al. 1984). Many products exist with proven efficacy against intramammary infections (IMI) caused by *Streptococcus agalactiae* and *S. aureus*. Mastitis caused by environmental pathogens such as coliforms and non–*S. agalactiae Streptococcus* spp. is more difficult to combat. Since the environment is the reservoir for these organisms, residual activity of an antibacterial is necessary for infection control. In a natural-exposure trial (Oliver et al. 1990), a 0.35% Chx/glycerine emollient was shown to lower new infections caused by non–*S. agalactiae Streptococcus* spp. This combination was also effective against coagulase-negative *Staphylococcus* spp. and *Corynebacterium bovis*. No irritation or chapping of the quarters resulted.

The in vitro germicidal activity of nine commercial teat dips was tested (Larocque et al. 1992). All products tested were found to be effective against *E. coli*, *S. aureus*, and *S. agalactiae*. Chx acetate was found to be only bacteriostatic against *Nocardia* organisms; thus, dips containing this compound should not be used if this organism is present on a farm. The automatic application of an iodine-containing teat dip through the milking machine cluster appeared to be as effective as manual teat dipping in preventing IMI under conditions of artificially high levels of bacterial exposure (Grindal and Priest 1989).

Chlorous acid and chlorine dioxide reduced IMI caused by *Streptococcus uberis* and *S. aureus* significantly better when used for premilk and postmilk dipping than when used as a postmilking teat dip alone. There were no treatment differences against gram-negative bacteria, coagulase-negative *Staphylococcus* spp., and *C. bovis* (Oliver et al. 1993). These authors warn against assuming all teat dips to be safe and effective as premilking dips. Correct use of a premilk dip requires careful drying of the udder since studies have shown that cleaning liquid containing bacteria can drain into the teat cups after milk machine attachment (Galton et al. 1986). These bacteria can both increase milk bacterial counts and cause mastitis. In addition, premilk dip liquid runoff may leave chemical residues in milk. In an attempt to avoid these pitfalls, a 0.5% iodophor-containing gel was developed and compared to routine udder preparation and to premilk dipping with a 0.5% iodophor solution. Gel treatment resulted in low bacterial contamination of milk and teat ends, low somatic cell counts, low milk iodine content, and reduced mastitis. In addition, parlor throughput was higher than with standard predip therapy (Ingawa et al. 1992).

DISINFECTANT USAGE IN VETERINARY MEDICINE. Disinfectants are widely used in veterinary medicine as hospital disinfectants on floors, tables, and walls, on surgical equipment and other instruments before storage, and for disinfection of animal housing facilities. For effective germicidal activity, manufacturer recommendations regarding contact time, dilution, and useful life of a disinfectant solution should be followed. The best disinfectant for a particular situation will depend on the surface's shape, structure, chemical reactivity, and use as well as on the type of contaminating organisms anticipated. It is beyond the scope of this chapter to provide guidelines for disinfectant use in all circumstances; however, a short discussion of their use in production medicine with emphasis on distinguishing features is worthwhile.

A newer disinfectant finding widespread application in over-the-counter human products is triclosan (Irgasan DP300). This compound is incorporated into hand cleansers, dermatologic creams, and even toys. The compound is essentially nontoxic, although data are not available on its relative efficacy compared to the existing compounds described above. It is likely that triclosan will be incorporated into veterinary products.

General Principles. In order to best target disinfection procedures, knowledge of the most likely agent responsible for a clinical outbreak is paramount. Using a compound to which the causative agent is resistant is wasted effort and money. Contamination caused by certain etiologic agents is more easily controlled than contamination by others (e.g., disinfection following *Salmonella* outbreak, a bacteria, compared to Aujeszky's disease, which is caused by a virus). It is also important to understand the mode of transmission of a disease outbreak since this will help identify other measures necessary for control. For example, a disease spread via insect vector would require a different approach than one spread via fomites or direct animal-to-animal contact. Knowledge of the causative agent also allows predictions of its survival in the environment. This would again impact the decision regarding how disinfection should proceed. For instance, survival time of most microorganisms is increased with humidity and in the presence of organic soiling.

For certain diseases (e.g., reportable diseases), a disinfection procedure has been outlined that should be followed to prevent the spread of highly contagious diseases (e.g., foot-and-mouth disease, bluetongue, vesicular stomatitis). This procedure includes the following:

1. Set up to prevent further spread of agent: shut down fans, block water runoff; establish perimeter area for showering in/out.
2. Preliminary disinfection: using low-pressure sprayer, cover all areas to damp down and control infective dust, etc., minimize pooling of disinfectant.
3. Equipment: all portable equipment should be disinfected by soaking; equipment used for decontaminating should be disinfected as well.
4. Removal of gross contamination: manure, soiled bedding, unused feed, insulation, top layer of dirt floors should be scraped and removed.
5. Cleaning: hot water with detergent or disinfectant should be used to remove soiling, starting from the top of the room and working downward; manual scrubbing may be necessary.
6. Water system: if applicable, the water system should be drained and disinfected.
7. Disinfection: following drying, the room should be disinfected again with the appropriate compound at the appropriate dilution.
8. Drying: the room should be allowed to fully dry.
9. Flaming: for some agents (e.g., swine vesicular disease) a flame gun may be necessary on stone or metal surfaces; surfaces should be wetted initially so that areas that have been completed are easily identified.
10. Fumigation: may be necessary for certain persistent agents (foot-and-mouth disease); it should be attempted only if the room can be sealed; formaldehyde is commonly used.

Although considered necessary for control of highly infective, easily spread pathogens, the above listed steps are valuable for the control of other organisms as well.

Special Considerations in Specific Applications

FOOD PRODUCTION AREAS. Two categories of food products exist. Low-risk products are stored at room temperature or need further cooking prior to eating; high-risk products require refrigeration, have short shelf lives, or are eaten without further cooking. Cleaning is necessary to maximize disinfection efficiency. The nature of possible pathogens and the appropriate cleaning agent depend upon the chemical nature of the food being prepared (e.g., sugars are water soluble whereas fats are not). Periodic routine cleaning/disinfecting is recommended to prevent the buildup of soil. Heat is the best disinfectant but impractical in certain situations. Surface-active (attach to surface to prolong contact time) amphoteric and QACs have been suggested as appropriate. See Holah 1995 for further information on disinfection of food production areas.

DAIRY PARLOR. The price of milk is dependent upon bacterial contamination in many countries, which illustrates the importance of hygiene in the dairy industry. Milk is sterile when secreted from the udder. Cleanliness and disinfection of the udder, milking equipment, and environment have been suggested to be more important to limiting contamination of raw milk than refrigeration during storage. The implementation of automated milking and three-times-daily milking have created increased conditions for contamination. The discussion of mastitis is beyond the scope of this chapter; however, it is important to note that the two major classifications of pathogens causing mastitis are those that are contagious and are found principally in the udder and those found in the environment. Control of contagious organisms should be focused on the cow, milking parlor, and barn using pre- and postmilk teat dipping and dry cow treatment. Chlorine, Chx, and iodophors have all been used effectively as teat antiseptics. It should be noted that teat disinfection should not be a substitute for adequate cleaning of the udder. Control of environmental pathogens is accomplished with general cleanliness, effective ventilation, fly control, and adequate sanitation of the milking apparatus (the main source of milk contamination). Procedures for disinfection of equipment vary with the type of equipment but in general will include manual cleaning, descaling, and heat/disinfectant treatment. Disinfectants used for this application, alone or in combination with detergents, include sodium hypochlorite, chlorine-releasing compounds, QACs, and iodophors. See Saran 1995 for further information on disinfection of dairy parlors.

STOCKYARDS. Stockyards, defined as places where groups of animals are brought temporarily before returning to their original housing or moving to new premises, present several unique obstacles to disinfection. Animals being transported to these areas are subject to shipping stresses and therefore decreased immunity. In some circumstances, different species are housed in proximity to one another, allowing the opportunity for organisms to spread to naive hosts. In public situations (e.g., fairs, exhibition centers), large numbers of visitors aid in the spread of infectious organisms. The

capabilities, which are reliant upon good hygiene and disinfection procedures.

Residues in Food Animals

The sulfonamides are one of the oldest groups of antimicrobial compounds still in use today. Sulfanilamide, an amide of sulfanilic acid, was the first sulfonamide used clinically. It was derived from the azo dye Prontosil, and all other sulfonamides produced since have structurally resembled it. Sulfonamides have been in clinical use for 50 years, and widespread resistance has developed against some of them. Sulfonamide-diaminopyrimidine combinations have been used to reduce the incidence of sulfonamide resistance, and this combination has all but replaced single or combination sulfonamide treatment regimens. In addition to microbial resistance, recent concern has focused on the possible carcinogenicity of some sulfonamides in laboratory animals, which may eventually preclude their widespread use in food-producing animals. Previous editions of this text should be consulted for a review of this extensive historical database.

PHARMACOLOGY OF SULFONAMIDES

General. All sulfonamides are derivatives of sulfanilamide (structurally similar to para-aminobenzoic acid), which was, in the 1940s, the first sulfonamide discovered to have antimicrobial activity (see Fig. 40.1). Since then, many structural derivatives of sulfanilamide with differing pharmacokinetic and antimicrobial spectrums have been used in veterinary medicine to treat microbial infections of the respiratory, urinary, gastrointestinal, and central nervous systems. Susceptible organisms include many bacteria, coccidia, chlamydia, and protozoal organisms, including *Toxoplasma* spp.

Sulfonamides are white crystalline powders that are weak organic acids, are relatively insoluble in water, and have a wide range of pK_a values, as shown in Table 40.1. They also show great variability in the extent to which they bind to plasma proteins (15–90%) with respect to individual drugs and species. Sulfonamides are more soluble in alkaline than in neutral or acidic pHs; solubility is enhanced when the sulfonamides are formulated as sodium salts or when in solution in more alkaline environments. Some sulfonamide solutions have pHs between 9 and 10, prohibiting extravascular use. Sulfonamides in general are relatively insoluble in water and tend to undergo crystallization in the urine (acid pH) in vivo, especially in animals that are overdosed, dehydrated, acidotic from disease, or given large doses of a sulfonamide by bolus injection. To minimize crystalluria and obtain high blood or urine levels of the sulfonamides, they are often given in combination with each other. Each sulfonamide in a mixture of sulfonamides exhibits its own solubility in solution (law of independent solubility); i.e., sulfonamides do not significantly affect the solubility of each other, which has important clinical considerations in the excretion of parent compound and any metabolites. However, the antimicrobial effect is additive; thus the use of "triple-sulfas" (three sulfonamides formulated in solution together) allows increased efficacy without a significant increased risk of adverse effects (Prescott and Baggot 1993; Bevill 1988).

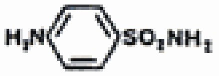

FIG. 40.1—Sulfanilamide

TABLE 40.1—pK$_a$ values for some sulfonamides

Compound	pK$_a$
Sulfanilamide	10.4
Sulfamethazine	7.4
Sulfadiazine	6.4
Sulfadoxine	6.1
Sulfamethoxazole	6.0
Sulfadimethoxine	6.0
Sulfachlorpyridazine	NA
Sulfaquinoxaline	5.5
Sulfamethazine (sulfadimidine)	2.65, 7.4
Sulfabromomethazine	NA
Sulfaethoxypyridazine	NA
Sulfamerazine	NA
Sulfamethazole	5.45
Sulfathiazole	7.1
Sulfisoxazole	4.7
Phthalylsulfathiazole	NA

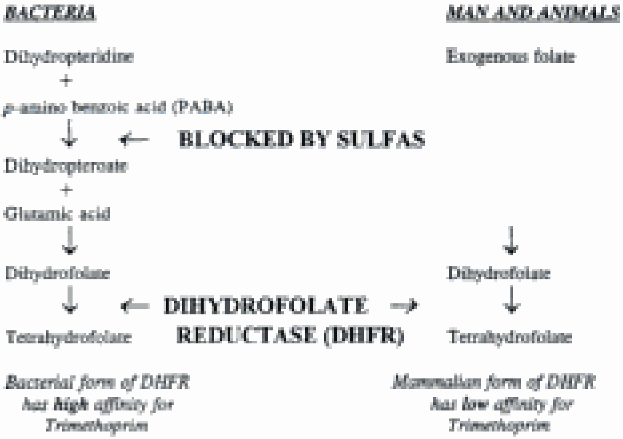
Note: NA = data not available.

Mechanism of Action. For sulfonamides to be therapeutically effective, organisms must intracellularly synthesize their own folic acid. Sulfonamides are antimetabolites, interfering with the normal production of RNA, protein synthesis, and microbial replication mechanisms. Sulfonamides inhibit intermediary metabolism by interfering with the production of folic acid, while the diaminopyrimidines (discussed later in this chapter) interfere in later steps of this metabolic cascade by arresting the production of tetrahydrofolic acid (THFA). Sulfonamides used in the absence of diaminopyrimidines are bacteriostatic. The existing folic acid supply within the susceptible organisms must be consumed before any metabolic effects can begin, which usually occurs within 4–6 hours after administration.

A simplified version of folic acid metabolism is presented in Fig. 40.2.

Para-aminobenzoic acid (PABA), pteridines, glutamic acid, and the enzyme dihydropterate synthase interact to form dihydropteroic acid, the immediate precursor to dihydrofolic acid. Dihydropteroic acid is enzymatically converted to dihydrofolic acid by dihydrofolate synthase, followed by another enzymatic conversion of dihydrofolic acid to THFA via dihydrofolate reductase (DHFR). THFA continues on in this pathway to permit RNA production and bacterial reproduction. PABA and sulfanilamide bear a strong enough structural resemblance for one to be chemically mistaken for the other in the folic acid production pathway. Sulfanilamide, and all sulfonamides, inhibit the biosynthesis of folic acid by being mistakenly substituted for PABA. However, there are sufficient structural differences between the sulfonamides and PABA to not allow the conversion to dihydropteroic acid, hence inhibiting bacterial protein synthesis. Folic acid synthesis can be restored by flooding the system with excess PABA. Mammalian cell metabolic pathways are not inhibited, because mammalian cells utilize preformed folic acid obtained from the diet. Sulfonamides have little effect on those microbial organisms that, like mammalian cells, can utilize preformed folic acid (Prescott and Baggot 1993; Bevill 1988).



BACTERIA
MAN AND ANIMALS
Dihydropteridine

Tetrahydrofolate
Bacterial form of DHFR has high affinity for Trimethoprim
Mammalian form of DHFR has low affinity for Trimethoprim

FIG. 40.2—Schematic representation of the mechanism of action of the sulfonamides and trimethoprim. (Adapted from Davis and Jackson 1973.)

Clinical Uses and Microbial Susceptibility. The spectrum of activity for the sulfonamides is broad, affecting gram-positive, gram-negative, and many protozoal organisms, and is bacteriostatic rather than bactericidal. As stated earlier, sulfonamides have been used clinically for approximately 50 years, with many organisms once quite susceptible to the sulfonamides now being resistant. Combining sulfonamides with diaminopyrimidines has markedly increased the spectrum of activity and is the most common sulfonamide preparation used in veterinary antimicrobial therapy today. Single or combination sulfonamide therapy is common in food-animal medicine, with sulfonamide-diaminopyrimidine combinations being used more frequently in large animals. Specific microbial susceptibility patterns for each sulfonamide will be discussed in more detail later in this chapter; however, Table 40.2 illustrates the general susceptibility/resistance patterns of most sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole combinations against the most commonly encountered veterinary pathogens. In vitro susceptibility patterns of many pathogens (Van Duijkeren et al. 1994b) and more specifically *Salmonella* spp. (Van Duijkeren et al. 1994a) that affect the horse have been recently reported.

Sulfonamides are used to treat infections of the CNS, respiratory tract, gastrointestinal tract (among a variety

TABLE 40.3—Classification of sulfonamides based on plasma concentration versus time profiles

Short-acting sulfonamides	Intermediate-acting sulfonamides	Long-acting sulfonamides	Enteric sulfonamides
Sulfacetamide	Sulfadimethoxine	Sulfamethylphenazole	Succinylsulfathiazole
Sulfamethazole	Sulfisoxazole	Sulfabromomethazine	Sulfaguanidine
Trisulfapyrimidine (triple sulfas)	Sulfamethoxazole	Sulfabromethazine	Sulfaquinoxaline
	Sulfapyridine	Sulfadimethoxine	Phthalylsulfathiazole (sulfathalidine)
Sulfathiazole	Sulfachlorpyridazine	Sulfamethazine	
	Sulfamethazine	Sulfaethoxypyridazine	Sulfasalazine
Sulfisoxazole	Sulfadiazine		

ever, diaminopyrimidine-sulfonamide combinations have been successful when administered orally or parenterally to treat susceptible microbial skin infections. Silver sulfadiazine and mafenide are the only two sulfonamides that may be used topically. Only sulfonamides with neutral or near-neutral pHs (e.g., sulfacetamide) can be used in ophthalmic preparations.

Sulfonamides are also classified as short-, intermediate-, and long-acting according to plasma concentration-time profile. Sulfonamides are considered short-acting if after one therapeutic dose, blood concentrations remain above 50 µg/mL for less than 12 hours after dosing, intermediate if these plasma levels are obtained between 12 and 24 hours, and long-acting if obtained 24 hours after dosing. A fourth class, the enteric sulfonamides, are not absorbed (or minimally absorbed) from the gastrointestinal tract after oral administration but act locally within the lumen of the gastrointestinal tract. Sulfonamides that are used in veterinary medicine are classified using this method in Table 40.3.

Distribution. Sulfonamides are widely distributed throughout the body and into many soft tissues, including the CNS (cerebrospinal fluid) and joints (synovial fluid), making these compounds one of the few antimicrobials that can obtain therapeutic concentrations of drug in these environments. Binding to plasma proteins, usually to albumin, varies from sulfonamide to sulfonamide and from species to species and ranges from 15 to 90% (USPDI 1998). High protein binding markedly increases the half-life of sulfonamides; however, only the un-ionized and non-protein-bound sulfonamide is pharmacologically active. Since the sulfonamides are weak acids, their pHs generally do not support significant partitioning into milk; however, passive diffusion does occur to some extent. Concentrations are generally low, making them of limited use for the treatment of mastitis in most mammals.

Metabolism. Acetylation (mainly occurring in the liver and lung) is the major pathway by which sulfonamides are metabolized in most species. Ruminants metabolize sulfonamides by acetylation pathways, and apparently acetylated metabolites are the major urinary metabolites in cattle, sheep, and swine. The canine lacks the ability to acetylate aromatic amines, relying on alternative metabolic pathways to convert sulfonamides to less active forms. Acetylated metabolites are less soluble than the parent compounds and increase the risks of renal tubular damage due to precipitation and crystal formation. Glucuronide conjugation and aromatic hydroxylation are two additional metabolic pathways by which sulfonamides are metabolized in animals. Glucuronide metabolites are highly water soluble and are generally excreted quickly without the possibility of precipitation in the urine. Deacetylation, oxidation, deamination, conjugation with sulfate, and cleavage of heterocyclic rings of sulfonamide molecules have also been reported (Bevill 1988). Regardless of the metabolic pathway taken, all metabolites either display reduced therapeutic activity (hydroxy metabolite) or are therapeutically inactive (N_4-acetyl metabolite).

Excretion. Sulfonamides that are capable of obtaining therapeutic blood concentrations (i.e., all sulfonamides except the enteric, or "gut-active," compounds) are excreted by the kidneys, either as the parent compound or as metabolites by way of glomerular filtration (unbound to plasma proteins), active carrier-mediated proximal tubular excretion, or passive absorption of the nonionized drug from the distal tubular fluid. Sulfonamides are also excreted in the tears, feces, bile, milk, and sweat. Low urine pHs favor tubular reabsorption and hence longer half-lives of the sulfonamides, whereas alkalinization of the urine increases urinary excretion by slowing this pH-dependent passive reabsorption in the tubules. Many of the long-acting sulfonamides, with extended half-lives in the body, undergo extensive tubular reabsorption in addition to some enterohepatic recycling. Enteric sulfonamides are primarily eliminated via the feces, with little of the active or metabolized drug being absorbed systemically to be excreted by these renal mechanisms.

Toxicity. Sulfonamide-induced toxicoses may be classified as nonimmunologic or immunologic in etiology. A retrospective evaluation of dermal adverse reactions due to trimethoprim-sulfonamide combinations used in male dogs and cats has been presented by Noli et al. (1995). Of the immunologic sulfonamide-induced toxicoses, most have been documented in the canine. Brief descriptions of possible sulfonamide toxicoses are given below.

CRYSTALLURIA. Crystalluria, hematuria, and renal tubule blockage can occur due to precipitation of the

Sulfadimethoxine has been formulated with ormetoprim to enhance the spectrum of antimicrobial activity against some bovine pathogens. This combination has been shown to be highly effective in treating calves with experimentally induced *Pasteurella hemolytica* pneumonia. Wilson et al. (1987) investigated the potential efficacy of a sulfadimethoxine-ormetoprim combination administered orally and IV to treat *Moraxella bovis* infections in cattle. In cattle, sulfadimethoxine-ormetoprim administered IV was effective in maintaining sufficiently high concentrations of both drugs in the tears to exceed the known MICs of 13 *Moraxella bovis* isolates and in maintaining those concentrations for approximately 6 hours. However, when the same concentration of sulfadimethoxine-ormetoprim was administered orally, sulfadimethoxine appeared in low concentrations and ormetoprim in very low or trace concentrations in the tears, indicating this combination of drugs when administered orally is not suitable for treating *Moraxella bovis* infections in cattle.

Studies by Righter et al. (1979) examined the pharmacokinetics of sulfadimethoxine in mature, growing, and suckling pigs. Mature pigs dosed with 20, 50, or 100 mg/kg of sulfadimethoxine IV had V_d values of 0.178, 0.258, and 0.331 L/kg and total body clearance of 4.21, 5.54, and 7.37 mL/hr/kg, respectively. The pharmacokinetic parameters of 55 mg/kg sulfadimethoxine given IV to growing and suckling pigs have also been reported. Suckling pigs (1–2 weeks old) had sulfadimethoxine half-lives of 16.16 hours, V_d = 0.483 L/kg, and total body clearance of 20.9 mL/kg/hr. In contrast, growing pigs (11–12 weeks old) had sulfadimethoxine half-lives of 9.35 hours, V_d = 0.347 L/kg, and total body clearance of 26.1 mL/kg/hr, indicating an age-related effect of sulfadimethoxine pharmacokinetics in young pigs. Weanling pigs consuming water dosed with 0.05 g sulfadimethoxine/100 mL showed mean plasma concentrations of 80 ppm 12 hours after introduction of the medicated water, with plasma concentrations declining to approximately 50 ppm thereafter. Total water consumption was not affected, indicating sulfadimethoxine may be of therapeutic use in swine provided that water consumption is maintained throughout the medication period. Mengelers et al. (1995) dosed 34–40 kg healthy and febrile (inoculated endobronchially with *A. pleuropneumoniae* toxins) pigs with 25 mg/kg sulfadimethoxine and 5 mg/kg trimethoprim IV. Sulfadimethoxine plasma half-lives for both healthy and pneumonic pigs were not significantly different (approximately 13 hr). Trimethoprim half-lives were not significantly different between healthy and pneumonic pigs (approximately 2.7 hr); however, the half-lives were significantly shorter than the half-life of sulfadimethoxine. In addition, the V_d values of healthy and pneumonic pigs receiving sulfadimethoxine were not significantly different (approximately 0.25 L/kg), but trimethoprim did show significant differences between healthy (1.21 L/kg) and pneumonic (1.49 L/kg) pigs. The mean area under the curve (AUC) of trimethoprim was decreased and the total body clearance was increased in the febrile pigs, but with no significant changes in these sulfadimethoxine pharmacokinetic parameters.

The in vitro susceptibility of some porcine pathogens to sulfadimethoxine, other sulfonamides, and other antimicrobial agents has been reported (Mengelers et al. 1990). Sulfadimethoxine has also been implicated as being goitrogenic to swine fetuses in late gestation (Blackwell et al. 1989).

Fewer reports are available on the pharmacokinetics of sulfadimethoxine in horses. Brown et al. (1989) administered sulfadimethoxine-ormetoprim (45.8 mg/kg:9.2 mg/kg) orally, followed by lower oral doses (22.9 mg/kg:4.6 mg/kg) at 24-hour intervals, to healthy adult mares. Sulfadimethoxine showed peak plasma concentrations 8 hours after the initial dose, and plasma concentrations above 50 µg/mL were maintained for the entire dosing schedule. Significant concentrations were also found in the synovial fluid, peritoneal fluid, endometrium, and urine, with a small amount (2.1 µg/mL) appearing in the cerebrospinal fluid approximately 100 hours after the initial dose.

The pharmacokinetic parameters of sulfadimethoxine-ormetoprim were determined in 1- to 3-day-old foals given a sulfadimethoxine-ormetoprim dose (17.5 mg/kg:3.5 mg/kg) orally (Brown et al. 1993). In the foals, sulfadimethoxine concentrations peaked at 8 hours (55 µg/mL) after the oral dose and declined to 37.6 µg/mL 24 hours after the dose.

Sulfadimethoxine usage has also been described in species in which sulfadimethoxine is less commonly used, including turkeys (Epstein and Ashworth 1989), dogs (Yagi et al. 1981; Fish et al. 1965; Dunbar and Foreyt 1985; Imamura et al. 1986; Imamura et al. 1989), primates (Adamson et al. 1970; Bridges et al. 1968), lobsters (James and Barron 1988), channel catfish (Squibb et al. 1988), and rainbow trout (Kleinow and Lech 1988). A promising method for detecting violative levels of sulfadimethoxine residues in channel catfish has also been reported (Walker and Barker 1993).

Sulfamethazine (Sulfadimidine). The chemical structure of sulfamethazine (sulfadimidine) is shown in Fig. 40.4. Sulfamethazine, like many sulfonamides, has been utilized for decades in veterinary medicine; hence, the veterinary literature contains many reports on its usage in a wide variety of animals, including cattle, horses, swine, poultry, small ruminants, and rabbits (among others). Table 40.4 summarizes some of the pharmacokinetic parameters of sulfamethazine in animals.

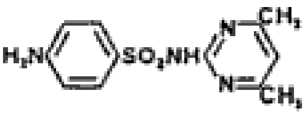

FIG. 40.4—Sulfamethazine (sulfadimidine)

Sulfamethazine has been utilized extensively in cattle and swine for a number of years. Sulfamethazine has been formulated for use in the drinking water (Church et al. 1979) and as a feed additive, an extended-release bolus, and an IV preparation. Sulfamethazine has been marketed by itself and in combination with other antimicrobials, such as other sulfonamides, tylosin, chlortetracycline, and procaine penicillin G. The basic pharmacokinetic parameters of sulfamethazine in cattle have been reported by Bevill et al. (1977a) and Nouws et al. (1988), among many others. Of particular interest are the oral forms of sulfamethazine that have been formulated in extended-release (sustained-release) form for cattle. Several reports on the efficacy and clinical uses of the extended-release form of sulfamethazine in cattle are available (Clark et al. 1966; Ellison et al. 1967; Miller et al. 1969; Carlson et al. 1976). This sustained-release formulation has been reported to achieve therapeutic blood levels (i.e., 50 μg/mL) within 6–12 hours after oral administration and to maintain or exceed that level for 2–5 days after dosing. The sustained-release formulation of sulfamethazine has been reported to be highly efficacious in the treatment of shipping fever pneumonia, diphtheria, and pneumonia in cattle (Carlson et al. 1976; Clark et al. 1966). Clearance of sulfamethazine and its metabolites in cattle are age and dose dependent (Nouws et al. 1986a; Lapka et al. 1980; Nouws et al. 1985; Nouws et al. 1983). Several metabolites of sulfamethazine have been identified and described in both adult cattle and calves (Nouws et al. 1988c).

The pharmacokinetics of sulfamethazine and its metabolites are of particular interest in swine. Sulfonamides had been one of the most common causes of food-residue violations reported by the US Food Safety Inspection Service, with swine being the food-animal species with the greatest number of residue violations (Sweeney et al. 1993). Sulfamethazine and its metabolites are most often associated with violative levels in pork products because of sulfamethazine's widespread use as a swine feed additive. Sulfamethazine has been used extensively to treat a host of susceptible microbial infections in swine, including *Salmonella typhisuis* (Fenwick and Olander 1987) and *Bordetella bronchiseptica* (Kobland et al. 1984). Pharmacokinetic parameters have been described by Sweeney et al. (1993) and others (see Table 40.4), including its metabolites (Nouws et al. 1989a; Nouws et al. 1986b). Several studies have used radiolabeled (Mitchell et al. 1986; Mitchell and Paulson 1986) and nonradiolabeled (Biehl et al. 1981; Ashworth et al. 1986) sulfamethazine to determine the elimination patterns of sulfamethazine and its metabolites from the tissues in swine. Other studies have shown that the major metabolites produced from sulfamethazine metabolism in swine are sulfamethazine (parent compound), N_4-acetylsulfamethazine, N_4-glucose conjugate of sulfamethazine, and desaminosulfamethazine (Mitchell et al. 1986). Studies using pigs fed 110 ppm of ^{14}C-sulfamethazine in the feed for 3–7 days, euthanized, and their tissues examined for total radioactivity and metabolite content found the highest concentration of radioactivity in the gut (undigested feed). Blood, kidney, urine, and liver all had high concentrations of radioactivity (i.e., parent compound and metabolite). Adipose tissue contained the least amount of radioactivity of all tissues assayed (Mitchell et al. 1986). Specific metabolites found in these and other tissues of swine given ^{14}C-labeled sulfamethazine in the feed have been reported by Mitchell and Paulson (1986). Other studies have also reported on sulfamethazine residues in swine (Ashworth et al. 1986; Biehl et al. 1981).

Cattle and swine are the two major species in which sulfamethazine is approved for use. There are fewer reports on the clinical use of sulfamethazine in other domestic animals. Pharmacokinetic parameters and/or tissue-depletion kinetics of sulfamethazine and metabolites have been established in ponies (Wilson et al. 1989; Nouws et al. 1987) and horses (Nouws et al. 1985a). Studies have focused on the pharmacokinetic parameters of sulfadimidine in goats (Abdullah and Baggot 1988; Witcamp et al. 1992; Nouws et al. 1989b; Elsheikh et al. 1991; Youssef et al. 1981; van Gogh et al. 1984; Witcamp et al. 1993; Nouws et al. 1988b), sheep (Srivastava and Rampal 1990; Bourne et al. 1977; Bevill et al. 1977c; Bulgin et al. 1991; Nawaz and Nawaz 1983), dogs (Riffat et al. 1982), chickens (Righter et al. 1971; Nouws et al. 1988a; Goren et al. 1987), rabbits (Yuan and Fung 1990), mice (Littlefield et al. 1989), buffalo (Singh et al. 1988), camels (Younan et al. 1989), and carp and rainbow trout (van Ginneken et al. 1991).

A recent report by Lashev et al. (1995) described altered pharmacokinetics in roosters treated with a single 50 mg/kg IV dose of sulfadimidine only or IV sulfadimidine after two weeks of four 3.5 mg/kg subcutaneous (SC) testosterone treatments. Normal and castrated roosters provided no significant differences in $t_{1/2\beta}$ values, which ranged from 7.62 hours (castrated) to 9.38 hours (intact). Roosters pretreated with testosterone and then dosed with sulfadimidine had a $t_{1/2\beta}$ value of 23.85 hours, as well as significantly decreased Cl_B and $V_{d(area)}$ values. Chickens metabolize sulfadimidine in relatively equal parts through hydroxylation and acetylation. It was hypothesized in this study that the acetylation pathway of sulfadimidine metabolism was retarded by the testosterone treatments and resulted in the prolonged half-lives.

Sulfaquinoxaline. The chemical structure of sulfaquinoxaline is shown in Fig. 40.5. Sulfaquinoxaline has primarily been utilized in poultry for control of coccidia and some susceptible bacterial diseases. The veterinary literature also contains a few reports of sulfaquinoxaline use in rabbits (Eppel and Thiessen 1984; Joyner et al. 1983) and canines (Brown et al. 1982; Patterson and Grenn 1975).

Sulfaquinoxaline alone or in combination with a diaminopyrimidine has been used extensively to con-

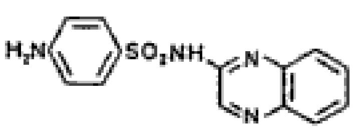

FIG. 40.5—Sulfaquinoxaline

trol coccidiosis in poultry in the United States. Mathis and McDougald (1984) described the therapeutic effectiveness of sulfaquinoxaline and sulfaquinoxaline-pyrimethamine against several species of *Eimeria* coccidia. It was determined from that study that both sulfaquinoxaline and sulfaquinoxaline-pyrimethamine were highly effective against *E. acervulina* but less effective against *E. tenella*. In addition, the potentiated mixture was determined to be more effective against *E. tenella* than sulfaquinoxaline alone, although neither mixture was found to be particularly effective against any cecal coccidia. Amprolium was found to be efficacious against cecal-dwelling forms of coccidia; hence amprolium has been combined with sulfaquinoxaline or sulfaquinoxaline-pyrimethamine to enhance the spectrum of activity. Ineffectiveness of sulfaquinoxaline-pyrimethamine against *E. tenella* has also been documented in another study (Chapman 1989), underlining the importance of correct coccidia species identification before instituting anticoccidial therapy with sulfaquinoxaline or any other sulfonamide.

Banerjee et al. (1974) reported that hens receiving 275 mg/kg PO once had average mean peak blood levels of 16.1 mg/dL of free drug 12 hours after administration, with this level decreasing to 12.7 mg/dL by 24 hours (8–10 mg/dL was considered to be therapeutically effective). In that same study, sulfaquinoxaline was found in high concentrations in the liver, kidney, and cecum, with the lowest concentrations found in the yolk sac and brain. A single oral dose of ^{35}S-labeled sulfaquinoxaline in 1-week-old chicks showed rapid uptake from the gastrointestinal tract and wide distribution throughout the body, including crossing of the blood-brain barrier. At 0.5 hours after dosing, autoradiography showed that all tissues (brain, lung, liver, kidney, fat, and muscle) except the lens of the eye had measurable concentrations of sulfaquinoxaline. Similar findings resulted from IV administration of ^{35}S-labeled sulfaquinoxaline, and it was also found that excretion of sulfaquinoxaline by the bile and secretion by the cecal mucosa, crop, and gizzard probably occur. Interestingly, oral dosing with sulfaquinoxaline of chickens with *E. acervulina* and *E. tenella* increases the absorption of the drug approximately 3.5 times over that found in uninfected birds (Williams et al. 1995). A study by Qiao et al. (1995) found that in 7- to 8-week-old male and female broilers given a single 200 mg/kg oral dose of sulfaquinoxaline, peak concentration times in plasma and liver were similar (4 hr) but were longer in the heart, kidney, and muscle (6 hr). The half-life of sulfaquinoxaline was the shortest in the muscle (4.5 hr), with significantly longer half-lives in the heart (10 hr), plasma (11 hr), liver (13 hr), and kidney (18 hr).

The safety and efficacy of sulfaquinoxaline alone or in combination with trimethoprim (trimethoprim:sulfaquinoxaline = 1:3) have been reported in poultry (White and Williams 1983; Piercy et al. 1984; Sainsbury 1988). A total dose of 30 mg/kg/day PO satisfactorily controlled experimentally induced colisepticemia and pasteurellosis in addition to 5 species of coccidia (White and Williams 1983). A wide margin of safety has been shown for the 1:3 combination of trimethoprim:sulfaquinoxaline in poultry, although decreased appetite and water consumption and lowered egg production, egg weight, and hatchability were noted when these antimicrobials were incorporated in the feed or water in higher than recommended concentrations (Piercy et al. 1984).

Toxicosis from sulfaquinoxaline use in animals has been infrequently reported. Toxicity from sulfaquinoxaline has occurred in Leghorn chickens (Daft et al. 1989), where a mortality of 47% was reported in a commercial flock given a 0.05% concentration of sulfaquinoxaline in the feed. Lesions included mildly enlarged livers; swollen and pale livers; hemorrhages on the epicardium, kidney, oviduct, small intestine, and cecum; pale bone marrow; and gangrenous dermatitis; and some lung involvement was present. Patterson and Grenn (1975) reported a situation where 12 adult Miniature Poodles that received 3.16 g/L of sulfaquinoxaline in the drinking water as treatment for coccidiosis suffered similar lesions as described above in poultry, in addition to depressed body temperature, pale mucous membranes, microscopic hemorrhages of the jejunum and ileum, and prolonged prothrombin times. Treatment with vitamin K was efficacious in all dogs treated. Although the exact mechanism has not been reported, sulfaquinoxaline possesses an ability to produce a marked hypothrombinemia, even in animals receiving balanced diets containing adequate amounts of vitamin K. It is thought that this adverse effect is not related to the individual sulfonamide or quinoxaline portion of the sulfaquinoxaline molecule but occurs only when the two entities are combined. A similar toxicosis has also been reported in coyote pups treated with sulfaquinoxaline (Brown et al. 1982).

Sulfamerazine. The chemical structure of sulfamerazine is shown in Fig. 40.6. Sulfamerazine has primarily been utilized in adult sheep and lambs to treat susceptible microbial infections. Sulfamerazine has been used alone or in combination with other

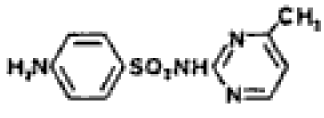

FIG. 40.6—Sulfamerazine

antibiotics (tylosin) and other sulfonamides (sulfamethazine, sulfadiazine).

The pharmacokinetics of sulfamerazine has been described for ewes and lambs. Hayashi et al. (1979) described the pharmacokinetics of sulfamerazine in ewes dosed IV or PO with 107 mg/kg. In the IV studies, the V_d was 0.266 L/kg, and the half-life calculated to be 2.55 hours. The biological half-life was determined to be 6.6 hours. For the oral study, the bioavailability of sulfamerazine administered as a 12.5% oral solution was 81 ± 19%. Urinary concentrations of parent compound and metabolites were also reported for both IV- and PO-dosing studies. Both routes produced appreciable concentrations of sulfamerazine and three metabolites in the urine (described as acetylsulfamerazine, "polar" metabolite, and third metabolite as determined by thin-layer chromatography). IV sulfamerazine produced more parent compound in the urine than did the PO route (31% vs. 21%), and more polar metabolite was produced via the PO route than via the IV route (19% vs. 10%). More parent compound was found in the IV study due to lack of rumen metabolism, while more metabolite than parent compound was found in the PO study due to rumen metabolism. In a similar pharmacokinetic study, Garwacki et al. (1991) administered 60 mg/kg sulfamerazine IV in fasted sheep and in sheep fed ad libitum. That study determined that sheep fed ad libitum had a sulfamerazine $t_{1/2}$ of 5.72 hours and a V_d of 0.40 L/kg, while those sheep that were fasted had a $t_{1/2}$ of 6.91 hours and a V_d of 0.41 L/kg. The authors proposed that since sulfamerazine is an acidic drug ($pK_a = 7$), it preferred the ruminal pH environment in the fasted state, and hence a reservoir of drug was established in the rumen that resulted in the prolonged half-life.

The pharmacokinetics of sulfamerazine has also been reported in neonatal and young lambs (Debacker et al. 1982). Lambs from birth to 16 weeks of age were dosed either IV or PO with 100 mg/kg of sulfamerazine. In the IV study, it was found that the sulfamerazine half-life was longest in the first week of life (9–14 hours) and decreased to 4–7 hours by 9–16 weeks of age. Likewise V_d was highest during the first week of life and steadily decreased with age, while clearance of sulfamerazine was lowest in the first week of life (20–40 mL/kg/hr) and steadily increased with age up to 9–16 weeks of age (50–80 mL/kg/hr). In the oral study, plasma concentrations of sulfamerazine tended to decrease more slowly after dosing in the early weeks of life (<4 weeks of age), with plasma clearance of the drug steadily increasing after 4 weeks of age until 16 weeks, when it approached the adult values.

Sulfathiazole. The chemical structure of sulfathiazole is shown in Fig. 40.7. Sulfathiazole has been used in veterinary medicine since its synthesis (Koritz et al. 1977), but today it is formulated in combination with chlortetracycline HCl and procaine penicillin G. Few recent reports are available on its use and thus earlier editions of this text should be consulted for more details. A few reports have described the pharmacokinetics of sulfathiazole in sheep and swine.

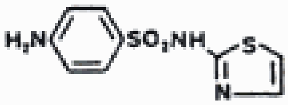

FIG. 40.7—Sulfathiazole

Sulfathiazole pharmacokinetics in sheep has been outlined by Koritz et al. (1977), and sulfathiazole tissue residues in sheep have been described by Bevill et al. (1977b). When 36 or 72 mg/kg of 5% aqueous solution of sulfathiazole sodium IV was given to ewe lambs, it cleared quickly from the plasma, having V_d values of 0.34 and 0.59 L/kg and half-lives of 1.2 and 1.4 hours, respectively. Ewes given 214 mg/kg orally of a 12.5% aqueous solution of sulfathiazole sodium cleared the drug from plasma much more slowly than by the IV route, with the systemic bioavailability being approximately 73%, with a half-life of approximately 18 hours. Both PO and IV routes resulted in parent compound accompanied by acetylsulfathiazole and a third "polar" metabolite in the urine of these sheep. In the study by Bevill et al. (1977b), sheep given IV doses of 36 mg/kg sulfathiazole sodium had a lower mean V_d value than the 72 mg/kg dose (0.389 L/kg), but a comparable half-life to that found by Koritz (1.1 hours). Sulfathiazole residues in sheep 2 hours after a 72 mg/kg IV dose were also determined, with the highest concentrations of drug found in the kidney (308 ppm), followed by the liver (40 ppm), heart (34 ppm), shoulder muscle (23 ppm), leg and loin muscle (22 ppm), body fat (11 ppm), and omental fat (6.7 ppm). Residues quickly dropped to very low (<0.13 ppm) or to nondetectable levels by 24 hours after dosing in all tissues tested.

Pharmacokinetic parameters have also been reported for swine. Pigs given 72 mg/kg of sulfathiazole sodium IV had quick plasma elimination of the drug, with mean V_d of 0.54 L/kg and a biological half-life of 1.39 hours, similar to those for sheep. Given 214 mg/kg orally, sulfathiazole had a V_d of 0.32 L/kg and a systemic bioavailability of 73%, identical to that of sheep.

Sulfasalazine (Salicylazosulfapyridine). The chemical structure of sulfasalazine is shown in Fig. 40.8. Sulfasalazine was originally developed as a possible treatment for rheumatoid arthritis in humans. It was found, however, to be more effective in the treatment of inflammatory bowel disease. Few reports are available in the veterinary literature on the pharmacokinetics and use of sulfasalazine in animals. It has been used with some success in some animals (mainly dogs) to treat various forms of colitis (Aronson and Kirk 1983). Many forms of inflammatory bowel diseases (most commonly ulcerative colitis and Crohn's disease) have been treated with sulfasalazine in humans.

It is usually found in the potentiated form with trimethoprim and may be combined with other antimicrobials such as sulfamethazine, sulfamerazine, and tylosin for use in food-producing animals. The trimethoprim-sulfadiazine combination (TMS) in a 1:5 ratio was found to be clinically useful in dogs and cats against a wide variety of pathogens, in particular *Staphylococcus* spp., *Streptococcus* spp., *Corynebacterium* spp., *Clostridium* spp., and several gram-negative organisms, such as *Proteus* spp., *Salmonella* spp., *Pasteurella* spp., and *Klebsiella* spp., among many others (Cannon 1976; McCaig 1970; Craig and White 1976). Toxicologic studies confirmed its safety in both dogs and cats (Craig and White 1976). In the Craig and White study, dogs were dosed with up to 300 mg/kg/day orally (10 times the normal dose) of TMS for as long as 20 days with no abnormal clinical signs or blood or serum chemistry abnormalities reported. Cats were dosed with 30–300 mg/kg/day orally for 10–30 days and were more sensitive to the TMS combination. The cats receiving the 300 mg/kg dose showed signs of lethargy, anorexia, anemia, leukopenia, and altered blood urea nitrogen (BUN). Despite these alterations, both dogs and cats have a wide margin of safety when administered TMS.

TMS combinations have been used to treat urinary tract infections in dogs and cats (Ling et al. 1984). TMS has been shown to be effective in treating urinary tract infections caused by *Staphylococcus intermedius* (Turnwald et al. 1986) as well as the more common pathogens such as *E. coli, Proteus mirabilis, Klebsiella pneumoniae,* and *Streptococcus* spp. (Ling and Ruby 1979; Ling et al. 1984). Beagle dogs treated with 40 mg:200 mg TMS or that dose divided into two were found to have high concentrations of both sulfadiazine and trimethoprim in their urine that greatly exceeded the MIC values for most susceptible pathogens (Sigel et al. 1981).

In addition to being of value in treating urinary tract infections, TMS has also demonstrated usefulness in the treatment of many bacterial skin diseases. Success rates of 90% (skin diseases either cured or improved) in bacterial skin infections, foot infections, interdigital abscesses, anal abscesses, and infections of the eye, ear, and mouth in dogs have been reported. A similar success rate was reported in cats (89%) with bites and other infections. An overall success rate of 85% was reported in dogs and cats treated with a TMS combination for microbial diseases involving the alimentary, respiratory, urogenital, skin, and other systems (Craig 1972). Dogs administered 30 mg/kg of TMS orally at 12- or 24-hour intervals were found to attain therapeutically useful concentrations of both trimethoprim and sulfadiazine in the skin (Pohlenz-Zertuche et al. 1992).

Sulfadiazine has also demonstrated an ability to control plaque and gingivitis in Beagles (Howell et al. 1989) and has attained concentrations in the cerebrospinal fluid (when administered IV) above the reported MIC values for many of the Enterobacteriaceae family (Vergin et al. 1984). TMS has also been reported to be of potential therapeutic use in cases of *Streptococcus zooepidemicus* (McCandlish and Thompson 1979) and *Bordetella bronchiseptica* (Powers et al. 1980) in dogs and in ocular infections (Sigel et al. 1981).

Sulfadiazine pharmacokinetics in dog prostates has also been reported (Robb et al. 1971). In that study, sulfadiazine (a weak acid) was found to penetrate the prostate to approximately 11% that of the mean plasma concentration. The penetration abilities of other sulfonamides (including sulfadiazine) are strongly pK_a dependent, with those sulfonamides with higher pK_a values penetrating at accelerated rates. Trimethoprim (a weak base with a pK_a of 7.3) penetrated the prostatic environment at a concentration 380% higher than that of plasma.

TMS has found similar uses in the treatment of susceptible microbial infections in cattle (Slaughter 1972). No difference in trimethoprim or sulfadiazine concentrations in the synovial fluid of normal neonatal calves administered TMS IV or in those calves with experimentally induced synovitis has been demonstrated (Shoaf et al. 1986). The pharmacokinetics of sulfadiazine and trimethoprim has been studied extensively in calves and in cattle (see Tables 40.5 and 40.6). Age and diet can markedly affect trimethoprim and oral sulfadiazine disposition in calves (Guard et al. 1986; Shoaf et al. 1987). Orally administered sulfadiazine (30 mg/kg) was absorbed very slowly in those calves fed milk diets, with absorption slightly higher in ruminating calves. Calves given sulfadiazine subcutaneously (30 mg/kg) had a rapid absorption of the drug; age and diet had no effect on sulfadiazine or trimethoprim disposition in those calves (Shoaf et al. 1987). In another study by Guard et al. (1986), calves 1 day of age showed higher serum and synovial fluid concentrations of trimethoprim and sulfadiazine than did calves of 1 week or 6 weeks of age. Sulfadiazine is acetylated to a great degree in calves and cows, with lower concentrations of the 4-hydroxysulfadiazine being observed and with no glucuronide or 5-hydroxy derivatives detected in this species (Nouws et al. 1988c). TMS concentrations can also be obtained in the cerebrospinal fluid of neonatal calves (Shoaf et al. 1989). A pharmacokinetic model has been developed for determining the metabolic depletion of sulfadiazine (Woolly and Sigel 1982).

Sulfadiazine's use has also been reported in pigs (Soli et al. 1990; Guise et al. 1986), carp (Nouws et al. 1993), ewes (Youssef et al. 1981), and horses (White and Prior 1982; Divers et al. 1981; Bertone et al. 1988). Trimethoprim (8 mg/kg)-sulfadiazine (40 mg/kg) was administered orally to pigs to determine bioavailability and other pharmacokinetic parameters. Bioavailability of sulfadiazine was 89% and 85% in fasted and fed pigs, respectively, while the trimethoprim resulted in bioavailabilities of 90% and 92%. After IV administration of trimethoprim (4 mg/kg)-sulfadiazine (20 mg/kg), sulfadiazine was detectable in plasma up to 30 hours after administration, while the trimethoprim was

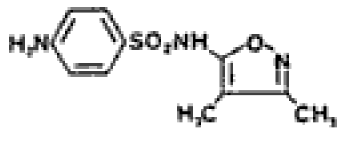

FIG. 40.12—Sulfisoxazole

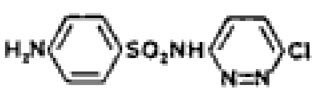

FIG. 40.13—Sulfachlorpyridazine

of urinary tract infections in the dog and cat, especially infections caused by *E. coli*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, and some gram-positive cocci (Bevill 1988). The pharmacokinetics of sulfisoxazole has been studied in dogs, swine, and humans (Suber et al. 1981) as well as its delivery across the skin using iontophoresis (Inada et al. 1989).

Sulfachlorpyridazine. The chemical structure of sulfachlorpyridazine is shown in Fig. 40.13. Horses intravenously given 5 mg/kg trimethoprim and 25 mg/kg sulfachlorpyridazine revealed an elimination $t_{1/2}$ of 2.57 hours (trimethoprim) and 3.78 hours (sulfachlorpyridazine) and a $V_{d(steady\ state)}$ of 1.51 L/kg (trimethoprim) and 0.26 L/kg (sulfachlorpyridazine). Bioavailability of the same dose of sulfachlorpyridazine in a powder formulation administered in the feed was about 46%. Interestingly, oral absorption appeared to be delayed, with the first peak appearing 1 hour after dosing and the second appearing 8–10 hours postdosing. Dual absorption peaks were not found after nasogastric administration. This phenomenon may be due to a number of reasons, such as differences in the time span of drug administration, physical barriers from the feed, biphasic gastric emptying, or recirculation/reabsorption of the drugs excreted in the bile. It was the authors' contention that the physical presentation (formulation) of the drug was likely the cause of the two absorption peaks (van Duijkerne et al. 1995).

Sulfachlorpyridazine is rapidly eliminated from the plasma following IV administration. Intramuscular injections in swine result in maximum blood concentrations within 30 minutes after injection, which are maintained for up to 3 hours (Bevill 1988). A single 50 mg/kg IV dose of sulfachlorpyridazine demonstrated significantly different $V_{d(area)}$ in cocks (0.34 L/kg) versus hens (0.36 L/kg), with the sulfonamide being more slowly excreted in hens (Lashev et al. 1995).

The pharmacokinetics of sulfachlorpyridazine after oral and intracardiac administrations has also been described in the channel catfish (*Ictalurus punctatus*), and the drug has been found to have a potential use in aquaculture (Alavi et al. 1993).

Other Sulfonamides. This chapter has discussed the major sulfonamides in use in veterinary medicine today. However, other sulfonamides do exist that are not currently or are no longer used in the US markets. Other sulfonamides that may be of interest include sulfadimethoxypyrimidine (Walker and Williams 1972), sulfasomidine and sulfamethomidine (Bridges et al. 1969), sulfamethoxypyridazine (Garg and Uppal 1997), sulfamethoxydiazine (Weijkamp et al. 1994), and sulfamethylphenazole (Austin and Kelly 1966). Sulfadimethoxine-sulfamethoxazole use in healthy and pneumonic pigs (Mengelers et al. 1995), trimethoprim-sulfamethoxazole in goats (kids) (Koudela and Bokova 1997), and trimethoprim-sulfamethoxazole combinations in Japanese quails (Lashev and Mihailov 1994) have also been reported. Previous editions of this textbook or the individual references listed above may be consulted for more in-depth information on the older and less commonly used sulfonamides not discussed in this chapter.

POTENTIATED SULFONAMIDES. The combination of sulfonamides with other antimicrobial drugs (most commonly trimethoprim) has been repeatedly shown to be therapeutically useful in treating veterinary microbial infections in both small and large animals. These combinations were discussed under the individual drug sections above. Sulfonamide and trimethoprim combinations have been reviewed in some depth by Bushby (1980), Van Miert (1994), and in the 1998 USPDI monograph on this subject. An extensive review of trimethoprim-sulfonamide combinations in the horse is also available (Van Duijkeren et al. 1994b). Combinations of a sulfonamide with trimethoprim (2,4-diamino-5-(3,4,5-trimethoxybenzyl) pyrimidine), aditoprim (2,4-diamino-5-[4-(dimethylamino)-3,5-dimethoxybenzyl] pyrimidine), ormetoprim (2,4-diamino-5-[4,5-dimethoxy-2-methylbenzyl] pyrimidine), or tetroxoprim (2,4-diamino-5-[3,5-dimethoxy-4(2-methoxy ethoxy)benzyl] pyrimidine), among others, are commonly termed "potentiated sulfonamides." The chemical structures of trimethoprim and ormetoprim are shown in Figs. 40.14 and 40.15. Potentiated sulfonamides have the desirable property of reducing, by several-fold, the MIC of both the sulfonamide and the diaminopyrimidine against a wide range of pathogenic organisms. Lowered MICs needed to control infections result in small doses of drugs used in each animal and thereby a reduction in the total dose of drug administered to the animal (Craig 1972).

Mechanism of Action. As seen in Fig. 40.2, the synthesis of dihydrofolic acid from PABA is blocked by competitive inhibition of PABA with a sulfonamide. Trimethoprim and other diaminopyrimidine analogs block the synthesis of tetrahydrofolic acid from dihydrofolic acid by competitive inhibition of dihydrofolate reductase. Trimethoprim and sulfonamides, each used separately, are bacteriostatic. By blocking both steps of

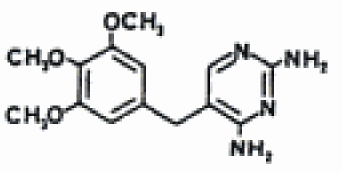

FIG. 40.14—Trimethoprim

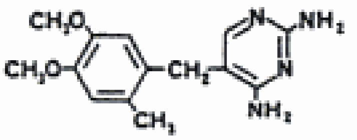

FIG. 40.15—Ormetoprim

folic acid metabolism, the combination becomes bactericidal and increases the spectrum of antimicrobial activity. Both mammals and bacteria use dihydrofolate reductase in folic acid metabolic pathways. However, trimethoprim and the other diaminopyrimidine analogs have a very low affinity for the enzyme in mammals and preferentially inhibit to a great extent the bacterial form of the enzyme at normal therapeutic doses.

Absorption, Distribution, Metabolism, Excretion. Trimethoprim is a lipid-soluble organic base that distributes to most tissues of the body and tends to concentrate in tissues with a greater acidity than plasma (e.g., prostate). Metabolism is by oxidation and conjugation reactions in the liver. Both parent compound and metabolites are excreted in the urine. Aditoprim has pharmacokinetic advantages over trimethoprim in that it has a larger V_d, longer $t_{1/2}$, and overall better tissue penetration.

Clinical Uses and Pharmacokinetics. The diaminopyrimidines are most commonly used in conjunction with sulfonamides to increase the antimicrobial spectrum of activity; rarely are they used alone in veterinary therapy due to the quick development of bacterial resistance. The therapeutic uses of trimethoprim and the other diaminopyrimidine analogs have been discussed with the individual sulfonamides they are used with in previous sections of this chapter and will not be covered in great detail here, except to delineate some of their general pharmacokinetic properties in animals. The pharmacokinetic parameters of trimethoprim and other diaminopyrimidines have been established for some species and are listed in Tables 40.6 and 40.7.

Readers requiring more information on specific properties of these diaminopyrimidines should consult Ascalone et al. 1986, Mengelers et al. 1990, Lohuis et al. 1992, Sutter et al. 1993, Wilson et al. 1987, Brown et al. 1989, Iversen et al. 1984, Vergin et al. 1984, or Aschhoff 1979.

RESIDUES IN FOOD ANIMALS. Tissue residues from sulfonamide use in food-producing animals are a concern of both US government agencies and the end consumers. The US Department of Agriculture (USDA)

TABLE 40.7—Some pharmacokinetic parameters of aditoprim, ormetoprim, tetroxoprim, and metioprim in animals

Species	Dose (mg/kg)	Route	V_d (L/kg)	$t_{1/2}$ (hr)	Clearance (mL/hr/kg)	Reference
		Aditoprim:				
Calves (80 kg, milk fed)	5.0	IV	10.44	13.0	11.03	Sutter et al. 1993
Calves (80 kg, conventionally fed)	5.0	IV	9.72	14.8	8.20	Sutter et al. 1993

Calves (80 kg, conventionally fed)	5.0	PO	NR	11.60	NR	Sutter et al. 1993
Calves (160 kg, milk fed)	5.0	PO	NR	10.2	NR	Sutter et al. 1993
Calves (160 kg, conventionally fed)	5.0	PO	NR	NR	NR	Sutter et al. 1993
Calves (210 kg, conventionally fed)	10.0	PO	NR	16.6	NR	Sutter et al. 1993
Dairy cows (3–7 yr old)	5.0	IV	6.28	7.26	820.0	Lohuis et al. 1992
Dairy cows (3–7 yr old, mammary endotoxin)	5.0	IV	12.25	about 7 hr	1000.0	Lohuis et al. 1992
		Ormetoprim:				
Calves (6-8 months old)	5.5/27.5[a]	IV	1.450	1.37	13.71	Wilson et al. 1987
Mare[b]	9.2/45.8[a]	IV	1.66	1.19	671.0	Brown et al. 1989
		Tetroxoprim:				
Dogs	5.0	IV	NR	5.45	NR	Vergin et al. 1984
		Metioprim:				
Dogs	5.0	IV	NR	3.07	NR	Vergin et al. 1984

Note: NR = not reported; IV = intravenously; PO = orally.

[a] First dose is trimethoprim; second dose is sulfadimethoxine.

[b] One mare studied.

has been charged with the task of inspecting meat and poultry destined for interstate sale. Both the Federal Insecticide, Fungicide, and Rodenticide Act of 1947 and the Toxic Substances Act authorize the USDA to test tissues of animals for drug residues and to determine if those tissues are in violation of federal residue guidelines. In 1973, the Food Safety Inspection Service (FSIS) of the USDA established the National Residue Program to be responsible for monitoring drug residues in animal tissues available for human consumption (Bevill 1989). FARAD (Food Animal Residue Avoidance Databank), a computerized databank of scientific and regulatory data, is available to assist the veterinarian, producer, and other individuals in solving drug- and chemical-residue problems in food-producing animals (Riviere et al. 1986) and also provides some excellent detection methods for sulfonamides and metabolites (Sharma et al. 1976; Agarwal 1992).

Sulfonamide residues were a problem in the United States for at least 25 years, having produced more drug-residue violations than any other drug, with the highest incidence occurring in pork, followed by veal and poultry. Residues in animal tissues consumed by humans are considered to be potential health hazards to humans. Toxic or allergic reactions to the sulfonamide class of antimicrobials have been reported in humans receiving therapeutic doses of sulfonamides. However, we are aware of no reports in the open literature about toxicity or other adverse reactions in humans consuming animal products containing trace amounts of sulfonamides or its metabolites. These trace amounts of drug may select for drug resistance to sulfonamides, especially those bacteria in the family Enterobacteriaceae, although the problem of transfer of drug-resistant strains of bacteria from animals to humans still needs further investigation (Bevill 1989). Recent evidence indicating that sulfonamides (in particular, sulfamethazine) may be carcinogenic in humans consuming small amounts over long periods of time (based on in vivo rat and mouse data) has heightened the FSIS's concern for controlling sulfonamide residues in food animals (USDA 1988).

The highest rate of sulfonamide-residue violations has historically occurred in swine. Sulfamethazine and sulfathiazole are the two most commonly used sulfonamides in swine feeds today. However, sulfamethazine is responsible for most of the sulfonamide-residue violations (97%) due to its mass incorporation in swine feeds and its longer half-life when compared to that of sulfathiazole (12.7 vs. 1.2 hr). The primary reasons for the occurrence of violative levels of sulfonamides in pork were failure to observe drug withdrawal time, improper feed mixing, and improper cleaning of feed-mixing equipment, causing a cross-contamination of feed (Bevill 1984, 1989). During the late 1970s, 13% of swine livers were found to be in violation of federal sulfonamide tissue concentrations. At that time the maximum amount of sulfonamide (parent compound) permitted in animal tissues was 0.1 ppm, with a 7-day withdrawal period. Drug manufacturers at this time increased the withdrawal time for sulfonamides used in animal feed from 7 to 15 days, and by 1980, the violation rate in liver tissue had fallen to 4%. In 1987, the rate was reported to be 3.8% (Augsburg 1989), with the rate decreasing significantly by the end of the 1990s.

In veal calves presented for slaughter, similar problems with sulfamethazine residues have been reported. The prevalence rate of sulfamethazine violations in veal calves was 1.9% in 1979 and 2.9% in 1981. Reasons for violations in this species include administering the drug to calves by individuals unaware of the drug withdrawal time constraints, unknowingly selling calves treated with sulfonamides, not following drug label directions, not seeking professional advice regarding drug use, and failing to maintain drug use records (Bevill 1989).

More information about residues in food-producing animals is presented in Chap. 58 of this textbook and also in previous editions. Several references are also available on this subject (Kaneene and Miller 1992; Bevill 1984; Dalvi 1988; Rosenberg 1985).

organism. Newer agents have increasing resistance to β lactamases. For example, the cephamycins (cefoxitin and cefotetan) are apparently stable to chromosomally mediated β lactamases, which may give them their excellent activity against anaerobic gram-negative rods (Williams 1987).

Gram-negative bacteria can produce a cell wall with a modified outer membrane that is no longer permeable to β-lactam antibiotics. While this mechanism can enhance resistance produced by the elaboration of β lactamases, it is usually not sufficient to markedly increase resistance by itself. Finally, some bacteria have an intrinsic resistance to β lactams because of reduced sensitivity of the penicillin-binding proteins and failure of the drugs to inhibit the operative pathways of cell wall formation.

PENICILLINS

General Pharmacology. The international unit (IU) for penicillin has been identified as the amount of activity present in 0.6 mg of the international pure crystalline standard sodium salt of penicillin G; 1 mg contains 1667 Oxford units. The dose of more recent β-lactam antibiotics is expressed in milligrams per unit of body weight rather than in international units.

The essential penicillin molecule contains a fused ring system, the β-lactam thiazolidine (Fig. 41.1). The physical and chemical properties, especially solubilities, of penicillins are related to the structure of the acyl side chain and the cations used to form salts.

Hydrolysis is the main cause of penicillin degradation and can take place in the syringe when penicillin is mixed with another drug. Some penicillins are rapidly hydrolyzed by gastric acid, making them unsuitable for oral administration. Aqueous solutions of the alkaline sodium salts of sulfonamides inactivate penicillin. Penicillin is incompatible with heavy metal ions, oxidizing agents, and strong concentrations of alcohol.

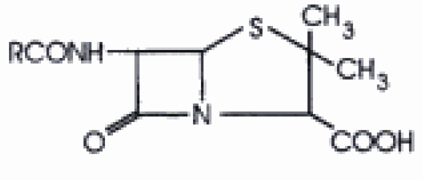

FIG. 41.1—Chemical structure of penicillins.

There are four groups of penicillins (Table 41.1):

1. Natural penicillins (e.g., penicillin G) are produced by mold cultures, then extracted and purified.
2. Aminopenicillins (e.g., amoxicillin) are semisynthetic derivatives that have a free amino group at the α position at R on the penicillin nucleus.
3. Penicillinase-resistant penicillins (e.g., oxacillin, cloxacillin) have a ring structure attached to the carbonyl carbon of the amide side chain. Substituents on the ring protect the lactam ring from β lactamases.
4. Extended-spectrum penicillins (e.g., ticarcillin, carbenicillin) have either a carboxylic acid group or a basic group at the α position at R, which gives these drugs a wider spectrum of activity than the other three groups of penicillins.

Microbial Susceptibility. The natural penicillins are active against many *Streptococci* spp. and non-penicillinase-producing *Staphylococci* spp. They are active against some gram-positive and gram-negative bacilli, including *Corynebacterium, Listeria monocytogenes, Pasteurella multocida,* and *Haemophilus influenzae.* These drugs are active against many gram-positive and gram-negative anaerobic bacteria, including *Fusobacterium, Peptococcus, Peptostreptococcus,* and some strains of *Bacteroides* and *Clostridium.* These drugs are also active against most spirochetes, including *Leptospira* and *Borrelia burgdorferi.* Natural penicillins are inactive against *Pseudomonas,* most Enterobacteriaceae, and penicillinase-producing *Staphylococcus* spp.

Aminopenicillins are generally active against the microbes that are susceptible to natural penicillins. They are also active against some Enterobacteriaceae, including strains of *E. coli, Proteus mirabilis,* and *Salmonella.* Aminopenicillins are inactive against *Pseudomonas, Bacteroides fragilis,* and penicillinase-producing *Staphylococcus* spp.

The penicillinase-resistant penicillins are active against many penicillinase-producing *Staphylococcus* spp. which are resistant to the natural penicillins and the aminopenicillins. They also have some activity against other gram-positive and gram-negative bacteria and spirochetes. However, they are generally less effective than the other penicillins.

Extended-spectrum penicillins have the most activity against gram-negative aerobic and anaerobic bacteria of all of the penicillin groups. The drugs are active

	Horses			0.90	Huber 1988

*V_d = volume of distribution.

against many strains of Enterobacteriaceae and some strains of *Pseudomonas*. Carbenicillin and ticarcillin are active against some strains of *E. coli, Morganella morganii, Proteus* spp., and *Salmonella*. In addition to these organisms, mezlocillin and piperacillin are active against some strains of *Enterobacter, Citrobacter, Klebsiella*, and *Serratia*. The extended-spectrum penicillins have some activity against gram-positive aerobic and anaerobic bacteria but are generally less effective against these organisms than are the natural penicillins and aminopenicillins. Extended-spectrum penicillins are generally more active against *Bacteroides fragilis* than are other available penicillins.

Pharmacokinetics. Table 41.2 lists the pharmacokinetic parameters of several penicillins in domestic species and Table 41.3 lists recommended dosages. Most penicillins are rapidly absorbed when injected in aqueous suspension by the IM or SC route. Maximum blood concentrations result in 15-30 minutes. IM injection is the most common route of administration. It is necessary to orally administer 5 times the amount of penicillin G necessary for IM injections to produce comparable blood concentrations, because of inactivation by the gastric acid and enteric bacteria.

Some absorption of penicillin occurs during the first few hours after intramammary infusion. Blood concentrations are consistently higher when penicillin is infused in infected quarters than when infused into normal quarters. Serum plays a significant role in transfer of penicillin from treated to untreated quarters. There is systemic absorption of sodium benzylpenicillin and procaine benzylpenicillin administered intrauterine to horses and cattle, respectively.

Sodium or potassium penicillin suspended in an inert oil prolongs absorption of penicillin from the site of infection for approximately 18 hours. Incorporation of the poorly soluble procaine penicillin in oil prolongs absorption for 24 or more hours. Addition of 2% aluminum monosterate to a suspension of penicillin in oil produces a gel with a high degree of water repellency, which markedly slows absorption of procaine penicillin suspended in the medium. Although the use of an oil vehicle helps prolong the duration of therapeutic blood concentrations, undesirable physical properties limit widespread use. Horses may show unfavorable acute and chronic tissue reactions to the parenteral administration of an antibiotic in an oil vehicle.

Procaine penicillin G is a buffered aqueous suspension available for IM injection. Absorption of penicillin from this preparation is prolonged. Absorption of procaine may become problematic in drug-testing programs used in racing horses. A small amount of sodium or potassium penicillin G may be added to establish a

TABLE 41.3—Recommended dosages for penicillins

Drug	Species	Dose	Route	Interval (hr)
Penicillin G (sodium or potassium)	Horses	20,000–60,000 IU/kg	IM, IV	6–8
	Dogs and cats	22,000–55,000 IU/kg	IM, IV, SQ	6–8
Procaine penicillin G	Horses	20,000–100,000 IU/kg	IM	12
	Cattle	10,000–66,000 IU/kg	IM, SQ	12–24
	Swine	40,000 IU/kg	IM	24
	Dogs and cats	20,000 IU/kg	IM, SQ	12–24
Benzathine penicillin	Horses	50,000 IU/kg	IM	48
	Cattle	10,000–66,000 IU/kg	IM, SQ	48
	Dogs and cats	40,000–50,000 IU/kg	IM	120
Penicillin V (potassium)	Horses	66,000–110,000 IU/kg	PO	6–8
	Dogs and cats	5.5–11 mg/kg	PO	6–8
Ampicillin	Horses	10–22 mg/kg	IV, IM	8
	Cattle	11–22 mg/kg	SQ, IM	12
		4–10 mg/kg	PO	12–24
	Dogs and cats	10–20 mg/kg	IV, SQ	6–8
		22–33 mg/kg	PO	8
	Swine	6–8 mg/kg	SQ, IM	8
Amoxicillin	Horses	20–30 mg/kg	IM, PO	6–2
	Cattle	6–11 mg/kg	IM, SC	12–24
	Dogs and cats	10–22 mg/kg	PO	8
		5–11 mg/kg	IM, IV, SQ	8
Amoxicillin + Cavulanate	Dog	12.5–25 mg/kg	PO	8–12
	Cat	62.5 mg/kg	PO	8–12
Cloxacillin	Dogs and cats	20–40 mg/kg	IM, IV, PO	8
Dicloxacillin	Dogs and cats	10–50 mg/kg	PO	8
Oxacillin	Horses	20–50 mg/kg	IM, IV	6–8
	Dogs and cats	20–40 mg/kg	PO	8
		5.5–11 mg/kg	IV, IM	4–8
Carbenicillin	Dogs and cats	55–100 mg/kg	IV, PO	8
Ticarcillin	Dogs and cats	40–110 mg/kg	IV, IM, SC	6

therapeutic concentration immediately following IM injection. Benzathine penicillin G is a repository salt of penicillin. Absorption of this compound may be prolonged for 7 or more days.

Diffusion of penicillin into the tissues and fluids occurs as long as the unbound plasma concentration exceeds that of the tissues and fluids. High concentrations of penicillins are generally reached in kidneys, liver, and lung. Penicillins do not penetrate the CNS to any great extent. Penicillin will diffuse across the placenta, into the fetal circulation. Tissue residues of penicillin in slaughtered animals are considered a public health hazard because of potential hypersensitivity reactions in people.

Penicillin G, penicillin V, nafcillin, ticarcillin, and the aminopenicillins are metabolized to some extent by hydrolysis of the β-lactam ring. The metabolites are microbiologically inactive. Penicillins and their metabolites are excreted in the urine by tubular secretion. Most of the drug is excreted in the urine within 1 hour of IM injection of sodium or potassium penicillin in aqueous solution. Probenecid competitively inhibits renal tubular secretion of penicillins. Penicillin is also eliminated in milk.

Compounds

NATURAL PENICILLINS. Only penicillin G and penicillin V are currently used clinically. The phenoxymethyl group on penicillin V imparts more acid stability, allowing for oral administration, but less antibacterial activity. Penicillin G is commercially available as a benzathine, procaine, potassium, or sodium salt. Penicillin V is available as a potassium salt. The potassium and sodium salts of the drugs are soluble in water while the benzathine and procaine salts are less soluble in water. Penicillin G can be injected IV, IM, or SC. Procaine penicillin G should not be administered IV, because procaine can adversely affect the cardiac conduction system. Oral administration of penicillin V is more applicable to humans and small animals than to food-producing animals. Penicillin is usually not administered orally to herbivores because it suppresses bacterial metabolism in the digestive tract. The exception are those herbivores that are very young or animals that require suppression of bacterial fermentation to prevent bloat.

Penicillin is administered via both intramammary and systemic routes to treat bovine mastitis. Milk contaminated with antibiotics may cause public health problems as well as inhibit the cheese-making process. Penicillin in milk and milk products may sensitize susceptible humans, with subsequent penicillin therapy more likely to produce an allergic reaction. Recommended withdrawal times must be adhered to. The type of vehicle used in intramammary infusion preparation is a factor that also determines time required for elimination of antibiotics via the milk. In general, penicillin in fat-soluble ointments or mineral oil vehicles persists longer in the bovine udder than penicillin administered in an aqueous vehicle. In contrast, aqueous vehicles favor rapid release of antibiotics to attain maximum therapeutic concentrations. This information is provided on the label.

AMINOPENICILLINS. Ampicillin and amoxicillin have been used in the treatment of a variety of diseases in domestic animals. The half-life of all aminopenicillins is approximately 60-90 minutes. Tissue drug concentrations may be higher than serum concentrations. Following oral administration, ampicillin is more quickly absorbed when mixed with water or glucose solutions than when added to milk or milk replacer. Amoxicillin differs from ampicillin by the addition of a parahydroxy group. It has greater resistance to gastric acid and is more completely absorbed than ampicillin. Hetacillin is prepared by a reaction of ampicillin with acetone. When administered as an aqueous solution, it is rapidly converted back to ampicillin and acetone. Thus the spectrum of activity is identical to that of ampicillin.

PENICILLINASE-RESISTANT PENICILLINS. Methicillin sodium is a water-soluble penicillinase-resistant penicillin that produces therapeutic concentrations in the CNS. Methicillin is primarily used as an antistaphylococcal drug. However, methicillin is a powerful inducer of penicillinase, and staphylococci may develop resistance by nonpenicillinase mechanisms. Methicillin is given by the IV or IM route and is usually well tolerated. Occasionally some pain may be observed following IM injection. Oxacillin, cloxacillin, dicloxacillin, and nafacillin resist acid hydrolysis and can be administered orally.

EXTENDED-SPECTRUM PENICILLINS. Carbenicillin and other members of this group have the major advantage that they are effective against *Pseudomonas*, *Proteus*, and other gram-negative bacteria resistant to other penicillins. Carbenicillin has a broad range of antibacterial activity that has been related to the carboxyl group substituted on the α carbon of the benzyl side chain. Carbenicillin is acid labile and must be administered parenterally. Carbenicillin indanyl, the indanyl ester of carbenicillin, is acid stable and suitable for oral administration. It is rapidly absorbed from the small intestine and peak plasma concentrations are achieved within 1 hour of oral administration. Carbenicillin is primarily eliminated by the renal tubules, with approximately 80% of the dose appearing in the urine within 9 hours. Peak serum carbenicillin concentrations achieved following oral administrations are low, and many infections are not treatable with this drug unless confined to the lower urinary tract. Ticarcillin and mezlocillin are not absorbed orally and must be administered IV or IM.

Toxicity. Penicillins are very safe drugs, with relative few adverse effects reported. Acute allergic reactions are the most common untoward effect in people. Acute anaphylaxis, collapse, hypersalivation, shaking, vomiting, urticaria, fever, eosinophilia, neutropenia, agranulocytosis, thrombocytopenia, leukopenia, anemia, and lymphadenopathy can occur in sensitized animals. Coomb's-positive hemolytic anemia has been reported in horses following penicillin administration (Blue et al. 1987; Step et al. 1991).

The IV administration of hypertonic solutions of sodium benzylpenicillin has resulted in ataxia and convulsions in cats and dogs. Procaine can also cause anaphylaxis and CNS disorders (Neilsen et al. 1988). Guinea pigs, chinchillas, birds, snakes, and turtles are sensitive to procaine penicillin (Jenkins 1987).

Anorexia, vomiting, and diarrhea can occur when penicillins are given orally. Changes in the intestinal flora induced by penicillin administration can also lead to diarrhea.

The extended-spectrum penicillins have been associated with coagulopathies in humans. The incidence of this is unknown in veterinary patients.

CEPHALOSPORINS

General Pharmacology. Cephalosporins contain a 7-aminocephalosporanic acid nucleus which is composed of a β-lactam ring fused with a 6-membered dihydrothiazine ring (Fig. 41.2). Additions of various groups at the R positions form derivatives with differences in antimicrobial activity, stability against β lactamases, protein binding, intestinal absorption, metabolism, and toxicity.

The cephalosporins are usually divided into 3 classes: first, second, and third generation (Table 41.4). Although this division is based largely on the chronological development of the drugs, some generalities can be made about the spectrum of antimicrobial activity of each generation, as given below. Cefoxitin, cefotetan, and loracarbef are cephamycins, and moxalactam is an oxa-β-lactam, but these agents are generally included with the cephalosporins because of their similar pharmacologic behavior.

Unless frozen, most cephalosporins are stable in solution for only short time periods. Some drugs, such as aminoglycosides, are potentially incompatible with cephalosporins when mixed in solution. Specific references should be consulted for compatibility information.

Microbial Susceptibility. There are substantial differences between cephalosporins with regard to microbial susceptibility. The National Committee for Clinical Laboratory Standards (NCCLS) uses cephalothin susceptibility as an indicator for all first-generation cephalosporins. The activity of the first-generation cephalosporins is essentially identical when given parenterally, except that cefazolin has somewhat lesser activity against staphylococci and somewhat greater

TABLE 41.5—Pharmacokinetic parameters of selected cephalosporins in domestic species

Drug	Species	V_d[a] (L/kg)	Clearance (mL/kg/min)	Elimination half-life (hr)	Reference
Cephapirin	Foals[b]	1.06	18.4	0.70	Brown et al. 1987
	Horses	0.17	10.0		Brown et al. 1986a
	Cows[c]		12.7		Prades et al. 1988
	Dogs	0.32	8.9	0.42	Cabana et al. 1976
Cephalothin	Horses	0.15	13.6	0.25	Ruoff and Sams 1985

	Foals	20–30	IV	6
	Goats	50	IV	12
Ceftiofur	Cattle	1	IM	24

cefamandole nafate, cefonicid sodium, ceforanide, cefuroxime sodium, cefoxitin sodium, and cefotetan disodium are available for parenteral administration. With the exception of cefotetan disodium and cefoxitin sodium, second-generation cephalosporins are less commonly used in veterinary medicine because of their expense.

THIRD-GENERATION CEPHALOSPORINS. This class of drugs was developed for use in specialized situations where antibiotic-resistant, gram-negative infections are common and safety is of prime concern. These drugs are very expensive and, with few exceptions, are infrequently used in veterinary medicine. Cefixime is an orally administered third-generation cephalosporin; the remaining compounds are available for parenteral administration. Ceftiofur sodium is approved for parenteral administration in nonlactating cattle. A product containing cefoperazone in an oil base for intramammary infusion is available in the United Kingdom but is not licensed for use in the United States. The nonirritant properties of cefoperazone plus the persistence of therapeutic concentrations of the drug in treated quarters for 3-4 milkings make this drug very useful for the

useful in treating borreliosis, chlamydiosis (especially in cats and poultry), *Mycoplasma* spp. *Leptospira* spp., and *Listeria* spp.

The toxicology of tetracycline has also been reported. Rats and mice given 0, 12,500, and 25,000 ppm of tetracycline in their feed for 2 years showed no evidence of carcinogenicity (Dietz et al. 1991). The use of tetracycline in conjunction with methoxyflurane anesthesia has been implicated as a causative factor in nephrotoxicosis, causing severe kidney failure and death in people and dogs. However, a study by Fleming and Pedersoli (1980) did not support the previous reports that the simultaneous use of tetracycline and methoxyflurane had deleterious effects on kidney function. Renal tubular nephrotoxicosis has also been reported when outdated tetracycline preparations were administered to humans and to calves. The degradation products of the tetracyclines have been found to be nephrotoxic and are formed in the presence of heat, low pH, and moisture (Cleveland et al. 1965; Teuscher et al. 1982; Lowe and Tapp 1966; Riond and Riviere 1989a).

Adverse reactions to tetracycline have also been reported. Tetracycline has been reported to induce anaphylactic shock in dogs after intravenous injection (Ward et al. 1982) as well as possibly increasing alanine transaminase activity in the cat (Kaufman and Greene 1993). The cardiovascular effects of tetracycline in cattle have also been reported (Gyrd-Hansen et al. 1981). Cattle were administered 5 or 10 mg/kg of tetracycline, with the total amount administered over a 10-, 60-, or 300-second time period. No cows collapsed when either dose of tetracycline was given slowly over a 300-second period, but 1 cow in 7 collapsed when given the 5 mg/kg dose over a 10-second period, and 2 cows in 7 collapsed when given the same dose over a 60-second period. For the 10 mg/kg dose, 2 cows in 7 collapsed when given the dose over a 10-second period, and 4 cows in 7 collapsed when given the dose over a 60-second period. Collapse at either dose and at any injection time was prevented when the cows were premedicated with calcium borogluconate, indicating that tetracycline may decrease the amount of calcium available to the heart for its role in contraction to the point of producing collapse of the animals. Other reports of the toxicity of tetracycline are available (McPherson et al. 1974; Wivagg et al. 1976).

Oxytetracycline. By far the most commonly used tetracycline in veterinary practice today is oxytetracycline. Numerous reports are available in the literature on the uses of oxytetracycline in veterinary medicine. Its chemical structure is shown in Fig. 42.3.

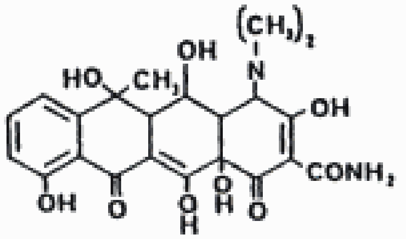

FIG. 42.3—Chemical structure of oxytetracycline.

The clinical usefulness of oxytetracycline has been studied in most domestic species of animals in recent years. Previous editions of this textbook should be consulted for historic work on oxytetracycline. Recently, oxytetracycline has been used to treat ehrlichiosis in dogs (Adawa et al. 1992) and in horses (Palmer et al. 1992). A long-acting formulation of oxytetracycline, administered intramuscularly with piroxicam, was found to be effective in treating canine ehrlichiosis, while the piroxicam minimized the pain and swelling associated with oxytetracycline injections. The study by Palmer et al. (1992) also found that low-dose oxytetracycline given once, instead of twice, daily (administered intravenously) was effective in eliminating *Ehrlichia risticii* in horses. Oxytetracycline has also been recently studied in normal and diseased ovine lung tissue (Baxter and McKellar 1990) and in calves with pneumonic pasteurellosis (Burrows et al. 1986). Long-acting oxytetracycline has also found clinical usefulness in the treatment of *Moraxella bovis*/infectious bovine keratoconjunctivitis infections in calves (Smith and George 1985; George and Smith 1985; George et al. 1985; George et al. 1988). The distribution of oxytetracycline in the genital tracts of cows has also been reported (Bretzlaff et al. 1982; Bretzlaff et al. 1983a,b). Absorption of oxytetracycline is known to vary with injection site in calves. A report by Nouws and Vree (1983) found that site-to-site intramuscular injection bioavailability varied widely at 52 hours postinjection, with bioavailability being 79% in the buttock, 86% in the neck, and 98% in the shoulder.

Oxytetracycline use in the horse has also been reported. Larson and Stowe (1981) reported high serum concentrations obtained in clinically normal horses given 10 mg/kg oxytetracycline intravenously, with serum concentrations peaking at 30 minutes postinjection (16.85 μg/mL) and high concentrations persisting through at least 240 minutes (4.67 μg/mL). In addition to the high serum concentrations, oxytetracycline was demonstrated to penetrate well into pulmonary and renal tissue, as well as into bronchial fluid. In another study of oxytetracycline in horses, Brown et al. (1981) used a dose of 5 mg/kg intravenously and found a peak concentration of oxytetracycline in the serum at 0.5 hours after dose, with a steady decline in serum levels through 36 hours after dose and no detection of oxytetracycline apparent 48 hours after dose. Similar fluid-concentration versus time profiles were also demonstrated for oxytetracycline detected in the synovial fluid, peritoneal fluid, and urine after intravenous injection, suggesting that oxytetracycline crosses those membranes easily and that the concentrations obtained would be adequate for combating such infections as *Corynebacterium equi*, *Streptococcus zooepidemicus*, and *Actinobacillus* spp., with limited efficacy in treat-

Adverse reactions to oxytetracycline have been reported in dogs (Abdullahi and Adeyanju 1985; Stevenson 1980) and calves (Gross et al. 1981). The report by Abdullahi and Adeyanju describes one case where the dog may have had a hypersensitivity reaction to oxytetracycline after an intramuscular injection and later by intraocular therapy. However, this is the only literature report of this event by these routes. In a case report by Stevenson (1980), two dogs were given two doses of oxytetracycline 24 hours apart at a dose of 130 mg/kg. Both dogs died and both had evidence of acute renal tubular necrosis, indicating that high doses of oxytetracycline can induce a nephrotoxicosis. In calves, Gross et al. (1981) studied the cardiovascular effects of both oxytetracycline and the different vehicles used for injection (propylene glycol, saline, polyvinylpyrrolidine). They determined that the cardiovascular responses observed were due to the vehicles used and not the oxytetracycline. The propylene glycol vehicle studied resulted in increased pulmonary arterial pressures and a decrease in cardiac output and stroke volume. Aortic pressure and heart rates were also depressed in association with vehicle. Using histamine, antihistamine, and propylene glycol in some of the calves, it was determined that the cardiovascular effects observed were due to the endogenous release of histamine after propylene glycol injection and this histamine release was not dependent on the animal being sensitized prior to exposure. No discernible cardiovascular effects were observed after injection with the oxytetracycline-saline combination, while the polyvinylpyrrolidine preparation and vehicle resulted in higher aortic pressure, heart rate, and overall systemic resistance.

Doxycycline. Doxycycline, like all other derivatives of tetracycline, is a structural isomer of the parent molecule and is synthesized from oxytetracycline or methacycline. Doxycycline and minocycline (discussed later in this chapter) differ from tetracycline, oxytetracycline, and chlortetracycline in that they are more lipophilic (5- to 10-fold increase), resulting in higher tissue penetration, larger volumes of distribution, and better overall antimicrobial properties. Doxycycline is unique in that it is excreted in the feces as an inactive conjugate or chelate and, in this form, has little impact on the lower intestinal microbial flora. Doxycycline also has greater plasma protein binding than the other tetracyclines, which produces a prolonged half-life of the drug in humans and animals. The chemical structure of doxycycline is shown in Fig. 42.4.

The pharmacokinetics of doxycycline has been studied in dogs and cats (Wilson et al. 1988; Riond et al. 1990), pigs (Riond and Riviere 1990a,b), calves (Meijer et al. 1993b; Riond et al. 1989b), goats (Jha et al. 1989), rhesus monkeys (Kelly et al. 1992), and birds (Prus et al. 1992; Greth et al. 1993). Some of the pharmacokinetic data for doxycycline for commonly encountered species of animals are listed in Table 42.5.

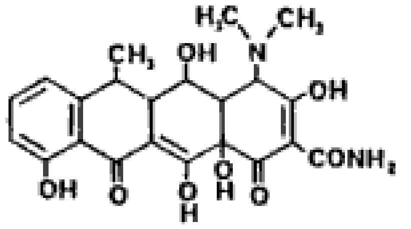

FIG. 42.4—Chemical structure of doxycycline.

Doxycycline pharmacokinetics has been extensively studied in humans and to a lesser degree in animals. An excellent review of doxycycline's use in humans is available (Cunha et al. 1982). Riond et al. (1990) compared the pharmacokinetics of doxycycline in dogs and cats given 5 mg/kg intravenously. In dogs, a peak serum concentration of 11.56 μg/mL was detected in serum 0.17 minutes after injection, steadily falling to 0.33 μg/mL 32 hours after injection and to nondetectable serum levels at 44 hours and beyond. Similar serum pharmacokinetics have been reported in dogs by others (Wilson et al. 1988). In cats, the peak serum concentration was 22.89 μg/mL and fell to 0.89 μg/mL 20 hours after injection, falling to nondetectable levels at 32 hours and beyond. Doxycycline was more extensively bound to serum proteins in cats than in dogs. Protein binding was reported to be 98.35% in cats and 91.40% in dogs, with albumin binding being 76.46% in cats and 53.87% in dogs (Riond et al. 1990). Doxycycline pharmacokinetics has been reported in pigs (Riond and Riviere 1990a). The $t_{1/2}$ for doxycycline in this species was significantly shorter than that in other food-producing animals. Also, no doxycycline biotransformation was detected in those pigs, and no metabolites were detected in calves (Riond et al. 1989b). Bioavailability in calves of doxycycline fed orally with milk replacer was approximately 70%, with an elimination $t_{1/2}$ of 9.5 (±3.0) hours. Plasma concentrations after repeated oral doses of doxycycline in those calves indicated doxycycline may be a potentially valuable drug in food-animal medicine (Meijer et al. 1993b). Doxycycline use in the goat has also been reported (Jha et al. 1989). The pharmacokinetics of doxycycline is easily extrapolated across species using allometric procedures (Riond and Riviere 1990b).

Riond and Riviere (1989b) reported on the binding of doxycycline to plasma albumin in dogs, sheep, cats, cows, pigs, and humans by measuring the association constants (Ka, L/mol). Doxycycline is associated with less gastrointestinal tract irritation and superinfection, and it has been suggested that intravenous doxycycline may be suitable for use in the equine because tetracycline-induced colitis may be avoided or minimized using this route. However, two reports have shown that even subtherapeutic doses of doxycycline in a proprietary vehicle administered via a slow intravenous injection induced collapse and death within 15 minutes in

cycline in milk-fed versus conventionally fed calves. J Vet Pharmacol Therap 5:267-78.

Paromomycin

Aminoglycoside antibiotics constitute a very important weapon in the veterinarian's armamentarium against gram-negative infections. As a group, they are the drugs of choice for the treatment of serious gram-negative infections in animals. Aminoglycosides are a therapeutically essential class of antibiotics whose usefulness is often restricted by their nephrotoxic and ototoxic potential. This chapter reviews the pharmacokinetics, toxicity, and tissue disposition of aminoglycoside antibiotics in various species.

PHARMACOLOGY OF AMINOGLYCOSIDES

General. Aminoglycosides are a class of antimicrobial compounds produced from strains of *Streptomyces* spp., *Micromonospora* spp., and *Bacillus* spp. Chemically, they are aminocyclitols: hydroxyl and amino or guanidine substituted cyclohexane with amino sugars joined by glycosidic linkages to one or more of the hydroxyl groups. These molecules have excellent water, but poor lipid, solubility, are thermodynamically stable over a wide range of pH values and temperatures (Lancini and Parenti 1982; Leitner and Price 1982; Nagabhusban et al. 1982; Pechere and Dugal 1979), and have molecular weights ranging from 400 to 500 g/mol. The aminoglycosides are basic polycations with pK_a values that range from 7.2 to 8.8 (Ziv and Sulman 1974; Katzung 1984; Prescott and Baggot 1988).

The chemical structures of some of the commonly used aminoglycosides are shown in Fig. 43.1. Chemical structure is important in determining antimicrobial activity, resistance patterns, and inherent propensity to cause toxicosis. The various mechanisms of nephrotoxicity (binding to proximal tubule brush-border vesicles and phospholipids, inhibition of mitochondrial function, etc.) may be related to an increased number of free amino groups on the aminoglycoside molecule. In general, the most ionized aminoglycosides (i.e., neomycin, with six groups) are more toxic and show greater binding affinity than the least ionized aminoglycosides of the class (i.e., streptomycin, with three groups) (Bendirdjian et al. 1982; Cronin 1979; Feldman et al. 1981; Humes et al. 1982; Just and Habermann 1977; Kunin 1970; Lipsky and Lietman 1982; Luft and Evan 1980a,b; Weinberg et al. 1980). Other structural characteristics may account for differences in toxicity within groups of drugs with similar total ionization potentials (i.e., netilmicin, tobramycin, and gentamicin, all with five ionizable groups). More specific information on aminoglycoside structure-toxicity relationships is not presently available.

Mechanism of Action. Aminoglycosides exert their antibacterial action by irreversibly binding to one or more receptor proteins on the 30S subunit of the bacterial ribosome and thereby interfering with several mechanisms in the mRNA translation process. These include disrupting an initiation complex between the mRNA and the 30S subunit, blocking further translation and thereby causing premature chain termination, or causing incorporation of an incorrect amino acid in the protein product. It is significant that most antimicrobials that interfere with ribosomal protein synthesis are bacteriostatic, while aminoglycosides are bactericidal. The postulated mechanism for this effect is either this ribosomal misreading or interference with the initiation of DNA replication (Busse et al. 1992; Jawetz 1984). However, the exact mechanism of the bactericidal effect on bacteria presently remains unclear.

The mechanism of bacterial penetration by the aminoglycoside through the cell membrane is biphasic. Drug diffuses through the outer membrane of gram-negative bacteria through aqueous channels formed by the porin proteins. Once in the periplasmic space, an oxygen-requiring transport process transports the drug into the cell, where it interacts with the ribosome. The

---

The authors would like to extend their appreciation to Dr. S. A. Brown as the coauthor of a review of the aminoglycosides (Brown and Riviere 1991) that served as the basis for some of this chapter.

[a] Urinary tract infections; based on IV infusion of 0.35 mg/kg/hr and a half-life of 2.5 hr.

routes. Peak plasma gentamicin levels occurred at 0 hours (72 μg/mL) after IV injection and 1.3 hours (22 μg/mL) after IM injection, well above the conventional blood concentration targets of 10-12 μg/mL. Such high blood concentrations would likely maximize the PAE. Packed-cell volume, creatinine, plasma total protein, urine specific gravity, and a number of other urinalysis data indicated no significant changes in these parameters based on predosing data. Based on this preliminary information, the authors suggested that horses could safely receive a SID dose of gentamicin; however, further work clearly needs to be performed in clinically ill horses to conclusively prove this supposition.

PHARMACOKINETICS OF AMINOGLYCOSIDES

General. A comprehensive review of aminoglycoside pharmacokinetics has been reported by Brown and Riviere (1991) and serves as the basis for this review. The pharmacokinetics of the aminoglycosides is similar across species lines, but the variability within each animal population is large, indicating a significant amount of heterogeneity in aminoglycoside disposition in both diseased and normal animals (Sojka and Brown 1986; Frazier et al. 1988). In addition, the inherent variability caused by many different disease states necessitates close monitoring of serum or plasma concentrations to optimize efficacy and minimize toxicosis. A similarly large variability in aminoglycoside pharmacokinetics has also been reported in humans (Kaye et al. 1974; Sawchuk et al. 1977; Zaske et al. 1982; Blaser et al. 1983).

Although there is variability in aminoglycoside pharmacokinetic parameters, the therapeutic range for all of the aminoglycosides is relatively narrow, and the potential for toxicosis is greater than for most other classes of antimicrobials. Serum or plasma concentrations may easily be higher or lower than desired within each dosing interval in normal animals. Altered physiologic or pathologic states such as pregnancy (Lelievre-Pegorier et al. 1985), obesity (Sketris et al. 1981), subnormal body weight (Tointon et al. 1987), renal disease (Frazier and Riviere 1987), dehydration (LeCompte et al. 1981), immaturity (Sojka and Brown 1986), sepsis (Mann et al. 1987), endotoxemia (Wilson et al. 1984; Jernigan et al. 1988c), and intraindividual variability (Mann et al. 1987), among many others, may alter the distribution, clearance, and half-life of aminoglycosides by as much as 1000-fold between individuals in a single study (Zaske et al. 1982). In order to achieve target therapeutic concentrations, dosage adjustment seems to be required in 80-90% of both human and equine patient populations receiving aminoglycosides therapeutically (Bauer and Blouin 1981; Sojka and Brown 1986), with therapeutic drug monitoring highly recommended for any patient receiving multiple doses of parenteral aminoglycosides (Sveska et al. 1985; Sojka and Brown 1986; Frazier et al. 1988). Timing of blood sampling is critical, with consistent sampling times near 1-1.5 hours after dose and immediately prior to the next dose being optimal in most instances (Blaser et al. 1985). This variability

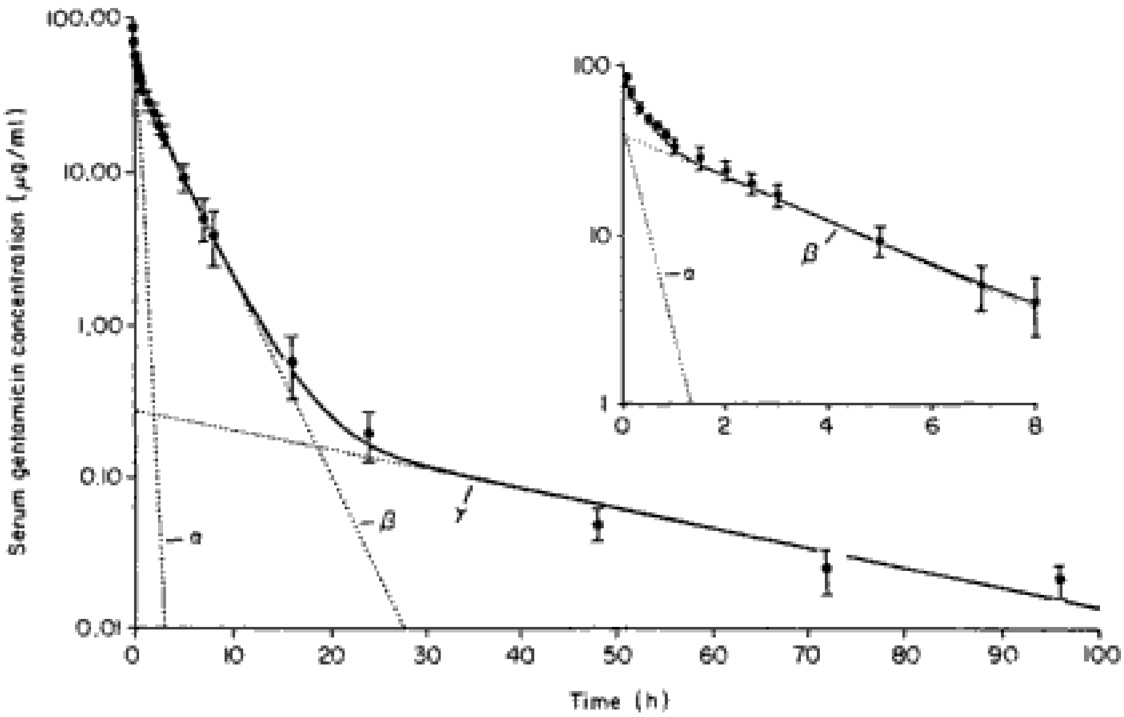

FIG. 43.2—Graphic representation of the three elimination curves associated with aminoglycoside excretion. (From Brown et al. 1991, reproduced by permission.)

and the γ phase occurs 24 hours after dosing and is the most important part of the elimination curve of aminoglycosides when considering drug residues in food-producing animals. The primary determinant of aminoglycoside disposition is reflected in the phase which correlates to renal glomerular filtration. The primary difference in kinetics between species is related to the glomerular filtration rate (GFR), which decreases on a weight basis in larger animals. Larger animals tend to have prolonged half-lives and require smaller doses on a mg/kg basis. In contrast, doses are similar across all species if based on a body surface area or a measure of basal metabolic rate (0.75 mg/kg) (Riviere 1985; Riviere et al. 1997).

The prolonged terminal elimination phase of aminoglycosides has major implication for veterinary therapeutics in food-producing animals. As discussed above, aminoglycosides accumulate in the renal cortex for prolonged periods of time, resulting in violative tissue residues even after short periods of administration. In some cases, aminoglycosides such as gentamicin may be detected for a year after parenteral administration! The veterinary profession had originally recommended a withdrawal time of 18 months for cattle treated with gentamicin but now suggests that the drug not be used in adult food-producing animals. Piglets may be treated up to 3 days of age, but even in this case the withdrawal time is 40 days.

TABLE 43.3—Selected risk factors that predispose to aminoglycoside toxicosis

- Age
- Volume contraction (shock)
- Acidosis
- Sodium or potassium depletion
- Sepsis
- Renal transplantation
- Prior renal insufficiency
- Prior aminoglycoside exposure
- Cumulative dose of aminoglycoside
- Peak and trough serum concentrations
- Hepatic disease
- Total dose of drug administered
- Duration of treatment
- Concurrent administration of loop diuretics
- Methoxyflurane anesthesia
- Cephalosporin antibiotics
- Nephrotoxic drugs

AMINOGLYCOSIDE TOXICITY. Aminoglycoside toxicity in domestic and laboratory animals has been reviewed by Riviere (1985). The possible risk factors that may predispose a patient to aminoglycoside toxicity are shown in Table 43.3.

Aminoglycosides can induce ototoxicity and nephrotoxicity because both organs have higher-than-normal concentrations of phospholipid (in particular, phosphatidylinositol) (Sastrasinh et al. 1982a; Sastrasinh et al. 1982b) in their cellular matrixes. Cationic aminoglycosides are chemically attracted to anionic membrane phospholipids, the so-called aminoglycoside receptors. The two tissues into which gentamicin preferentially accumulates (renal cortex and cochlear tissue) have disproportionately high amounts of phosphatidylinositol in their membranes compared with

control hyperglycemia. Other endocrine disorders such as familial hypothyroidism also affect the terminal elimination phase (and perhaps renal accumulation) of certain aminoglycosides in certain species (Riond et al. 1986; Riviere and Carver 1984).

As stated previously, the exact mechanism behind aminoglycoside nephrotoxicosis is unknown, with controversy existing over the precise mechanism by which aminoglycosides initially damage the proximal renal tubule cells (Swann et al. 1990; Schumacher et al. 1991; Beauchamp et al. 1992). Abundant evidence suggests that lysosomal dysfunction is a component of this early phase of cellular injury (Carbon et al. 1978; Feldman et al. 1982; Hull et al. 1981; Kaloyanides and Pastoriza-Munoz 1980; Laurent et al. 1982; Lipsky and Lietman 1982; Mazze 1981; Meisner 1981; Morin et al. 1980; Morin et al. 1981; Tulkens and Trouet 1978). This view is consistent with the idea that lysosomes are the primary locus of aminoglycoside sequestration in proximal tubule cells. Lysosomes are also the first organelle to demonstrate morphologic changes (myeloid body or cytosegresome formation) after exposure to the drugs (Riviere et al. 1981a). Studies have demonstrated that lysosomal enzyme activities (i.e., sphingomyelinase, cathepsin B, α-D-galactosidase) are decreased and that the structural latency of lysosomes, reflected by leakage of *N*-acetyl-β-D-glucosaminadase in the cytosol is increased. Inhibition of lysosomal enzymes may cause an intralysosomal accumulation of membrane-associated lipids which would be reflected morphologically as myeloid body formation. However, this process by itself should not be acutely lethal to the cell. Decreased lysosomal function may also result in a decreased ability to degrade endogenous intracellular proteins and exogenous low-molecular weight proteins reabsorbed from the tubular filtrate, events that would perturb nephron function (Cojocel et al. 1983; Cojocel and Hook, 1983). The increase in lysosomal permeability could result in proximal tubule cell dysfunction, although this event is probably a late change in aminoglycoside-induced toxic nephropathy occurring after cell necrosis has been initiated by another factor (Humes et al. 1982). Myeloid body formation is most likely a marker of aminoglycoside exposure rather than toxicosis. The appearance of lysosomal enzymes in the urine of aminoglycoside-induced toxic nephropathy patients is secondary to proximal tubule cell necrosis, apical plasma membrane damage, or lysosome exocytosis.

Mitochondria are a second possible target of aminoglycosides because, both in vitro and in vivo, aminoglycosides decrease mitochondrial respiration, thereby impairing the tubule cell's bioenergetic profile (Appel and Neu 1977; Cuppage et al. 1977; Kaloyanides and Pastoriza-Munoz 1980; Kluwe and Hook 1978a; Sastrasinh et al. 1982b; Simmons et al. 1980; Weinberg et al. 1980; Weinberg and Humes 1980; Weinberg et al. 1990). This could selectively produce tubule dysfunction which would initially be detectable biochemically but not morphologically. The mechanism of this toxicity may be secondary to a direct aminoglycoside interaction with mitochondrial membrane phospholipids, to a competitive interaction with the divalent cations magnesium or calcium, or to an alteration in the intracellular milieu that would indirectly affect mitochondrial function. The magnitude of aminoglycoside effects on mitochondrial respiration is *roughly* correlated to the net positive charge of the specific drug.

The third possible site of initial intracellular aminoglycoside interaction is the proximal tubule cell plasma membrane's phospholipids and enzymes (Feldman et al. 1981; Humes et al. 1982; Knauss et al. 1983; Lullmann and Vollmer 1982; Sastrasinh et al. 1982a; Sastrasinh et al. 1982b; Schacht 1979; Silverman and Mahon 1979; Williams et al. 1981a,b). Binding of aminoglycosides to membrane polyphosphoinositides could perturb the regulation of membrane permeability, thereby promoting cellular dysfunction. Aminoglycosides induce a phospholipidosis that may be secondary to inhibition of cytoplasmic phospholipase activity. This event affecting multiple membrane systems may affect other cellular metabolic processes. Aminoglycosides also inhibit basolateral membrane Na^+,K^+-ATPase activity in vitro and in vivo when used at high doses or incubating concentrations (Appel 1982; Chahwala and Harpur 1982; Cronin et al. 1982). Aminoglycosides have also been found to inhibit adenylate cyclase activity in proximal tubule basolateral membranes and in toad bladder epithelium in vitro (Humes and Weinberg 1980; Ross et al. 1980; Souliere et al. 1978). The enzyme interactions at the basolateral membrane could result in significant cellular dysfunction by altering intracellular electrolyte balance or osmolality.

A final possible site of aminoglycoside interaction with the nephron is at the level of the glomerulus, where gentamicin has been demonstrated to reduce the glomerular ultrafiltration coefficient and to reduce the number and size of glomerular endothelial fenestrae (Avasthi et al. 1981; Huang et al. 1979; Luft and Evan 1980a,b; Luft et al. 1978). These effects may be mediated by a charge interaction between the cationic aminoglycosides and the anionic endothelial cell surfaces or, alternatively, could be a feedback response to a primary tubular injury. The mediator of this mechanism is not known.

The relative contributions of the lysosomal, mitochondrial, and membrane tubular mechanisms and glomerular injury to clinical aminoglycoside-induced toxic nephropathy is not known. The relative importance of each as a primary insult is largely a function of the pattern of intracellular distribution of toxicologically active aminoglycosides. In all probability, cellular dysfunction is a result of a combination of the above processes. Whatever the mechanism, dysfunction of the proximal tubule cell ultimately results in a decrease in nephron function, the sum of which determines whole kidney function.

Aminoglycoside-induced nephropathy has been studied in many species of animals. In general, the syndrome is similar across species lines, with any peculiarities being a result of pharmacokinetic factors or

toxic nephropathy marked by increased serum creatinine and urea nitrogen concentrations, decreased creatinine clearance, decreased urine specific gravity, cylindruria, proteinuria, and enzymuria (γ-glutamyltranspeptidase and alanine aminopeptidase) (Crowell et al. 1981). On histopathologic examination, tubular hyaline droplet change, degeneration, and necrosis were present. This apparent sensitivity is again primarily due to the large body size of cows, for which 5-9 mg/kg/day is an overdosage on a 0.75 mg/kg basis. Finally, neomycin concentrations in the renal cortex ranged from approximately 200 to 400 µg/g. Gentamicin-induced toxic nephropathy was not detected in adult sheep given 9 mg/kg/day for 7 days when serum creatinine and urea nitrogen concentrations were monitored and tissues were examined at necropsy by light microscopy (Brown et al. 1985). Sheep have recently been advocated as a stable animal model for human renal diseases (Eschbach et al. 1980). They may be a useful animal model of gentamicin toxic nephropathy because body weight is essentially identical to that seen in humans and the pharmacokinetic parameters describing gentamicin disposition are also similar. The use of urinary enzyme indices as a function of aminoglycoside nephrotoxicosis has been reported (Garry et al. 1990a,b).

GENTAMICIN. Gentamicin has been the most widely studied aminoglycoside antibiotic to date. Gentamicin is a combination of four components produced by *Micromonospora purpurea,* which all cross-react in common immunoassay procedures and are usually considered a single antimicrobial entity.

The plasma elimination phase (β phase) is correlated well with GFR in dogs and horses (Sojka and Brown, 1986; Frazier et al. 1988). Selected pharmacokinetic data for gentamicin in animals are shown in Tables 43.4 and 43.5.

The parenteral absorption patterns of gentamicin have been studied in several species of animals. Bioavailability (*F*) of gentamicin from IM sites is reported to be 68 ± 13% in cats (Jernigan et al. 1988e), 92 ± 15% in cows (Haddad et al. 1986), 87 ± 14% in horses (Haddad et al. 1985b), 95 ± 20% in dogs (Wilson et al. 1989), 95 ± 18% in roosters (Pedersoli et al. 1990), 21% in turkeys (Pedersoli et al. 1989), ≥95% in hawks and owls (Bird et al. 1983), ≥70% in eagles (Bird et al. 1983), and 60% in catfish (Setzer 1985). Bioavailability from different IM sites is considered identical (Wilson et al. 1989) and bioavailability from SC sites is similar to IM bioavailability (Gilman et al. 1987; Jernigan et al. 1988e; Wilson et al. 1989). The maximum concentration after SC administration is usually lower and occurs later after injection than that observed after an equivalent IM dose (Jernigan et al. 1988a; Wilson et al. 1989), which is most likely due to less blood flow to the SC injection sites than to the IM injection sites, resulting in a slower *rate* of absorption but not altering the *extent* of absorption. Systemic availability from intrauterine (IU) administration is 30% in normal cows, with maximum plasma concentrations of 3.70 mg/L and 17.5 mg/L being observed 30 minutes after IU doses of 2 and 4 mg/kg, respectively (al-Guedawy et al. 1983). Oral availability is near 0% in normal animals with intact intestinal mucosa, although necrotizing enteritis and/or diarrhea have been reported to increase availability in humans (Gemer et al. 1983; Miranda et al. 1984). Concentrations in renal tissue are observed after oral doses of 1 mg/kg/day for 7 days, for 10 days (>0.1 µg/g of renal tissue), and for 30 days (>0.02 µg/g of renal tissue) after the last dose in calves (Takahashi et al. 1985). Serum concentrations after IU dosing were minimal in normal horses; however, in horses treated with progesterone, systemic availability was 8-10 times higher, with greater penetration into endometrial tissue (Pedersoli et al. 1985). Estradiol also increased the systemic availability and endometrial penetration after IU infusion, but not to the same extent as that observed after progesterone. Gentamicin's use in the treatment of coliform mastitis in dairy cattle has also been investigated (Erskine et al. 1992; Jones and Ward 1990). The pharmacokinetics of gentamicin administered IM in budgerigars (*Melopsittacus undulatus*) (Itoh and Okada 1993) and cockatiels (Ramsay and Vulliet 1993) has also been described.

Several studies have shown that after multiple parenteral doses, pharmacokinetic values derived from blood samples taken within 8 hours of drug administration do not change appreciably in cats (Short et al. 1986; Jernigan et al. 1988a), although there is some evidence that shows a systematic circadian rhythm of peak and trough serum gentamicin concentrations, with peak and trough concentrations after the second and third doses of each day consistently higher than those obtained after the first daily dose.

Age appreciably affects gentamicin disposition. Because neonatal and infant animals have a larger proportion of their body weight as extracellular fluid, gentamicin volume of distribution (V_d) is larger in immature animals than in adults. For example, $V_{d(area)}$ of gentamicin in juvenile dogs is 0.35 L/kg (Riviere and Coppoc 1981a), whereas $V_{d(area)}$ in normal dogs is 0.227 L/kg (Brown et al. 1991). Foals less than 3 months of age exhibited a V_d of 0.344 L/kg, whereas adult horses in the same study had V_d of 0.184 L/kg (Sojka and Brown 1986). Another study, in young horses 2-3 months old, demonstrated $V_{d(ss)}$ of 0.306 L/kg (Riviere et al. 1983). Clarke et al. (1992) reported that the $t_{1/2}$, $V_{d(area)}$, and Cl_B (clearance) of gentamicin (3 mg/kg IV, once) did not change appreciably between groups of horses ranging from 0 to 10, 10 to 20, and 20 to 30 years of age and there was no pharmacologic reason to adjust the dose in older animals. However, it was noted in that study that the γ phase of gentamicin elimination was not studied and that the effect of advanced age on this phase of elimination is presently unknown.

Clearance of gentamicin is notably dependent upon renal function and has been shown to be so in (among

(Sketris et al. 1981). When converted to LBW, gentamicin V_d is increased from 0.19 L/kg LBW in normal patients to 0.24 L/kg LBW in obese patients. Also, dehydration in rats reduces the V_d from normal (0.19 L/kg and 0.26 L/kg) (LeCompte et al. 1981). Similar results have been reported in dehydrated cattle (Hunter et al. 1991). Gentamicin pharmacokinetics changes appreciably between lean and obese cats (Wright et al. 1991). Obese cats given a 3 mg/kg IV dose of gentamicin had significantly lower $V_{d(ss)}$ and Cl values compared to lean cats. Bioavailability and $t_{1/2}$ values for obese cats were unchanged when compared to the values obtained in lean cats. These changes were attributed to the chemical characteristics of gentamicin, in that the poorly lipid soluble gentamicin fails to distribute adequately into the excess adipose tissue, resulting in reduced V_d values and necessitating a dose adjustment based on the cat's estimated lean body mass and not its overall body mass. In a related study, obese rats were found to sustain more nephrotoxicity due to increased renal uptake and retention of gentamicin in the kidneys than did their lean counterparts (Salazar et al. 1992).

Gentamicin disposition has been extensively studied in animals given IV endotoxin. Endotoxemia decreased plasma gentamicin concentrations in dogs by approximately 20-30% (Pennington et al. 1975) and reduced the area under the plasma concentration-time curve (AUC) after IM dosing in cats from 1620 ± 390 μg/min/mL to 1170 ± 400 μg/min/mL (Jernigan et al. 1988c). Other conditions that have been shown to alter gentamicin disposition include endocrinopathies, pregnancy, and other concurrent drug administrations.

In dogs, familial hypothyroidism effectively abolishes the phase of serum disposition (Riviere and Carver 1984), as does experimentally induced and naturally occurring diabetes mellitus (Brown et al. 1991). In rats, hypoparathyroidism (Holohan et al. 1987) and streptozotocin-induced diabetes mellitus (Ramsammy et al. 1987) reduce the renal accumulation of gentamicin without affecting the number or affinity of the gentamicin binding sites (Holohan et al. 1987). In pigs, hypothyroidism reduced mean (±SEM) gentamicin Cl_B from 2.51 ± 0.17 (normal pigs) to 1.52 ± 0.12 mL/min/kg (Riond et al. 1986), an effect caused by reduction in the GFR. Finally, horses under halothane anesthesia showed longer gentamicin $t_{1/2}$ than when in the awake state (4.03 hours vs. 2.01 hours), as a result of reduced GFR during anesthesia.

Limited work has been done with gentamicin and regional limb perfusion to treat joint infections in horses (Whitehair et al. 1992a, Whitehair et al. 1992b). In another study, where horses were being treated for bacterial infections (pleuropneumonia, peritonitis, pericarditis, abscess, etc.) with gentamicin, it was found that an IV dose of 2.2 mg/kg QID resulted in satisfactory serum levels in most horses, but dose adjustments seem to be necessary to account for individual gentamicin disposition in both normal and diseased horses. Gentamicin clearance was also found to be correlated with the plasma creatinine concentration in both healthy and clinically ill horses (Sweeney et al. 1992), allowing serum creatinine concentrations to be used to individualize gentamicin doses in horses (Martin et al. 1998). The disposition of gentamicin in equine plasma, synovial fluid, and lymph has also been reported (Anderson et al. 1995). Horses had a subcutaneous lymph vessel on the medial aspect of the metatarsus cannulated and were then given a single 2.2 mg/kg IV dose of gentamicin. Plasma and lymph samples were collected together at predetermined times after dosing. The $t_{1/2}$ of gentamicin in the plasma was 2.17 hours (range = 1.92-2.5), and the $t_{1/2}$ in the lymph was 3.03 hours (range = 2.63-3.57). It was concluded that the plasma concentration of gentamicin was a reliable predictor of concentration in lymph fluid and that plasma-based pharmacokinetics could be used with a good degree of confidence to predict the concentrations that would be obtained in the lymph in horses.

Gentamicin is accumulated in renal proximal tubules to concentrations several-fold higher than in serum or any other tissue in every species investigated (Schentag and Jusko 1977; Riviere et al. 1981a; Aronoff et al. 1983; Trnovec et al. 1984; Brown et al. 1985; Brown et al. 1986b; Haddad et al. 1987; Jernigan et al. 1988c). Concentrations in normal calf kidney have accounted for 46% of the dose 4 hours after administration and 6.3% of the dose 48 hours after IV injection (Ziv et al. 1982); in dogs, less than 2% of the dose was present in the renal cortex 1-2 hours after the start of a continuous infusion to maintain blood levels at 11.1 ± 0.5 μg/mL (Chiu et al. 1976).

Renal uptake is inhibited by urinary alkalinization with sodium bicarbonate, theoretically because gentamicin is less ionized and therefore is less able to bind to the acidic phospholipids of the proximal tubular membranes (Chiu et al. 1979). On the other hand, alkalinization with acetazolamide does not reduce gentamicin uptake, presumably because acetazolamide acidifies the proximal tubular lumen (Chiu et al. 1979). High proteinuria due to high-protein diet or diabetes mellitus and proteinuria induced primarily by renal disorders reduce gentamicin uptake into renal proximal tubules (Pattyn et al. 1988), although factors other than proteinuria may also play a role (Ramsammy et al. 1987). In sheep, diet may also play a significant role in gentamicin pharmacokinetics. A study by Oukessou and Toutain (1992) reported that sheep fed a low-protein diet (25 g/day) had significantly lower $V_{d(ss)}$ and Cl values for gentamicin (4 mg/kg IV) than did sheep fed a high-protein (120 g/day), while AUC values were higher in the sheep fed the low-protein diet, indicating higher overall serum concentrations of gentamicin in this treatment group. Coupled with IV insulin clearance data, it was surmised that the protein content of the diet can appreciably modify the distribution of body water and also modulate kidney function, resulting in altered gentamicin kinetics. A similar study in horses found that horses fed a diet of oats (low in calcium and potassium) had a higher incidence of gentamicin-induced nephrotoxicosis than horses fed an all-alfalfa hay diet high in vitamins and minerals (Schumacher et al. 1991). Based on these results, anorectic horses or horses consuming diets low in mineral content are seemingly predisposed to aminoglycoside nephrotoxicosis. A pharmacokinetic model of IM gentamicin has also been described for sheep (Errecalde and Marino 1990).

Gentamicin also reaches therapeutic concentrations in a number of other tissues in addition to the kidney and inner ear. Studies of a variety of wild birds and game birds, including the greater sandhill crane, rosy-bill duck, pigeon, eastern bobwhite quail, argus pheasant, North American wood duck, ruddy shelduck, pintail duck, and emu, as well as laboratory rats show a similar rank order of tissue concentrations of gentamicin, with skeletal muscle concentrations being either very low or nondetectable (Bush et al. 1981; LeCompte et al. 1981). After 5 mg/kg gentamicin every 8 hours in ponies, after 4 and 7 days, the endometrial concentrations were 5.02 ± 3.3 μg/g and 12.7 ± 1.6 μg/g (Haddad et al. 1985a). Milk concentrations after 30 IM doses of 3.5 mg/kg gentamicin were 0.47 ± 0.08 μg/mL 30 minutes after the last dose and 0.19 ± 0.02 μg/mL 14 hours after the last dose (Haddad et al. 1987). In that same study, negligible concentrations were observed in the brain after doses of either 3.5 or 5 mg/kg.

Gentamicin residues can be found in milk after IV, IM, or intramammary (IMM) administration. Pedersoli et al. (1995) administered a single IV or IM dose of gentamicin (5 mg/kg) or a single 500 mg dose of gentamicin to the udder of lactating cows and followed the elimination of the drug via the milk over several days. After a single IMM infusion, the gentamicin levels did not fall below a safe level (≤30 ng/mL) until the seventh milking, 84 hours after treatment. Single IV or IM doses of gentamicin yielding safe milk levels of gentamicin occurred at the third milking, 36 hours after dosing. In another experiment, the cows were given two IV or IM doses of gentamicin (5 mg/kg) or two 500 mg doses of gentamicin to the udders of lactating cows for 5 days. Gentamicin levels did not fall below a safe level (≤30 ng/mL) until the eleventh milking, 132 hours after treatment. Single IV doses again produced safe milk levels of gentamicin at 36 hours after dosing. Because of concerns about residues, gentamicin is not recommended for use in cattle.

Although gentamicin does not partition into and sequester in skeletal muscle (Brown et al. 1986b; Haddad et al. 1987; Riond and Riviere 1988), substantial retention of gentamicin did occur at the site of IM injections (Haddad et al. 1987), reaching concentrations of 16.7 ± 11.3 μg/g at the IM injection site in sheep (Brown et al. 1986b).

Urine concentrations are reported to be as high as 107 ± 33 μg/mL after 2.2 mg/kg every 8 hours in dogs (Ling et al. 1981), and 362 ± 163 μg/mL 3 hours after 3 mg/kg in cats (Jernigan et al. 1988b). Urine concentrations in animals with pyelonephritis (Bergeron et al. 1982) and endotoxemia (Jernigan et al. 1988b) are lower than in control animals given gentamicin, perhaps in part due to retention in the renal medulla (Jernigan et al. 1988b). Changes in urine parameters have been reported in sheep (Garry et al. 1990a,b).

There is some information on the use of gentamicin in sheep and goats. Elsheikh et al. (1997) dosed male Nubian goats and male desert sheep with 3 mg/kg gentamicin IV and found no significant differences in V_d, clearance, and elimination half-lives between the species. Gaddi goats were administered 5 mg/kg gentamicin by IV, IM, and SC routes (Garg et al. 1995). The elimination half-lives were 0.96, 2.37, and 3.56 hours for IV, IM, and SC routes, respectively. The study did show that the half-lives of gentamicin do not appear to be route dependent, as they are in the feline. The pharmacokinetics of gentamicin in normal and febrile goats has also been examined (Ahmad et al. 1994). Healthy and febrile female goats received a single 5 mg/kg IV dose of gentamicin, and its kinetics was examined. Differences in blood serum concentrations between normal and febrile goats were not observed. Apparent volumes of distribution and clearance values did not differ between the groups; however, the median value of gentamicin blood half-life was shorter in normal goats (103.6 min) than in febrile goats (136.0 min). Based on these data, the authors suggested small adjustments in IV doses based on steady-state and peak and trough serum concentrations.

AMIKACIN. Tables 43.6 and 43.7 list some selected pharmacokinetic parameters for amikacin in various species of animals. The parenteral absorption patterns of amikacin have been studied in several species of animals, including red-tailed hawks (*Buteo jamaicensis*) (Bloomfield et al. 1997). Bioavailability of amikacin ranges from 90% after IM and 100% after SC doses in cats (Jernigan et al. 1988d). Mean absorption time is 55 ± 36 minutes after IM doses and 53 ± 19 minutes after SC doses in cats (Jernigan et al. 1988d). The availability of amikacin after IU infusion in horses is minimal; however, availability after intraperitoneal (IP) administration (via instillation in continuous ambulatory peritoneal dialysis) was 53 ± 14% in humans, with therapeutic IP concentrations obtained for 72 hours after an IP dose of 7.5 mg/kg (Smeltzer et al. 1988). The absorption $t_{1/2}$ is 5.7 ± 2.8 hours after IM dosing in snakes and is independent of the ambient temperature (Mader et al. 1985).

In dogs and calves, amikacin concentrations peak at approximately 0.5-0.85 hours (Cabana and Taggart 1973; Ziv 1977), with plasma depletion half-lives slightly longer after IM dosing and particularly after SC dosing than after an IV dose (Baggot et al. 1985; Carli et al. 1990). The urine amikacin concentration in dogs after 15 mg/kg divided into three daily doses was 342 ± 153 μg/mL when obtained as a 6- to 9-hour collection after dosing (Ling et al. 1981). Amikacin use has also been investigated in gopher tortoises (Caligiuri et al. 1990). The V_d of amikacin in tortoises at 20° C (0.221 L/kg) was not appreciably different from that

TABLE 43.7—Nonintravenous disposition values for amikacin in various species (means with standard deviations in parentheses)

[a] mL/min.

amikacin in this study. Five-day-old foals did have statistically significant higher Cl_B values than the 3-day-old foals. The study concluded by stating that the IO infusion methodology in neonatal foals is a safe and effective technique for drug delivery when the IV route cannot be used, particularly in cases of circulatory collapse. Amikacin, like other aminoglycosides, is poorly absorbed from the gastrointestinal tract of the horse. Horspool et al. (1994) administered a single dose of amikacin IV and two PO doses to horses, ponies, and donkeys. Detectable blood levels of amikacin were not found in any of the animals dosed orally with amikacin; likewise, no amikacin was found in the fecal material of animals dosed with amikacin by the IV route. Amikacin had little, if any, effect on the numbers of viable bacteria of the normal gastrointestinal flora of these study animals. Given the mode of action of the aminoglycosides, amikacin appears to have negligible effects in the anaerobic environment of the gastrointestinal tract.

Serum concentrations of amikacin have also been studied in mares in estrus. After induction of estrus, mares were dosed with 1.0 or 2.0 g amikacin by intrauterine (IU) infusion every 24 hours for 3 days, or given an IM injection of either 9.7 or 14.5 mg/kg every 24 hours for 3 days. Amikacin was not detected in the serum of mares given the 1 g IU dose of drug. Low blood levels (0.51-0.71 μg/mL) were detected at 1, 2, and 4 hours after IU infusion after the first and third treatments. As expected, IM injections produced detectable serum levels of amikacin, with peak concentrations attained at 1 hour (9.7 mg/kg) and 2 hours (14.5 mg/kg) after dosing.

KANAMYCIN. Because of the structural similarities between kanamycin and amikacin (amikacin is synthesized from kanamycin), the pharmacokinetics of kanamycin and amikacin are very similar. Lashev et al. (1992) studied species differences in the pharmacokinetics of kanamycin in sheep, goats, rabbits, adult chickens, and pigeons given a 10 mg/mL IV dose of kanamycin. The differences in the V_d in these animals were small, all being between 0.254 and 0.292 L/kg. Eighteen-day-old chicks had the largest V_d (0.671 L/kg). In calves, IM doses of 10, 25, and 50 mg/kg produced peak concentrations at 30 minutes of 31 ± 3.1 μg/mL, 57.3 ± 4.9 μg/mL, and 64 ± 14 μg/mL, respectively. The kanamycin elimination half-lives of 2 hours in all three instances were identical to amikacin (Ziv 1977). Similar half-lives of 1.80 ± 0.17 hours were observed in horses (Baggot et al. 1981) and sheep (Andreini and Pignatelli 1972). IM availability (F) of kanamycin in horses has been reported to be approximately 100% (Baggot et al. 1981). After a dose of 25 mg/kg of either kanamycin or amikacin IV in dogs, V_d was 0.23-0.25 L/kg, and after IM dosing in that same study, absorption $t_{1/2}$ were 0.4-0.75 hours, with apparent elimination $t_{1/2}$ of 0.9-1.2 hours for both amikacin and kanamycin (Cabana and Taggart 1973). The kanamycin $t_{1/2}$ in dogs after a 10 mg/kg IV dose was 0.97 ± 0.31 hours; after IM dosing, the *F* mean was 89 ± 16%, with an absorption $t_{1/2}$ of 0.15 ± 0.003 hours (Baggot 1978). Synovial fluid kanamycin concentrations in horses were equivalent to serum concentrations 4 hours after a 5 mg/kg dose IM, whereas peritoneal kanamycin concentrations were equal to or higher than serum kanamycin concentrations at 3 hours postadministration. The maximum serum concentrations of 12.6 ± 1.89 (mean ± SEM) were observed 1 hour after IM dosing (Brown et al. 1981). Although a γ phase was observed in the bloodstream of horses, the drug apparently did not penetrate into the peritoneal or synovial fluid, because after 12 hours those concentrations did not parallel serum concentrations (Brown et al. 1981). Firth et al. (1993) gave adult ponies a single 10 mg/kg kanamycin dose IM. At 2 and 5 hours after dosing, the metacarpophalangeal, intercarpal, radiocarpal, tibiotarsal, and metatarsophalangeal joints underwent arthrocentesis to determine kanamycin concentrations in the synovial fluid. There was considerable variation between joints sampled at each time point, and the authors reported that the variations were not consistent between animals and that these variations were not statistically significant. At 2 hours after dosing, synovial fluid concentrations fluctuated between joints but averaged 50% that of serum concentration. At 5 hours, synovial fluid concentrations were approximately 145% of plasma concentrations. Urine concentrations of kanamycin in dogs given 5.5 mg/kg twice a day were 473 ± 306 μg/mL urine when obtained as a 6-hour collection after dosing (Ling et al. 1981).

APRAMYCIN. Apramycin, an aminoglycoside derived from *Streptomyces tenebrarius* (Ryden and Moore 1977), is the newest aminoglycoside introduced for veterinary use. Administration of 10 mg/kg apramycin IV to preruminant dairy calves resulted in a $V_{d(ss)}$ of 0.71 ± 0.042 L/kg, a V_c of 0.34 ± 0.065 L/kg, a Cl_B of 3.22 ± 0.44 mL/min/kg, and a $t_{1/2}$ of 4.4 ± 1.2 hours (Ziv et al. 1985). Urine recovery of apramycin accounted for approximately 85% of the dose after 24 hours. Apramycin peak concentrations after IM doses of 10 and 20 mg/kg were 19 and 40 μg/mL, respectively, although peak concentrations occurred somewhat later after the larger dose. There was no plasma accumulation when IM doses of 10 or 20 mg/kg were given daily. Bioavailability of apramycin from IM sites was quite variable, ranging from 50 to 100% (Ziv et al. 1985).

Apramycin pharmacokinetics has also been described in lactating cows, ewes, and goats (Ziv et al. 1995). The IV pharmacokinetics of 20 mg/kg apramycin was very similar in the lactating cow, ewe, and goat, with an elimination $t_{1/2}$ of about 2 hours, a V_d between 1.26 and 1.5 L/kg, and an IM absorption bioavailability between 60% and 70%. All species had higher penetration of apramycin in the milk from inflamed udders than from clinically normal (nonmastitic) udders. The pharmacokinetics of apramycin in Japanese quails has also been described (Lashev and Mihailov 1994).

Pharmacokinetic data for apramycin in selected species are presented in Table 43.8.

TOBRAMYCIN. Tobramycin is produced by *Streptomyces tenebrarius* and is structurally similar to kanamycin. Tobramycin is not extensively used in veterinary medicine, although it is used occasionally in dogs and cats because of its enhanced efficacy against most *Pseudomonas aeruginosa* organisms. In cats, tobramycin possesses a Cl_B of 2.21 ± 0.59 and 1.69 ± 0.36 mL/min/kg after doses of 5 mg/kg and 3 mg/kg IV, respectively, and a $V_{d(ss)}$ of 0.19 ± 0.03 and 0.18 ± 0.03 L/kg, respectively (Jernigan et al. 1988b). In that same study, IV doses of 3 mg/kg and 5 mg/kg resulted in mean residence time (MRT) of 90 ± 16 and 108 ± 21 minutes, respectively. Bioavailability after IM and SC tobramycin administration in cats was reported as

TABLE 43.8—Selected pharmacokinetic parameters of apramycin

Species	$V_{d(ss)}$ (L/kg)	Cl_B (L/kg/hr)	$t_{1/2}$ (hr)	Reference
Sheep	0.167	0.078	90.96	Lashev et al. 1992
Cow (lactating)	1.263	12.164[a]	2.10	Ziv et al. 1995

Japanese quail	0.133[b]	0.186	0.50	Lashev and Mihailov 1994
Pigeons	0.077	0.210	15.24	Lashev et al. 1992

[a] Value in mL/kg/min.

[b] V_d is area, not steady state.

greater than 100%, most likely caused by residual drug left in tissue depots from previous tobramycin administrations (Jernigan et al. 1988*d*). The mean absorption times were 35 and 60 minutes, respectively. Urine tobramycin concentrations following 2.2 mg/kg 3 times a day were 66 ± 39 µg/mL when urine was obtained as a 6-hour collection in dogs (Ling et al. 1981).

Camels (*Camelus dromedarius*) have been dosed with IV and IM tobramycin and their pharmacokinetics described (Hadi et al. 1994). After a single IV dose of tobramycin (1.3 mg/kg), the distribution phase half-life ($t_{1/2\alpha}$) was 10.8 minutes, followed by an elimination phase ($t_{1/2\beta}$) of 189 minutes. The apparent V_d (area method) was 245 mL/kg and $V_{d(ss)}$ was 228 mL/kg. Clearance was measured at 0.9 mL/min/kg. After a 1.0 mg/kg IM dose of tobramycin, bioavailability was almost 91%, with an elimination half-life ($t_{1/2\beta}$) of 201 minutes. The disposition kinetics of IV tobramycin in all camels evaluated was best described by a two-compartment open model, whereas all but one of the camels were best described by a one-compartment open model after IM dosing. In humans, using a three-compartment model, tobramycin $V_{d(ss)}$ and Cl_B decreased and $t_{1/2}$ increased slightly with decreasing renal function (Schentag et al. 1978).

NEOMYCIN. Neomycin is not used systemically in human medicine. Pharmacokinetic information about neomycin's use in human and veterinary medicine is very limited. In calves administered 12 mg/kg IV, $V_{d(B)}$ was 0.39 ± 0.13 L/kg, and $t_{1/2\beta}$ was reported as 167 ± 48 minutes (Black et al. 1983) although half-lives of approximately 1 hour have been observed (Drury 1952). Bioavailability after IM dosing of neomycin was 56 ± 5.4% in calves (Black et al. 1983) and 74 ± 27% in horses (Baggot et al. 1981). The pharmacokinetics of IV, IM, single PO, and repeated PO neomycin in ruminating Holstein calves has been described (Pedersoli et al. 1994). Variable absorption rates were also observed. In horses, a $t_{1/2\beta}$ of 2.1 ±1.0 hours has been reported, in addition to a V_d(area) of 0.232 ± 0.061 L/kg and a Cl_B of 1.3 ± 0.4 mL/min/kg (Baggot et al. 1981). Neomycin did not accumulate in inner-ear tissue as did other aminoglycosides (Desrochers and Schacht 1982) but was more potent than any other clinically used aminoglycoside at displacing gentamicin from renal binding sites (Josepovitz et al. 1982). Concentrations in guinea pig tissues other than the kidney continued to increase during 3 weeks of treatment with a dosing regimen of 100 mg/kg/day administered SC (Desrochers and Schacht 1982). Terminal half-lives have been estimated in cattle to be between 55 and 65 hours after single parenteral doses (Siddique et al. 1965). Neomycin's use today is limited to topical antibacterial therapy (see Chap. 53).

DIHYDROSTREPTOMYCIN. Pharmacokinetic studies are sparse for dihydrostreptomycin, the first aminoglycoside used clinically. After IM doses of 5.5 mg/kg dihydrostreptomycin, maximum concentrations ranged from 5.1 to 17.0 µg/mL, with peak concentrations occurring earlier and more variable from the commercial preparation containing procaine penicillin G, dihydrostreptomycin, dexamethasone, and chlorpheniramine than from the commercial product containing only dihydrostreptomycin and procaine penicillin G (Rollins et al. 1972). Half-lives range from 2.35-4.50 hours in cattle to 1.5-9.3 hours in horses, with a calculated γ-phase half-life of 6.3 hours in horses to a protracted 40 hours in cattle (Hammond 1953; Mercer et al. 1971; Riviere et al. 1990). Streptomycin (*not* dihydrostreptomycin) in horses had a $t_{1/2\beta}$ of 3.4 ± 0.4 hr, a $V_{d(area)}$ of 0.231 ± 0.041 L/kg, and a Cl_B of 0.77 ± 0.14 mL/min/kg (Baggot et al. 1981). Because streptomycin and dihydrostreptomycin are chemically very similar, their dispositions also may be nearly identical. Dihydrostreptomycin has been used successfully in the treatment of cows infected with *Leptospira interrogans* serovar *hardjo* subtype *hardjobovis* (Gerritsen et al. 1994).

PAROMOMYCIN. Paromomycin is a wide-spectrum aminoglycoside antibiotic produced by *Streptomyces rimosus* var. *paromomycinus* and, unlike others in this class, has both gram-positive and gram-negative activity. Paromomycin is poorly absorbed from the gastrointestinal tract, which is clearly an advantage if used to treat certain bacterial or protozoal gastrointestinal infections. The pharmacokinetics of paromomycin in the dog has been described by Belloli et al. (1996); see Table 43.9.

Giardia, Leishmania, Entamoeba histolytica, and *Balantidium coli* have all been demonstrated to be susceptible to paromomycin (Barr et al. 1994; Belloli et al. 1996). Paromomycin has been used to treat cryptosporidiosis in a cat (Barr et al. 1994) and leishmaniasis (*Leishmania infantum*) in the canine (Poli et al. 1997). However, a retrospective case study in cats treated with high-dose oral paromomycin (165 mg/kg) suggested that 4 of 31 individuals developed acute nephrotoxicity, deafness, and/or possible cataract

TABLE 43.9—Pharmacokinetic parameters of paromomycin in the dog

Parameter	IV	IM	SC
$t_{1/2\alpha}$	21.54	15.31	12.43

formation (Gookin, et al., 1999), implying that enough oral absorption occurred for this large and highly charged aminoglycoside to exert an adverse effect. Therefore, use of this drug at these high doses should be approached with caution until further data are available.

Several of the drugs discussed in this chapter do not fit into other categories or are not important enough for a separate chapter. They are grouped together here because they have certain features in common: they inhibit protein synthesis in bacteria (with macrolides, lincosamides, and chloramphenicol acting at a similar site), are relatively broad spectrum, and have a large volume of distribution (i.e., they achieve effective concentrations in most tissues).

Some of these drugs are not as common or as available as in previous years. Some older drugs have given way to newer derivatives. For example, newer macrolides such as azithromycin have replaced erythromycin for some uses in small-animal medicine, and florfenicol has replaced chloramphenicol for use in cattle. Earlier editions of this text should be consulted for more in-depth discussion of these older agents.

CHLORAMPHENICOL

Chemical Features. Chloramphenicol chemically is D-(−)-threo-1-*p*-nitrolphenyl-2-dichloroacetamido 1,3-propanediol (Fig. 44.1), has a pK_a of 5.5, and was first isolated from the soil organism *Streptomyces venezuelae* in 1947. The chloramphenicol used today is manufactured synthetically. Chloramphenicol is slightly soluble in water and freely soluble in propylene glycol and organic solvents. Chloramphenicol is a broad-spectrum antibiotic, affecting gram-positive and gram-negative organisms, aerobic and anaerobic bacteria, and many intracellular organisms. Chloramphenicol has three functional groups that largely determine its biological activity: the *p*-nitrophenol group, the dichloroacetyl group, and the alcoholic group at the third carbon of the propanediol chain (Yunis 1988). Replacement of the *p*-NO_2 group by a methylsulfonyl (HC_3-SO_2) moiety produces thiamphenicol and a substantial change in biological activity, while modification of the propanediol

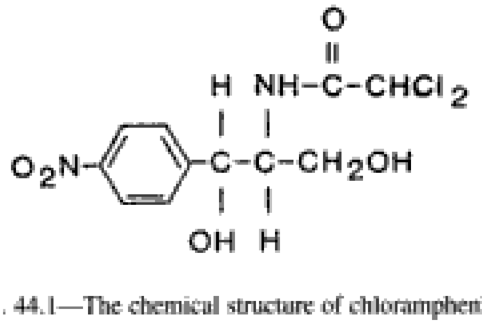

FIG. 44.1—The chemical structure of chloramphenicol

group by the addition of a fluorine atom results in the synthesis of florfenicol. Both thiamphenicol and florfenicol will be discussed in more detail later in this chapter. Loss of the dichloroacetyl group altogether results in loss of biological activity (Yunis 1988; Hird and Knifton 1986).

Drug Formulations. Three formulations of chloramphenicol have been administered for systemic therapy in animals. Chloramphenicol base is the unconjugated form of chloramphenicol and is available only in an oral formulation. Chloramphenicol base has a bitter taste, so to increase the palatability, the ester chloramphenicol palmitate was manufactured as an alternative oral formulation. Chloramphenicol palmitate is insoluble in water but soluble in acetone and ether. Before systemic absorption, chloramphenicol palmitate is hydrolyzed in the small intestine by esterases, which release the free base form of chloramphenicol to systemic circulation. Similarly, chloramphenicol succinate is a formulation for parenteral use that requires hydrolysis reactions in the plasma to produce the active drug (Ambrose 1984). The succinate form of the drug is freely soluble in water and can be administered intravenously (IV) or intramuscularly (IM). Topical formulations of chloramphenicol have been used for otic and ophthalmic use. Because of the decreased use of chloramphenicol in human medicine, some of the formulations mentioned above are not as readily available today, if at all.

Mechanism of Action. Chloramphenicol inhibits protein synthesis. Its biologic activity is due to interference with peptidyltransferase activity at the 50S ribosomal subunit, which is near the site of action of macrolide antibiotics and for which there can be competition (Yunis 1988). Because of the interaction with peptidyltransferase, binding with the amino acid substrate cannot occur, and peptide bond formation is inhibited. Chloramphenicol affects mammalian protein synthesis to some degree, especially mitochondrial protein synthesis. Mammalian mitochondrial ribosomes have a strong resemblance to bacterial ribosomes (both are 70S), with the mitochondria of the bone marrow especially susceptible. Prolonged administration to animals has been associated with a dose-related bone marrow suppression, especially in cats (Watson 1980).

Spectrum of Activity. Chloramphenicol has a broad spectrum of activity. It is active against *Staphylococcus intermedius*, *S. aureus*, streptococci, and some gram-negative bacteria, such as *Pasteurella multocida*, *P. haemolytica*, and *Haemophilus somnus*. *Escherichia coli*, *Proteus vulgaris*, and *Salmonella* spp. may be susceptible, but resistance can occur with many gram-negative bacteria, especially the Enterobacteraceae. Resistance by staphylococci may occur with increased use. Anaerobic bacteria, *Mycoplasma* spp., and many rickettsiae also are susceptible. The National Committee for Clinical Laboratory Standards (NCCLS) approved breakpoint for susceptibility is ≤4 μg/mL for streptococci and ≤8 μg/mL for other organisms (Watts et al. 1999).

Bacterial Resistance. Four mechanisms of resistance to chloramphenicol have been described (Yunis 1988). The most important is plasmid mediated due to the presence of the chloramphenicol acetyltransferase enzyme, which catalyzes a reaction that modifies the hydroxyl groups. Chloramphenicol acetyltransferase was reviewed by Shaw and Leslie (1991). Other mechanisms of resistance include decreased bacterial cell wall permeability, altered binding capabilities at the 50S ribosomal subunit, and inactivation by nitroreductases.

Pharmacokinetics

ABSORPTION AND DISTRIBUTION. The pharmacokinetic parameters of chloramphenicol have been studied in several animal species and are summarized in Table 44.1. Chloramphenicol in animals is well absorbed via both oral and parenteral routes, with a few notable species exceptions. Plasma half-lives vary, ranging from 0.9 hours in ponies to 5.1 hours in the cat (Davis et al. 1972). Watson (1992) reports that fasted cats showed differences in absorption between the chloramphenicol tablets and the chloramphenicol palmitate suspension. The liquid formulation showed a lower systemic drug availability, indicating that hydrolysis of the palmitate form is necessary and that there is a higher risk of drug failure when the palmitate suspension is used to treat sick cats that are also not eating. In ruminants, microflora present in the ruminant forestomach tend to metabolize chloramphenicol faster than it can be absorbed, making chloramphenicol administered orally of little systemic therapeutic use in ruminant animals. This point is rather moot since administration of chloramphenicol to food animals in the United States is currently illegal (discussed in more detail later in the chapter). In most animals, 30–46% of chloramphenicol is bound to plasma proteins, leaving much of the drug in the free and active form. Chloramphenicol is widely distributed to many areas of the body due to its nonionized state and high lipophilicity, enabling it to cross lipid bilayers quite easily. The volume of distribution (V_d) is typically greater than 1.0 L/kg and has been measured at 1–2.5 L/kg (Table 44.1). Chloramphenicol reaches sufficient concentrations in most tissues of the body, including the eye, central nervous system (CNS), heart, lung, prostate, saliva, liver, and spleen, among others (Ambrose 1984; Hird and Knifton 1986). Chloramphenicol concentrations in cerebrospinal fluid (CSF) are approximately 50% of corresponding plasma concentrations. In horses, because of rapid elimination rates, tissue fluid concentrations persisted for only 3 hours after IV administration of chloramphenicol sodium succinate (Brown et al. 1984). Chloramphenicol can also cross

TABLE 44.1—*Continued*

the placental barrier in pregnant animals and can diffuse into the milk of nursing animals.

METABOLISM AND EXCRETION. Chloramphenicol is metabolized by the liver after absorption into the systemic circulation. Phase II glucuronidation is the principal pathway for the hepatic biotransformation of chloramphenicol, with the principal metabolite being chloramphenicol glucuronide. A few hydrolysis products have also been identified. Cats excrete chloramphenicol more slowly than other animals, perhaps owing to the cat's deficiency in some glucuronidase enzymes. One report notes that 25% of the total dose of chloramphenicol is excreted in the urine in the active form in cats compared to 6% in normal dogs (Hird and Knifton 1986). Most of the absorbed chloramphenicol (approximately 80%) is excreted into the urine as inactive metabolites via tubular secretion.

When chloramphenicol is administered to young animals, there may initially be reduced excretion. Calves showed decreased hepatic glucuronidation of chloramphenicol soon after birth, but this metabolic pathway matured quickly. Calves also showed higher oral availability than older animals because of immaturity of the rumen, with a marked decrease in oral absorption as the calves age (Burrows et al. 1984). Brumbaugh et al. (1983) found that in neonatal horses, elimination and V_d did not differ from adults. Bioavailability in foals was 83%, with an oral half-life of 2.54 hours. A dose of 50 mg/kg orally every 6 hours should be adequate for treating most susceptible bacteria in foals.

Adverse Effects and Precautions. Bone marrow suppression has been the most important adverse effect associated with chloramphenicol administration to people. Bone marrow injury from chloramphenicol takes two forms (Yunis 1988). The first type is the most common and involves a dose-related suppression of the bone marrow precursor erythroid series. This toxicosis is reversible and usually occurs when blood chloramphenicol levels are greater than 25 µg/mL. The evidence suggests that this bone marrow suppression is the result of mitochondrial injury and the suppression of mitochondrial protein synthesis in bone marrow cells. Studies in animal species have described the pathology of bone marrow cell toxicity as a decreased entry into S phase in dividing bone marrow cells, vacuolation of the myeloid and erythroid series precursor cells, and inhibition of erythroid and granulocytic colony forming units (IARC 1976, 1990).

The second type of bone marrow toxicity, aplastic anemia, has been described in people but not in animals. In people, it is rare and independent of dose and treatment duration, and it causes bone marrow aplasia, chiefly characterized by a profound and persistent pancytopenia. This aplastic anemia occurs in approximately 1:10,000 to 1:45,000 humans who receive chloramphenicol. There may be a genetic predisposition to this form of toxicity. It appears that the para-nitro group of the chloramphenicol molecule is responsible for this more serious form of bone marrow toxicity. The para-nitro group undergoes nitroreduction, leading to the production of nitrosochloramphenicol and other toxic intermediates, which trigger the stem cell damage in humans (IARC 1976, 1990; Yunis 1988). Modification of the molecule to eliminate the para-nitro group to produce either thiamfenicol or florfenicol reduces the risk of chloramphenicol-associated aplastic anemia.

Chloramphenicol-induced aplastic anemia in humans is important from a food-animal residue standpoint. If chloramphenicol is used to treat infections in food animals, it is possible that low concentrations of chloramphenicol in milk, meat, and other edible tissues from the animals will be consumed by people and cause aplastic anemia in susceptible individuals. Chloramphenicol residues have been known to persist for prolonged periods in food animals (Korsrud et al. 1987). Even though the amount consumed may be small, the reaction is not concentration dependent. Thus, there is a public health risk for individuals consuming these products. For this and other reasons, the use of chloramphenicol in food-producing animals has been banned in the United States. *Chloramphenicol is prohibited by the Food and Drug Administration (FDA) for use in food-producing animals in the United States.* The hazards of using chloramphenicol in food animals have been reviewed (Settepani 1984; Lacey 1984).

Other adverse effects caused by chloramphenicol in animals are uncommon. However, young animals and cats are the most sensitive to intoxication due to impaired glucuronidation pathways. Cats given 60 and 120 mg/kg/day PO every eight hours for 21 and 14 days (respectively) showed clinical signs of depression, dehydration, reduced fluid intake, weight loss, emesis, and diarrhea. Bone marrow hypoplasia was also documented in addition to pancytopenia (Watson 1980). Other investigators (Penny et al. 1967, 1970) administered to cats 50 mg/kg/day IM, with the cats showing marked depression and inappetence by day 7 of administration and severe bone marrow changes by day 14 and becoming extremely ill by day 21. Dogs showed milder signs of toxicity, mainly gastrointestinal (GI), but doses required to produce these effects were higher than what was administered to cats (225 mg/kg for 2 weeks). In dogs, no changes were noted in peripheral blood cell populations. In both the dog and the cat, signs of toxicity reverse when chloramphenicol therapy is discontinued. Animals with impaired liver function may also have a higher risk of chloramphenicol intoxication.

Drug Interactions. Chloramphenicol is an inhibitor of the cytochrome P-450 drug-metabolizing enzymes. It is not known which specific family of enzymes is inhibited in animals. However, chloramphenicol administration to dogs has been shown to inhibit drug metabolism, and in dogs and cats, it prolongs pentobarbital anesthesia (Adams and Dixit 1970). Sleeping times may be prolonged by 120% in dogs and 260% in cats due to impaired metabolism of pentobarbital. Chloramphenicol also may inhibit the metabolism of digoxin, phenobarbital, propofol, primidone, and perhaps other drugs metabolized by the same enzymes. Erythromycin and chloramphenicol compete for the same site of action on bacteria, and both drugs used together may produce antibacterial antagonism.

Clinical Use. Chloramphenicol has been used for treatment of a wide range of susceptible microbial infections, including those caused by salmonellae, intracellular and extracellular bacteria, rickettsiae, and mycoplasmata; infections of the eyes and CNS; and infections due to anaerobic organisms (IARC 1976, 1990). One of the reasons for its popularity has been the high lipophilicity. Chloramphenicol readily penetrates cells, making it active against intracellular bacteria, and it penetrates tissues that otherwise are difficult to treat, such as the CNS. Chloramphenicol was shown in one study to be equally effective for treatment of Rocky Mountain spotted fever in dogs as enrofloxacin and tetracyclines (Breitschwerdt et al. 1990). Although less popular than it once was, chloramphenicol has been used to treat infections caused by *Staphylococcus* spp., streptococci, *Brucella* spp., *Pasteurella* spp., *E. coli*, *Proteus* spp., *Salmonella* spp., *Bacillus anthracis*, *Corynebacterium pyogenes*, *Erysipelothrix rhusiopathiae*, and *Klebsiella pneumoniae*. It is consistently active against anaerobic bacteria and has been a rational choice for treating these infections.

Chloramphenicol has been popular for treatment of infections of the CNS (encephalitis, meningitis) because it is able to cross the inflamed or uninflamed blood-brain barrier and attain therapeutic concentrations in the CSF and the brain. Despite the popularity for this use, some experts have suggested that since chloramphenicol is merely bacteriostatic against gram-negative pathogens, and there is a lack of phagocytes or immunoglobulins in CSF, chloramphenicol is not well suited to treat serious infections of the CNS (Rahal and Simberkoff 1979).

Chloramphenicol attains high concentrations in the eye when given systemically or after topical application on the cornea and is useful in treating susceptible bacterial conjunctivitis, panophthalmitis, endophthalmitis, and bacterial diseases of the cornea (Conner and Gupta 1973). Topical formulations are not as readily available owing to the risk of aplastic anemia (discussed previously), which can be caused by topical exposure. Florfenicol has been administered systemically for treating eye infections in cattle (see below.)

Chloramphenicol has been used to treat bacterial infections of the respiratory tract because it may have better penetration across the blood-bronchus barrier into respiratory secretions and respiratory lining fluid than more polar or less lipophilic antibiotics. Respiratory infections are among the infections in horses treated with oral chloramphenicol.

Chloramphenicol is one of the few drugs that can be administered orally to horses with safety. It achieves moderate systemic absorption of 21–40% (Gronwall et al. 1986) and has no serious adverse effects on the equine digestive system. However, oral administration resulted in intestinal mucosal damage and diarrhea in calves and reduced glucose absorption (Rollin et al. 1986). For treatment in horses, tablets or capsules are mixed with substances like molasses or corn syrup to facilitate oral administration. Chloramphenicol has been administered to horses for respiratory infections,

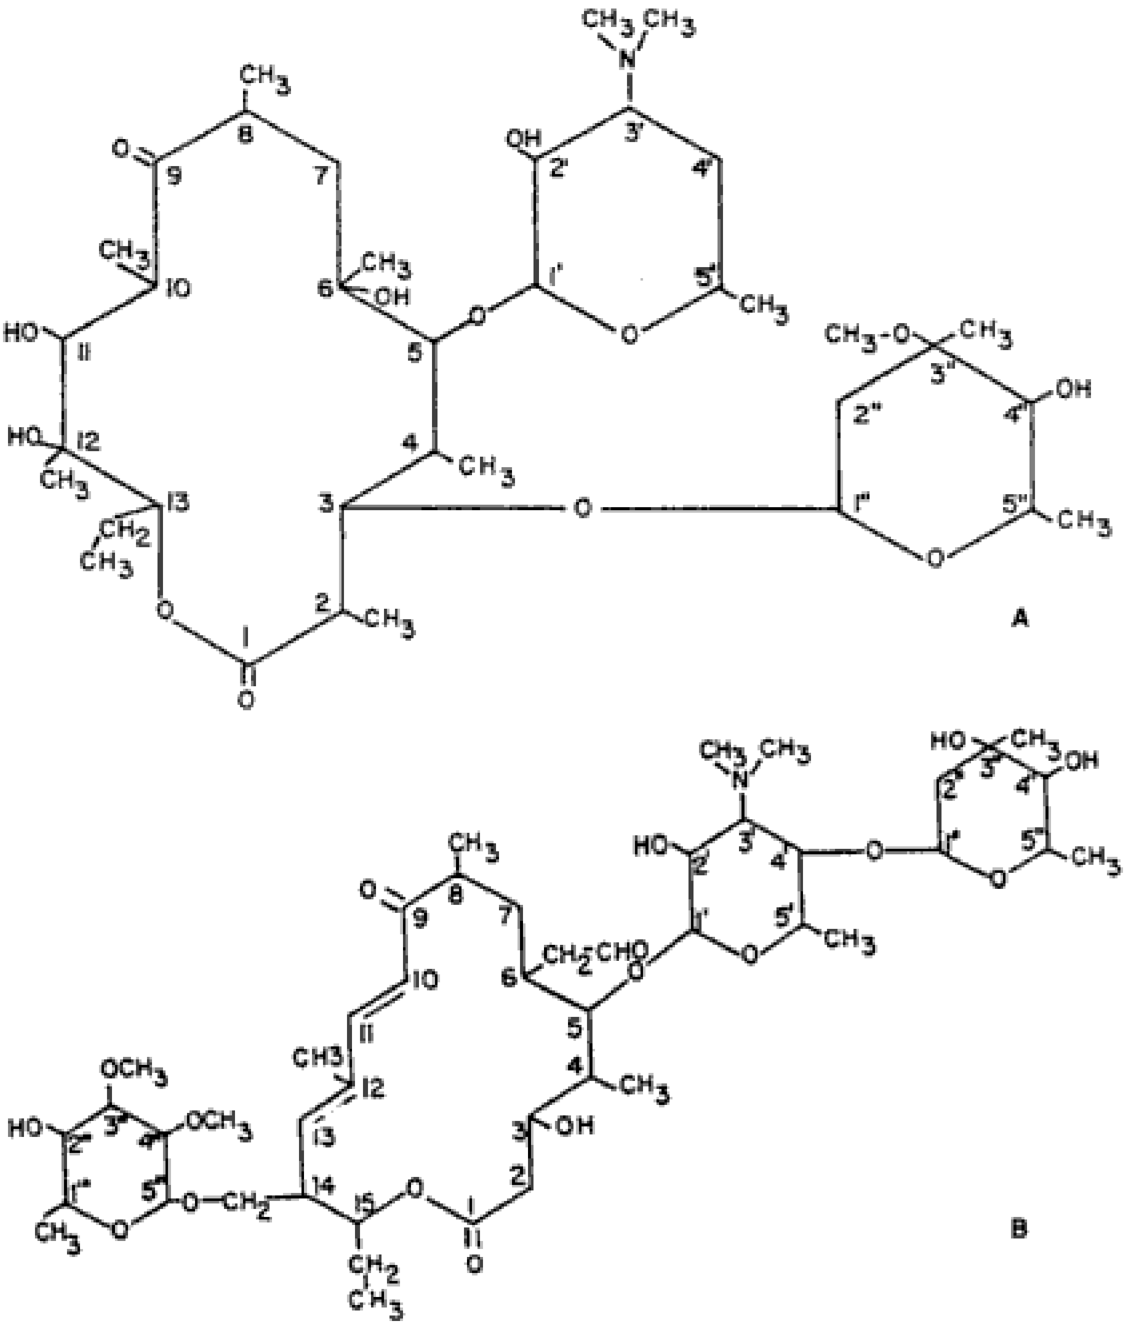

FIG. 44.4—The chemical structures of erythromycin and tylosin.

antibiotics that preferentially bind to these sites, such as other macrolides and lincosamides (Wilson 1984). Resistance to erythromycin in animals in several microorganisms has been discussed in more detail elsewhere (Maguire et al. 1989; Dutta and Devriese 1981, 1982a,b; Leclercq and Courvalin 1991; Devriese and Dutta 1984). In small animals with staphylococcal infections, resistance was more likely if antibiotics had previously been prescribed, especially in cases of recurrent pyoderma (Lloyd et al. 1996; Medleau et al. 1986; Noble and Kent 1992). As summarized by Noli and Boothe (1999), an increasing trend toward resistance to macrolides by staphylococci has been demonstrated when treating pyoderma (increasing from 7 to 22%), whereas in some countries, the incidence of resistance has remained relatively stable at around 22–24%.

Spectrum of Activity. Erythromycin is mainly effective against gram-positive organisms such as streptococci, staphylococci, including staphylococci that may be resistant to β lactams because of β lactamase synthesis or modification of the penicillin-binding protein target. Other organisms that show in vitro

macrolide azithromycin is discussed in more detail later in this section. Its distribution to tissues is higher than other macrolides discussed so far, and its V_d has been measured at over 20 L/kg in animals. Protein binding for macrolides is low, with values of 18–30% for most species.

Tylosin has good absorption from the GI tract, and no enteric coating is required to maintain the stability of the compound in the stomach. It is widely distributed to basically the same tissues as described for erythromycin, metabolized by the liver, and excreted via the bile and feces.

Tilmicosin has slow absorption, 22% bioavailability, a half-life in plasma of 4 hours, and extensive penetration in milk (Ziv et al. 1995). However, because of the high and persistent distribution to tissues, especially lungs, the plasma pharmacokinetics seem to have little correlation to the observed clinical effects (Gourlay et al. 1989).

METABOLISM AND EXCRETION. Metabolism of erythromycin is via hepatic microsomal enzymes, which causes a demethylation of one of the methyl groups on the desosamine sugar moiety of the erythromycin molecule. Little of the antimicrobial action is retained after demethylation by these enzymes. These metabolic enzymes can be induced with phenobarbital; therefore, patients given phenobarbital and erythromycin simultaneously may experience more antimicrobial treatment failures due to increased metabolism. Most (90%) of the drug in the bile is in the metabolized form. Some active erythromycin (2–5%) is found excreted into the urine, with higher levels found in the urine after IV dosing. Renal dysfunction seemingly does not have an appreciable effect on its elimination half-life in the body (Wilson 1984). Although macrolides are not a popular choice for treating urinary tract infections because of their limited spectrum of activity, high urine pH tends to favor antimicrobial activity in the urine environment (Sabath et al. 1968).

Half-lives for erythromycin range from less than 1.0 hour in rodents and rabbits to 3–4 hours in cattle. Tylosin follows a similar pattern, with half-lives of 1–2 hours in most animals.

Adverse Effects and Precautions. Side effects are reported more frequently in humans than in animals. Humans dosed with macrolides (in particular, erythromycin) have experienced nausea and vomiting (oral forms), fever, skin eruptions, cholestatic hepatitis, elevated serum aspartate aminotransferase, epigastric distress, and transient auditory impairment, among many other side effects. Cholestatic hepatitis, most commonly associated with the estolate ester, is the most common of these adverse reactions, with the symptoms starting 10–20 days after beginning therapy and ending a few days after the cessation of therapy. Cholestasis associated with erythromycin use in humans is considered to be a hypersensitivity reaction (Sande and Mandell 1990a). In animals, however, few of these side effects are observed, and hepatitis has not been a reported association. However, regurgitation and/or vomiting has been commonly reported in small animals, especially dogs after oral administration of erythromycin. In one report, erythromycin was the drug that most frequently caused side effects after oral dosing in dogs (Kunkle et al. 1995). Stimulation of GI motility may play a role in small-animal vomiting (discussed below under clinical uses). In horses, erythromycin may induce diarrhea, which stops after therapy is discontinued and is generally not fatal. Although these reactions in the horse may limit its use by some clinicians, erythromycin is still commonly used in horses to treat a variety of infections, especially in the foal.

Drug Interactions. Erythromycin is a well-known hepatic microsomal enzyme inhibitor. Erythromycin is both a substrate and an inhibitor for the cytochrome P-450 enzyme (CYP3A4), which is the enzyme system that is most often involved in drug metabolism. As an inhibitor of the cytochrome P-450 enzyme, it may inhibit metabolism of drugs such as theophylline, cyclosporine, digoxin, and warfarin. Concentrations of these drugs may increase when animals receive erythromycin, resulting in a potentiation of the pharmacologic effect or toxicity.

Clinical Use of Erythromycin. Doses of erythromycin are listed in Table 44.3. Erythromycin is primarily used for treating infections caused by gram-positive organisms. Because of the high distribution into tissues and long persistence in some cells, macrolides are particularly useful for treating some infections caused by bacteria that more-polar or less-lipid-soluble drugs may have difficulty reaching. Erythromycin and other macrolide antibiotics are sometimes used as a penicillin alternative when penicillins have either failed or when there is allergy to penicillins. Infections treated by erythromycin include those caused by *Staphylococcus* spp., *Streptococcus* spp., *Corynebacterium* spp., *Clostridium* spp., *Listeria* spp., *Bacillus* spp., *Erysipelothrix* spp., *Haemophilus* spp., *Brucella* spp., *Fusobacterium* spp., *Pasteurella* spp., *Borrelia* spp., and *Mycoplasma* spp. (Wilson 1984).

In small animals, erythromycin is used to treat pyoderma caused by staphylococci (Noli and Boothe 1999), respiratory infections caused by *Mycoplasma*, and diarrhea caused by *Campylobacter* organisms. When treating *Campylobacter*, erythromycin stopped the shedding but did not eliminate the organism. Respiratory infections are sometimes treated with erythromycin, even when a causative organism has not been identified because erythromycin crosses the blood-bronchus barrier and achieves favorable concentrations in respiratory tract secretions. Erythromycin has also been used as a treatment for undifferentiated bovine respiratory disease and for pig infections caused by *Erysipelothrix* and for pig respiratory infections caused by *Streptococcus* and *Pasteurella*. In poultry, erythromycin is used for treatment of respiratory infections caused by *Mycoplasma*. In foals, erythromycin is used, in combination with rifampin, for treatment of pneumonia caused by *Rhodococcus equi*. However, there is some evidence that erythromycin administered alone may be equally efficacious.

EFFECTS ON GI MOTILITY. Erythromycin is a common cause of vomiting and regurgitation in small animals. In one study erythromycin oral administration produced the most common adverse effects in comparison to other drugs (Kunkle et al. 1995). Although some nausea from the oral preparations is possible, most of this effect is believed to be related to a drug-induced increase in GI motility. This mechanism appears to be related to an increase in activation of motilin receptors, via release of endogenous motilin, or via cholinergic mechanisms in the upper GI tract (Hall and Washabau 1997; Lester et al. 1998). At small doses (1 mg/kg) erythromycin has been considered for use as a motility-stimulating drug in animals. Its clinical benefits for treating GI motility disorders in horses is being explored. Not all macrolide antibiotics exhibit this property.

REGULATORY CONSIDERATIONS. Erythromycin has a 6-day withdrawal time when used according to label in cattle in the United States. Erythromycin added to feed or water for poultry has a withdrawal time of 1–2 days; the specific product label should be consulted for the exact withdrawal time. In the United States erythromycin should not be administered to lactating dairy cattle because macrolides concentrate in the milk for a long time after treatment. However, Canadian labeling lists a milk withholding time of 72 hours after a dose of 2.2–4.4 mg/kg.

Tylosin. Pharmacokinetic data for tylosin are listed in Table 44.4. Tylosin has been used therapeutically to treat "pinkeye" (*Moraxella bovis*) in cattle, respiratory tract infections (Sampson et al. 1974b,c; Ose 1976; Jones 1974; Matsuoka et al. 1980), swine dysentery, pleuropneumonia due to *Haemophilus parahemolyticus*, and a variety of infections such as colitis in dogs (Sampson et al. 1974a) and other infections in cats, chickens (Ose and Tonkinson 1985), quail (Jones et al. 1976), and turkeys (Wilson 1984). Tylosin has been used more extensively as a feed additive to promote growth in food-producing animals, such as swine, cattle, and chickens, among others (Wilson 1984). Residues from tylosin have been discussed in other papers (Knothe 1977a,b; Anderson et al. 1966). After administration to cattle there is a 21- and 14-day withdrawal time for slaughter for cattle and pigs, respectively. Tylosin concentrates in milk for a long time after administration and should not be administered to lactating dairy cattle. Specific product information should be consulted for withholding times when tylosin is administered in feed or water to pigs or poultry because withdrawal times can vary from 0 to 5 days, depending on the use.

Tilmicosin. Tilmicosin is 20-deoxo-20-(3,5-dimethylpiperidin-1-yl)desmycosin, a newer macrolide antibiotic that is closely related to erythromycin. Tilmicosin phosphate (Micotil 300) has been effective for treating bovine respiratory disease and is as effective or more effective than other established treatments, such as ceftiofur, oxytetracycline, or florfenicol (Musser et al. 1996; Hoar et al. 1998; Jim et al. 1999). One study (Ose and Tonkinson 1988) reports that 90% of the *Pasteurella haemolytica* and *Pasteurella multocida* isolates tested were sensitive to tilmicosin at concentrations of ≤6.25 μg/mL, and the drug was also active against *Mycoplasma*, including those from bovine isolates. Other organisms with in vitro susceptibility to tilmicosin include staphylococci and streptococci. Most gram-negative organisms other than *Pasteurella* and *Haemophilus* are resistant.

Tilmicosin (in a 25% propylene glycol carrier) is reported to be effective as a single-dose treatment of neonatal calf pneumonia at dosages of 10, 20, and 30 mg/kg administered subcutaneously. In another study,

calves with pneumonia were found to respond better when treated with 10 mg/kg SC tilmicosin than with a 20 mg/kg IM dose of oxytetracycline (Laven and Andrews 1991). In a study by Gourlay et al. (1989) using calves treated with 20 mg/kg SC tilmicosin, the high success rate in treating bovine pneumonia was believed to be due in part to the prolonged presence of therapeutic concentrations of tilmicosin in the lung tissues. Due to high affinity for certain tissues, tilmicosin concentrations remain above the MIC of susceptible organisms for at least 72 hours. Resistance among cattle respiratory pathogens has been recognized (Musser et al. 1996). However, because tilmicosin has such a high concentration in some tissues (e.g., the lung), in vitro measurements of resistance may have little relationship to whether or not the drug produces a cure in cattle with respiratory disease (Musser et al. 1996).

Tilmicosin also has been used as a prophylactic antibiotic for administration to calves entering a feedlot situation. Tilmicosin reduced the incidence of pneumonia in susceptible calves when administered prophylactically as a single 10 mg/kg SC injection (Morck et al. 1993; Schumann et al. 1990). Tilmicosin used as a metaphylactic treatment in newly arrived feedlot calves reduced prevalence of bovine respiratory disease and improved growth of calves (Vogel et al. 1998).

The NCCLS guidelines for tilmicosin susceptibility list a breakpoint of ≤8 µg/mL (Watts et al. 1999). The currently approved dose is 10 mg/kg SC as a single treatment. After treatment with tilmicosin phosphate in cattle, there is a 28-day withdrawal time. Tilmicosin should not be administered to lactating dairy cattle because residues may persist in milk for more than 30 days.

Injections of tilmicosin to horses, goats, swine, or nonhuman primates can be fatal. The heart is the target of toxicity in animals, perhaps mediated via depletion of cardiac intracellular calcium, resulting in a negative inotropic effect (Main et al. 1996). Epinephrine worsens the cardiac toxicity in pigs, but dobutamine has alleviated the cardiac depression in dogs (Main et al. 1996). The effects of toxicity are increased heart rate, arrhythmia, and depressed contractility. Injected doses of 20 and 30 mg/kg to pigs caused death, but oral tilmicosin in pigs produces no toxic effects. In cattle, injected SC doses of 50 mg/kg caused myocardial toxicity; 150 mg/kg was lethal. Doses as low as 10 mg/kg IV have caused cardiac toxicity as well (Ziv et al. 1995).

Tilmicosin phosphate is approved for treatment of swine respiratory disease caused by *Actinobacillus pleuropneumoniae* and *Pasteurella multocida*. This form (Pulmotil) is administered as a feed additive and has been shown to be effective for controlling pneumonia in swine (Moore et al. 1996). When injected in swine, tilmicosin has caused toxic reactions and death due to cardiovascular reactions. Horses should not have access to feeds medicated with swine tilmicosin. There is a 7-day withdrawal time for slaughter when administered to swine.

The only other reports of tilmicosin treatment in animals is for treatment of pasteurellosis in rabbits (McKay et al. 1996). Single doses of 25 mg/kg SC were an effective treatment for pasteurellosis in rabbits. There were no toxic side effects.

Clarithromycin. Clarithromycin (Biaxin®) is a new macrolide that is semisynthetically derived from erythromycin. It is primarily used in people because it is tolerated better than erythromycin, has a broader spectrum, and concentrates in leukocytes. Clarithromycin in combination with ranitidine and bismuth (Tritec®) is currently used to treat *Helicobacter pylori* infections in people. In dogs, clarithromycin does not have pharmacokinetic features that are as favorable as those of azithromycin (the half-life is not as long), and except for pharmacokinetic studies, its use in veterinary medicine has not been reported (Vilmányi et al. 1996).

Azithromycin. Azithromycin (Zithromax®) is the first drug in the class of azalides. Azalides are derived from erythromycin and their mechanisms of action are similar. (Erythromycin has a 14-member ring structure, and azithromycin has a 15-member ring structure.) Azithromycin has better oral absorption, is better tolerated, has a much longer half-life (especially in tissues), and has a broader spectrum of activity than erythromycin.

Azithromycin is active against gram-positive aerobic bacteria (staphylococci and streptococci) and anaerobes. However, the activity against staphylococci is not as good as erythromycin. It has some activity against gram-negative bacteria such as *Haemophilus* but not against enteric gram-negative bacteria or *Pseudomonas*. It has good activity against many intracellular organisms, including *Chlamydia* and *Toxoplasma*. It is also active against mycobacteria and *Mycoplasma* (Lode et al. 1996)

The primary pharmacokinetic difference between azithromycin and erythromycin is the long half-life and high concentration in tissues. Azithromycin has an extraordinary ability to concentrate in tissues, particularly leukocytes, macrophages, and fibroblasts. The tissue concentration can be as much as 100 times serum concentrations. Concentrations in leukocytes can be at least 200–300 times the concentrations in serum (Panteix et al. 1993). In cats, the serum half-life is 35 hours, tissue half-lives vary from 13 to 72 hours, and the V_d is 23 L/kg (Hunter et al. 1995). In dogs, it also exhibits rapid uptake and persistent concentrations in tissues; the V_d is 12 L/kg, and plasma and tissue half-lives are 29 and 90 hours, respectively (Shepard and Falkner 1990). Oral absorption is high, with bioavailability values of 58% in cats (Hunter et al. 1995) and 97% in dogs (Shepard and Falkner 1990). In people, azithromycin is absorbed much better on an empty stomach (Lode et al. 1996).

Of particular interest is the fact that the intracellular reservoir of azithromycin can apparently produce effective drug concentrations in the interstitial fluids,

tion. Lincomycin is well distributed in the body, with highest tissue concentrations in the liver and kidneys, while very low levels are obtained in the CSF (Burrows 1980; Ford and Aronson 1985; Kleckner 1984). The V_d in animals ranges from 1 to 1.3 L/kg.

METABOLISM AND EXCRETION. The half-life after oral, IM, or IV administration is approximately 2–4 hours. Most of the oral dose, measured as ^{14}C-labeled lincomycin, was recovered in the feces and 14% in the urine after a single oral administration to the dog (Kleckner 1984); thus, biliary secretion of lincomycin appears to be an important route of elimination. After a single IM injection, 38% of the dose was found in the feces and 49% in the urine of the dog. Urine excretion of the radiolabeled drug was complete in 24 hours and fecal excretion was complete within 48 hours for both dosing routes. It is not known whether this radioactivity was associated with an unchanged/unmetabolized lincomycin or with the metabolites of this compound. An unpublished report cited by Hornish et al. (1987) stated the parent drug was the primary form present in the urine of dogs and humans.

Because of the potential for residues in meat, from a food-animal residue viewpoint, the metabolism and excretion of lincomycin have been studied more extensively in swine and chickens (Hornish et al. 1987). When administered to animals, lincomycin concentrations are highest in the liver and kidney, with low, albeit detectable, levels in muscle and skin. Lincomycin can pass unchanged from the body via the bile and feces or urine or can be metabolized to the glucuronide, *N*-demethyl lincomycin, or lincomycin sulfoxide forms by the liver. Swine given oral doses of lincomycin showed that 11–21% was excreted into the urine: 50% unchanged lincomycin, trace amounts of *N*-demethyl lincomycin, no lincomycin sulfoxide or glucuronide forms, and the rest labeled "unidentified substances." The feces contained the remainder of the excreted lincomycin: 17% unchanged lincomycin, possible trace amounts of lincomycin sulfoxide, and 83% uncharacterized metabolites (Hornish et al. 1987). Similarly conducted studies in chickens treated orally for 7 days with lincomycin showed that the excreta contained ≈80% lincomycin, ≤10% lincomycin sulfoxide, ≤5% *N*-demethyl lincomycin.

ADVERSE EFFECTS AND PRECAUTIONS. Dogs and cats have few adverse reactions to lincomycin. Loose stools in the dog and vomiting in the cat have been the major side effects reported (Kleckner 1984). Pigs may occasionally develop diarrhea and/or swelling of the anus within the first 2 days of treatment and will self-correct within a week after withdrawal from the antibiotic.

The most serious adverse effect from lincomycin reported in people is that of pseudomembranous colitis. This is a serious disease in people caused by an overgrowth and production of toxin from *Clostridium difficile*, which may be fatal. In animals with fermenting GI tracts (horses, ruminants, rabbits, hamsters, chinchillas, and guinea pigs) there also is a high risk of GI bacterial overgrowth with *Clostridium* from lincomycin treatment. Severe enteritis, enterocolitis, may lead to diarrhea and death. Other bacteria also have been implicated in this reaction, such as *Salmonella* spp. or *E. coli* (Burrows 1980; Plenderleith 1988). Rehg and Pakes (1982) have implicated *Clostridium difficile* and *Clostridium perfringens* toxins in lincomycin toxicity in rabbits. Lincomycin-induced enterocolitis has been reported for rabbits (Maiers and Mason 1984; Thilsted et al. 1981), horses (Raisbeck et al. 1981; Plenderleith 1988), sheep (Bulgin 1988), and large ruminants (Plenderleith 1988). Lincomycin has been reported to produce ketosis in dairy cows (Rice and McMurray 1983).

CLINICAL USE. Lincomycin is used to treat gram-positive aerobic and anaerobic infections in patients for many of the same indications for which one would use erythromycin or other macrolide. In dogs and cats, lincomycin has been used to treat penicillin-resistant or suspected penicillin-resistant strains of *Staphylococcus* spp. and *Streptococcus* spp. bacteria found in bone, the upper respiratory tract, and the skin. The use for skin infections has been particularly popular (Noli and Boothe 1999). Doses in dogs and cats generally are 22 mg/kg every 12 hours orally. The use of lincomycin to treat bacterial infections in dogs and cats has been largely replaced by clindamycin therapy.

Lincomycin has been utilized to treat bacterial arthritis in swine caused by *Staphylococcus* spp., *Streptococcus* spp., *Erysipelothrix* spp., and *Mycoplasma* spp. and pneumonia caused by *Mycoplasma* spp. Doses in pigs are 11 mg/kg every 24 hours IM. It has also been used as a feed additive (Rainier et al. 1980), drinking-water supplement (Hamdy 1978), and parenteral product (Hamdy and Kratzer 1981) to control or treat swine dysentery.

In broiler chickens, lincomycin has been used as a feed additive to increase the rate of weight gain and improve feed efficiency, in addition to treating necrotic enteritis in this species. The addition of 2 g/ton of lincomycin to the feed of broilers resulted in a significant decrease in the incidence of necrotic enteritis (Maxey and Page 1977). Lincomycin has also been used with success in psittacines (Mandel 1977). Lincomycin use in the eyes of rabbits has also been reported (Kleinberg et al. 1979). Topical corneal administration of 1% lincomycin in water to rabbits showed local therapeutic levels could be maintained from 30–45 minutes to 2 hours postdose in the cornea, aqueous humor, and iris-ciliary body and that deepithelialization of the corneal epithelium served to enhance the ocular topical absorption of this antibiotic.

Sheep, goats, and calves have been treated with parenteral lincomycin-spectinomycin antibiotic combinations for gram-positive and gram-negative respiratory tract infections. The lincomycin-spectinomycin combination (50 mg lincomycin with 100 mg spectinomycin ["Linco-Spectam"] per mL) at a dose of 1 mL/10 kg body weight IM has been used to treat foot rot in sheep caused by *Bacteroides nodosus* with better success than systemic penicillin-streptomycin therapy (Venning et al. 1990).

REGULATORY CONSIDERATIONS. When added to feed for poultry and pigs, the slaughter withdrawal time ranges from 0 to 6 days, depending on the preparation and dose. Consult the package insert for specific recommendations. When injected in pigs, the withdrawal time for slaughter is 2 days.

Clindamycin

SOURCE AND CHEMISTRY. Clindamycin chemically is 7-chlorolincomycin, a derivative of lincomycin and an antibiotic produced by *Streptococcus lincolnensis* var. *lincolnensis*. The replacement of the hydroxyl group at the C7 position of the lincomycin molecule by a chloride results in a more active antibacterial effect when compared to lincomycin. The chemical structure of clindamycin is shown in Fig. 44.6. It is a weak base with a pK_a of 7.6. Both clindamycin hydrochloride (HCl) and clindamycin palmitate are for oral administration. Clindamycin HCl is directly active when administered, whereas the palmitate form must be converted to clindamycin in the small intestine. Clindamycin palmitate is more palatable than clindamycin HCl. Clindamycin phosphate is the parenteral form of clindamycin and must undergo hydrolysis in the plasma for it to become active.

MECHANISM OF ACTION. Clindamycin exerts its antibiotic activity by inhibiting protein synthesis at the 50S ribosomal subunit (Hedstrom 1984) in a manner identical to that described for lincomycin. Plasmid-mediated resistance to clindamycin has been reported in *Bacteroides fragilis* (Tally et al. 1979) and cross-resistance to lincomycin can occur (Harari and Lincoln 1989).

SPECTRUM OF ACTIVITY. Clindamycin is distinguished from the macrolide antibiotics and lincomycin by its high activity against anaerobic bacteria, including gram-negative anaerobes such as *Bacteroides* spp.

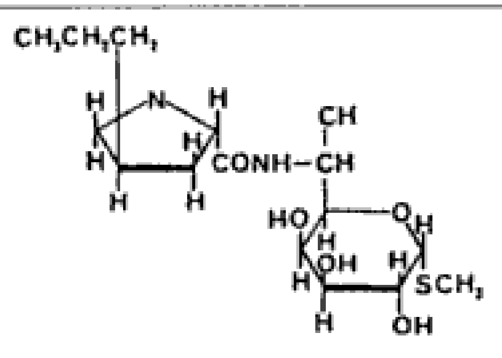

FIG. 44.6—The chemical structure of clindamycin.

In small animals, anaerobic infections are one of the major uses of clindamycin. However, one report (Jang et al. 1997) indicated that only 83% of *Bacteroides* from small animals were sensitive to clindamycin and only 80% of the *Clostridium*. Other than anaerobes, clindamycin is active against the same bacteria previously listed for macrolides and lincomycin. An additional organism for which there is activity is *Toxoplasma*. The clinical use of clindamycin for treating toxoplasmosis in cats is controversial.

PHARMACOKINETICS

ABSORPTION AND DISTRIBUTION. Clindamycin is better absorbed from the GI tract in humans and animals than lincomycin, yielding higher serum concentrations, and is more active than lincomycin due to the chlorine substitution (Nichols and Keys 1984). Brown and coworkers (Brown et al. 1989; Brown et al. 1990) have described the pharmacokinetics of oral clindamycin HCl disposition in the cat. Groups of cats were given oral doses of either 5.5, 11.0, or 22.0 mg/kg once daily of clindamycin (Antirobe), with physical, histologic, and hematologic changes recorded during therapy. Mean residence time was reported to be 276, 274, and 393 minutes, respectively. It was also found that the 5.5 and 11.0 mg/kg oral doses maintained a serum MIC above that necessary for most *Staphylococcus aureus* infections and that the 11.0 and 22.0 mg/kg doses gave serum concentrations above the MIC for many susceptible anaerobes. Clindamycin is distributed well to tissues and attains high intracellular concentrations as exhibited by the high V_d. The apparent V_d in cats was 1.62, 1.76, and 3.06 L/kg for the 5.5, 11, and 22 mg/kg doses, respectively. The highest concentrations of clindamycin were found in the lung, followed by liver, spleen, jejunum, and colon. Although the CSF had very low but detectable levels of clindamycin, the brain had higher than anticipated concentrations. This was most likely due to clindamycin's lipophilic nature, having a greater affinity for the lipid matrix of the brain than for the aqueous CSF. Bone marrow also had appreciable levels of clindamycin accumulation, due to sequestration of clindamycin in the fat, the concentration of clindamycin in the white blood cell precursors, or a combination of both factors.

In the dog (Budsberg et al. 1992; Lavy et al. 1999), clindamycin phosphate was administered IV, IM, and SC at 10 and 11 mg/kg. The elimination half-life was 2–3.2 hours IV but longer (5–7 hr) from IM and SC injection. The V_d was 0.9–1.4 L/kg. The bioavailability of clindamycin in one study after IM injection was 87% (Budsberg et al. 1992), but in another study bioavailability was greater than 100% from an IM dose and over 300% from the SC dose (Lavy et al. 1999). It appears that the prolonged elimination half-life from the SC administration ("flip-flop" effect) resulted in a falsely high estimate of the true availability following IM and SC administration in these studies. In one

treatment of these infected dogs, resulting in a 94% recovery rate in the clindamycin-treated dogs. Clindamycin also has been shown to be effective for treatment of superficial pyoderma in dogs and is a common choice as an alternative to β-lactam antibiotics (Harvey et al. 1993; Noli and Boothe 1999). In dogs, dosing 11 mg/kg IV every 12 hours should be sufficient for treating most *Staphylococcus* spp. infections, and increasing the frequency of dosing to every 6 or 8 hours should increase serum concentrations sufficiently to combat most susceptible pathogenic anaerobes.

MISCELLANEOUS ANTIBIOTICS

Bacitracin. Bacitracin is a complex labile polypeptide consisting of 5–10 separate chemical components first isolated from a *Bacillus subtillus*–contaminated wound in 1943 (Teske 1984). Bacitracin A ($C_{66}H_{103}N_{17}O_{16}S$) is the major component of this mixture and accounts for most of the antibiotic activities. Bacitracin inhibits peptidoglycan synthesis in bacteria by nonspecifically blocking phosphorylase reactions, some of which occur during cell wall synthesis (Lancini and Parenti 1982). Development of resistance to bacitracin is rare.

Bacitracin is effective against gram-positive organisms when administered topically or parenterally. Bacitracin is not absorbed from the GI tract when given orally. Systemic administration has resulted in a high incidence of nephrotoxicity (albuminuria, cylindruria, azotemia), in addition to pain, induration, and petechiae at the site of injection. In contrast, bacitracin is nonirritating and rarely induces allergic reactions when used topically. Bacitracin (bacitracin, bacitracin methylenedisalicylate, bacitracin manganese, zinc bacitracin) has been used as a feed additive to promote growth in many species of animals, but its most common use today is in topical applications to treat susceptible skin, ear, and eye infections. Bacitracin inhibits many organisms found on skin, such as hemolytic and nonhemolytic *Streptococcus* spp., coagulase-positive *Staphylococcus* spp., and some *Clostridium* spp., and it is often combined with other antibiotics that have a gram-negative spectrum of activity (polymyxin B, neomycin). Zinc bacitracin administered topically may increase the activity of bacitracin due to zinc's astringent properties, which decrease inflammation (Harvey 1985).

Novobiocin. Novobiocin is a dibasic acid ($pK_a = 4.3$ and 9.1) derived from coumarin and is utilized clinically as a mono- (Na^+) or dibasic (Ca^{++}) salt form. Novobiocin possesses activity against both gram-positive and gram-negative bacteria but is more efficacious against the gram positives, in particular *Staphylococcus aureus*. Other susceptible organisms include *Neisseria* spp., *Haemophilus* spp., *Brucella* spp., and some strains of *Proteus* spp. It may be used as an alternative to penicillins in cases involving penicillin-resistant *Staphylococcus* spp., although other penicillin substitutes (cephalosporins, macrolides, clindamycin) are better clinical choices.

Novobiocin has several toxic effects on bacteria, but its exact mechanism and site of action are unknown. Novobiocin has been shown to cause nonspecific inhibition of cell wall synthesis by inhibiting formation of alternating *N*-acetylmuramic acid pentapeptide and *N*-acetylglucosamine residues; it also inhibits teichuronic acid in some species of bacteria. The concentrations needed to inhibit these cell wall components are greater than the minimal concentration needed to inhibit growth, suggesting these effects on bacteria are secondary effects. DNA and RNA synthesis, protein synthesis (β-galactosidase), respiration, and oxidative phosphorylation are also inhibited in some species of bacteria and in rat liver homogenates (Morris and Russell 1971), with none seemingly being the primary antibiotic effect. Novobiocin is also known to induce an intracellular magnesium deficiency, but there is no direct convincing evidence that this is the mechanism responsible for novobiocin's antimicrobial activity.

Novobiocin is initially highly effective against *Staphylococcus* spp. infections, but resistance to this antibiotic develops quickly (Morris and Russell 1971; Harvey 1985). Synergism occurs when novobiocin is combined with tetracycline. Novobiocin has been combined with tetracycline in a commercial preparation (Delta-Albaplex, Upjohn) to broaden the spectrum of activity and to decrease the resistance to novobiocin. Novobiocin and tetracycline have been reported to be efficacious in cases of canine upper respiratory diseases such as "kennel cough" and tonsillitis (Maxey 1980). Toxic side effects in animals and humans given novobiocin systemically have been reported and include skin rashes, leucopenia, pancytopenia, anemia, agranulocytosis, thrombocytopenia, nausea, vomiting, and diarrhea. Few side effects have been reported for this antibiotic used in its topical form in domestic animals.

Thiostrepton. Thiostrepton is a polypeptide antibiotic produced by *Streptomyces aureus* and has a predominately gram-positive spectrum, although some gram-negative organisms are also affected. Thiostrepton is not absorbed from the GI tract and is used primarily for topical local therapy, usually combined with other antibiotics and/or glucocorticosteroids for dermatologic therapy (Huber 1982).

Rifampin. Rifampin is a complex macrocyclic high-molecular-weight semisynthetic antibiotic derived from rifamycin B, produced by *Nocardia mediterrea*. Rifamycin B is chemically modified to produce rifampin (US and Canadian name), also known as rifampicin in Europe. The chemical structure of rifampin is shown in Fig. 44.7. Rifampin has a high activity against gram-positive bacteria (*Staphylococcus* spp.), *Mycobacterium* spp., *Haemophilus* spp., *Neisseria* spp., and *Chlamydia* spp., and some limited activity against the gram-negative bacteria.

to veterinarians include *Staphylococcus aureus* and *Staphylococcus epidermidis* (including methicillin-resistant strains), *Streptococcus* spp., *Rhodococcus equi, Corynebacterium pseudotuberculosis,* and most strains of *Bacteroides* spp., *Clostridium* spp., *Neisseria* spp., and *Listeria* spp. Organisms known to be resistant to rifampin are *Pseudomonas aeruginosa, E. coli, Enterobacter* spp., *Klebsiella pneumoniae, Proteus* spp., and *Salmonella* spp. Wilson et al. (1988) obtained samples from clinically ill horses and tested the isolated bacteria for susceptibility to rifampin. It was found that all strains of coagulase-positive *Staphylococcus* spp., *Streptococcus zooepidemicus, Streptococcus equi, Streptococcus equisimilus, Rhodococcus equi,* and *Corynebacterium pseudotuberculosis* were highly susceptible to rifampin at MICs of 0.25 μg/mL. Gram-negative organisms isolated in that study were *Actinobacillus suis, Actinobacillus equuli,* and *Bordetella bronchiseptica,* and MIC values ranged from <0.008 to >16 μg/mL. Other isolates, such as *Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella pneumoniae, Proteus* spp., and *Salmonella* spp., were found to be resistant, having MICs greater than 4 μg/mL.

Rifampin is used to treat equine diseases of a gram-positive bacterial origin (e.g., *Rhodococcus equi, Streptococcus equi*). However, resistance to rifampin is quickly acquired when administered alone to combat these infections. Resistance is readily accomplished by a single mutation of the amino acid sequence of the β subunit of the DNA-dependent RNA polymerase enzyme. Mutations result in rifampin having less affinity for the RNA polymerase enzyme. Higher concentrations of rifampin are necessary to overcome this resistance in vitro. Resistance can be minimized if other antibiotics are used concurrently with rifampin that will kill the mutant strains of bacteria produced in response to rifampin. Antibiotics that can be so used are erythromycin, most of the β-lactam antibiotics, vancomycin, and gentamicin, depending on the bacterial sensitivity to these drugs (Frank 1990).

Synergism may occur between amphotericin B and rifampin against some fungi, particularly *Saccharomyces cerevisiae, Histoplasma capsulatum,* several species of *Aspergillus,* and *Blastomyces dermatitidis* (Medoff 1983). Increased permeability of rifampin across the fungal cell wall (and hence increased inhibition of RNA polymerases) due to amphotericin B–induced cell wall damage is probably the mechanism responsible for this synergism.

Rifampin is a potent inducer of hepatic microsomal enzymes and is also teratogenic in laboratory animals, so its use in pregnant animals should be restricted. Rifampin has also been reported to turn the urine red. Dogs given the human dose of 10 mg/kg orally developed increases in hepatic enzyme activity, some of which eventually progressed to clinical cases of hepatitis. Hepatitis is the most common reason to discontinue rifampin treatment in dogs. However, lowering the total daily dose of rifampin will decrease the chances of inducing toxic side effects, especially in dogs. Although rare, rifampin can induce thrombocytopenia, hemolytic anemia, anorexia, vomiting, and diarrhea. Preexisting renal disease does not normally require a dose modification of rifampin.

Nitrofurans. Nitrofurans comprise several synthetic compounds derived from 5-nitrofuran and possess antimicrobial activity, the 5-nitro group being required for this activity. Over 3500 nitrofurans have been synthesized to date, with only a handful being useful in animal chemotherapy. Nitrofurans and furazolidone are banned from use in food-producing animals.

Nitrofurans as a group are bacteriostatic and function by blocking oxidative decarboxylation of pyruvate to acetyl coenzyme A, depriving susceptible organisms of vital energy production pathways. Their spectrum of activity encompasses gram-positive and gram-negative bacteria and some protozoans, but they are most effective against the gram-negative bacteria. Nitrofurans can be administered orally or topically. Oral absorption is enhanced when administered with feed; it is widely distributed throughout the body but in low concentrations. Approximately 50% of the total dose of nitrofurans is excreted in the active form. Acidification of the urine promotes tubular reabsorption, which also decreases the overall urine concentration of the drug. An acid environment is required for the nitrofurans to diffuse across the cell membranes. Nitrofurantoin has a broad gram-positive and gram-negative spectrum and also high concentrations in the urine, making it useful as a urinary antiseptic in small animals. Nitrofuran use today is mainly in topical preparations for the eye, ear, mucous membranes, and skin; it finds limited use in treating bacterial GI tract and urinary tract disorders (Ali 1989; Ford and Aronson 1985).

The major disadvantage of nitrofurans to treat systemic infections is that the concentrations needed to reach the MIC also induce systemic toxicity. There are many reports in the veterinary literature on the toxicities induced when the nitrofurans are used systemically (Ali 1983). The toxicology of furazolidone (*N*-5-nitro-2-furfurylidene amino-2-oxazolidinone) has been investigated extensively in laboratory, food, and companion animals as well as in humans and has been reviewed by Ali (1989). The effects of feeding furazolidone to poultry have been reported (Ali 1989; Mustafa et al. 1975; Czarnecki et al. 1974a; Jankus et al. 1972; Czarnecki et al. 1974b).

Furazolidone has also been demonstrated to be carcinogenic when used at a 0.15% w/w concentration in feed for 1 year, inducing mammary tumors in a dose-related manner. Mice fed a 0.03% w/w concentration in feed for life developed bronchial adenocarcinomas in both sexes (Ali 1983). DNA is the principal target of furazolidone in some cells in vivo, causing cuts and mutations in DNA and binding to DNA, hence blocking the replication and transcription processes. Mutagenesis by nitrofurans in general also occurs and has been extensively reviewed by McCalla (1983), who

the bacterium's rapid death. Over 80 *n*-alkyl vancomycins have been synthesized by reductive alkylation of vancomycin, with some forms being 5 times more active than vancomycin and with some having longer elimination half-lives (Nagarajan et al. 1989).

ADVERSE EFFECTS. The most common adverse effect is kidney injury. Early formulations of vancomycin were associated with a high incidence of adverse effects. Most of these effects were associated with rapid IV administration, which induced flushing of the skin, pruritus, tachycardia, and other signs attributed to histamine release. Nephrotoxicity and ototoxicity also were reported. Newer formulations are safer, but histamine release still is possible from IV administration. Toxicity studies on vancomycin have been performed in many species of laboratory animals (Wold and Turnipseed 1981). The LD_{50} for the canine was 292 mg/kg, but death did not occur until several days after dosing. Dogs that died typically had blood urea nitrogen (BUN) values between 250 and 300 mg/dL, death presumably being due to acute nephrotoxic renal failure.

CLINICAL USE AND ADMINISTRATION GUIDELINES. Clinical use of vancomycin has been limited in veterinary medicine and most of our clinical recommendations for use are derived from pharmacokinetic studies performed in dogs and recommendations of effective blood concentrations for people. Vancomycin must be administered via IV infusion, although in rare instances intraperitoneal administration has been used. Vancomycin is poorly absorbed orally and this route is not used except to treat intestinal infections. IM administration is painful and irritating.

In dogs the half-life is somewhat shorter and the V_d smaller than in humans (Zaghlol and Brown 1988). In order to keep the plasma concentration within a suggested window of 10–30 µg/mL, the dose rate of 15 mg/kg q6h IV is recommended. (This dose actually produces peaks and troughs of approximately 40 and 5 µg/mL, respectively, but it is the most convenient dose that can be used because of the short half-life in dogs.) This dose should be infused slowly over 30–60 minutes, or a rate of approximately 10 mg/min. The total dose to be administered can be diluted in 0.9% saline or 5% dextrose solution, but not alkalinizing solutions. Vancomycin is available in vials of 500 mg to 5 g (Vancocin, other brands, and generic). If vancomycin is used to treat enterococcal infections, it is strongly recommended to coadminister an aminoglycoside (e.g., amikacin or gentamicin) because when used alone, vancomycin is not bactericidal.

If vancomycin is administered according to the recommended dosing rates, adverse reactions described earlier are rare. A slow infusion is recommended to minimize histamine release. To avoid other toxic reactions, dose recommendations are designed to avoid high plasma concentrations. In people, therapeutic drug monitoring is often performed to ensure that peak concentrations are below 50 µg/mL and the trough concentrations are above 5 µg/mL. If animals have renal disease or unique physiologic changes (e.g., pregnant or a neonatal animal), drug disposition may change, and peak and trough plasma concentrations should be monitored to adjust the dose appropriately.

REGULATORY CONSIDERATIONS. In August 20, 1997, the USFDA prohibited the extralabel use of glycopeptides in food-producing animals for fear of glycopeptide-resistant bacteria being transmitted to humans from treated animals (Bates et al. 1994). Feeding glycopeptides to animals is not legal in the United States.

Methenamine. Methenamine (hexamethylenetetramine) is a urinary antiseptic most commonly used to treat urinary tract infections in small animals. It may be used in conjunction with an antibiotic or occasionally by itself in some cases of bacterial urinary tract infections that have become refractory to conventional antibiotic therapies. Methenamine is activated by a hydrolysis reaction to form formaldehyde and ammonia in acidic urine. It has been proven to be effective against a wide variety of gram-positive and gram-negative organisms but will not affect the growth of *Candida albicans*. It can be either bacteriostatic or bactericidal depending on the pH of the urine (Huber 1982; Harvey 1985).

Methenamine is quickly absorbed when given orally, is excreted via the urine, and is associated with a low systemic toxicity. For this drug to be efficacious, the urine must be at an acidic pH in order to liberate free formaldehyde. Methenamine is often found combined with mandelate (mandelic acid), which assists in lowering the urine pH and also exerts some independent weak antibacterial activity. Concurrent use of other urinary acidifiers, such as ascorbic acid, arginine HCl, methionine, cranberry juice (hippurate), and ammonium chloride, will enhance the antibacterial action of methenamine. Methenamine is most effective when the urine pH is 6 or below. Sulfonamides should not be administered with methenamine due to the formation of insoluble formaldehyde-sulfonamide precipitates. Since methenamine is largely eliminated via the kidney, its use should be restricted or closely monitored in cases of renal insufficiency (Huber 1982; Harvey 1985). Methenamine is less effective for treating infections caused by urea-splitting organisms which increase the urine pH (e.g., *Proteus mirabilis*).

Methenamine mandelate has been used experimentally in the treatment of burn wounds in rats. Topical doses of 5% and 10% were highly efficacious against experimentally induced burns infected with a virulent strain of *Pseudomonas* spp. (Taylor et al. 1970).

Polymyxins. Polymyxins are a group of *N*-monoacetylated decapeptides discovered in 1947 and are produced by *Bacillus polymyxa*. They contain 7 amino acids in a cyclic configuration and have a molecular weight of approximately 1000. Several polymyx-

The use of the fluoroquinolone antibacterial agents in veterinary medicine has increased tremendously in the last 10 years. The fluoroquinolones are synthetic antibacterial agents introduced in veterinary medicine first as enrofloxacin. Since then, there has been a great deal of research on this class of drugs to better understand their mechanism of action, antimicrobial spectrum, pharmacokinetics in a wide variety of animal species, and clinical use (Brown 1996). In addition, pharmaceutical companies have developed new compounds to increase the number of these drugs available to veterinarians. The advantages of the fluoroquinolones are that they are rapidly bactericidal against a wide variety of clinically important bacterial organisms, are potent, are well-tolerated by animals, and have been administered via a variety of routes (orally via tablets and drinking water, subcutaneously, intramuscularly).

Fluoroquinolones approved for use in veterinary medicine for small animals include enrofloxacin, difloxacin, orbifloxacin, and marbofloxacin. Danofloxacin, enrofloxacin, and sarafloxacin are approved for livestock or poultry. Flooroquinolones that are labeled for humans and are of potential interest for veterinary medicine include ciprofloxacin, enoxacin, lomefloxacin, and ofloxacin. The newest generation of fluoroquinolones with increased activity against gram-positive cocci and anaerobic bacteria includes grepafloxacin, trovafloxacin, levofloxacin, moxifloxacin, gatifloxacin, and premafloxacin. Grepafloxacin and trovafloxacin already have been discontinued because of toxicities.

CHEMICAL FEATURES. The currently available fluoroquinolones have the same quinolone structure (Fig. 45.1); various chemical substitutions and side groups account for the different physical characteristics of each drug. These differences may account for variations in lipophilicity, volume of distribution (Vd), oral absorption, and elimination rate, but they do not change the antibacterial spectrum appreciably. For example, enrofloxacin has one fluorine substitution, difloxacin has two fluorine substitutions, and orbifloxacin has a three-fluorine substitution, but the presence of more than one fluorine does not increase antibacterial effects (Asuquo and Piddock 1993). When lipid solubility is expressed as the octanyl:water partition coefficient, enrofloxacin and difloxacin have high lipophilicity. Ciprofloxacin has a partition coefficient that is approximately 100-fold less than that of enrofloxacin; the corresponding partition coefficients of orbifloxacin and marbofloxacin are slightly higher than that of ciprofloxacin (Asuquo and Piddock 1993; Takács-Novák et al. 1992). (Some of these octanyl:water partition coefficients were determined in the laboratory of one of the authors and are unpublished.)

No studies are available to show that these chemical differences among the drugs can account for differ-

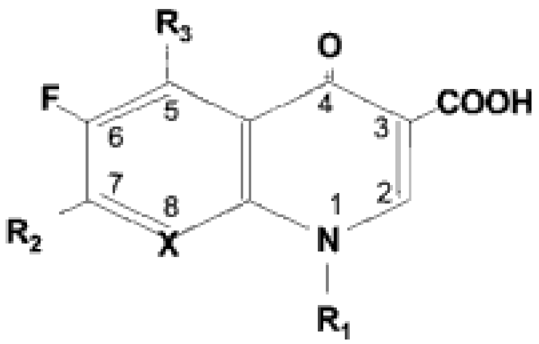

FIG. 45.1—Structure of fluoroquinolone. Features necessary for antibacterial activity are fluorine at position 6, ketone at position 4, and carboxyl at position 3. Addition of cyclopropyl, ethyl, or fluorophenyl at position 1 and of piperazine at position 7 increases the spectrum of antibacterial activity.

ences in clinical response. However, the differences may account for some variation in absorption and distribution. For example, ciprofloxacin oral absorption is approximately one-half that of enrofloxacin in dogs. The less lipid-soluble fluoroquinolones (marbofloxacin, orbifloxacin) have a lower Vd than the ones with higher lipid solubility (enrofloxacin, difloxacin) (Table 45.1). One explanation for this observation is that the more lipid-soluble drugs have higher intracellular concentrations, but higher tissue binding also could explain the differences in Vd.

Quinolones are amphoteric molecules that can be protonated at the carboxyl and the tertiary amine portion of the molecule. The pK_a varies among the drugs slightly, but generally the pK_a for the carboxyl group is 6.0–6.5 (5.5–6.3 in some references) and the pK_a for the nitrogen of the piperazine group is 7.5–8 (Nikaido and Thanassi 1993) (as high as 7.6–9.3 in some references). For two common drugs, enrofloxacin and ciprofloxacin, the pK_a for the carboxyl group is 6.0 and 6.1, respectively, and 8.8 and 7.8 for the amine, respectively. The isoelectric point is midway between the pK_a for each ionizable group. Therefore, at physiologic pH fluoroquinolones exist as zwitterions, in which both of the respective anionic and cationic groups are charged. It is at the isoelectric point that fluoroquinolones are the most lipophilic (Takács-Novák et al. 1992).

Structure-Activity Relationships. Fig. 45.1 shows the basic quinolone structure. The carboxyl group at position 3 and the ketone at position 4 are necessary for the antibacterial activity. The fluorine at position 6 differentiates the quinolones from the fluoroquinolones and accounts for the improved gram-negative and gram-positive activity over the nonfluorinated quinolones, increased potency, and increased entry into bacteria. At position 1, addition of a cyclopropyl (as for enrofloxacin and ciprofloxacin in Fig. 45.2), an ethyl, or a fluorophenyl improve the spectrum of activity against gram-positive and gram-negative bacteria. Addition of a piperazine at position 7, as demonstrated for ciprofloxacin and enrofloxacin (Fig. 45.2), improves the spectrum of activity to include pseudomonads, among other gram-negative bacteria. The change to a carbon from a nitrogen at position 8 decreased some of the adverse central nervous system effects and increased activity against staphylococci.

MECHANISM OF ACTION. Quinolones are bactericidal by inhibiting bacterial DNA replication and transcription. Two-stranded DNA is tightly coiled in the cell and must be separated for transcription and translation. To facilitate coiling, winding, and unwinding, the enzyme DNA gyrase allows the strands to be cut and reconnected. This allows coiling because negative supercoils can be introduced. DNA gyrase, a topoisomerase, consists of A and B subunits. The most common target site for quinolones is the A subunit of DNA gyrase coded by the gene *gyrA*. Mammals are resistant to the killing effects of quinolone antimicrobials because Topoisomerase II in mammalian cells is not inhibited until the drug concentration reaches 100–1000 µg/mL. Bacteria are inhibited by concentrations less than 0.1–10 µg/mL. The National Committee for Clinical Laboratory Standards (NCCLS) breakpoint for ciprofloxacin, the prototypical fluoroquinolone, for susceptible bacteria is ≤1.0 µg/mL. Another target is the Topoisomerase IV enzyme composed of subunits *parC* and *parE*. This site of action is less important for gram-negative bacteria but is a target of fluoroquinolones in some gram-positive bacteria such as streptococci and staphylococci (Ferrero et al. 1995). The action of quinolones on DNA gyrase and Topoisomerase IV has been reviewed in extensive detail by Drlica and Zhao (1997).

ACTIVITY. Fluoroquinolones in general exhibit good activity against most gram-negative bacteria, especially those of the *Enterobacteriaceae*. Representative minimum inhibitory concentration (MIC) values are shown in Table 45.2. *Escherichia coli*, *Klebsiella* spp., *Proteus* spp., *Salmonella* spp., and *Enterobacter* spp. are usually susceptible. *Pseudomonas aeruginosa* is variably susceptible and, when it is susceptible, usually has a higher MIC than other susceptible organisms. Against *P. aeruginosa*, ciprofloxacin is the most active.

Gram-positive bacteria are variably susceptible. *Staphylococcus aureus* and *Staphylococcus intermedius* usually are susceptible. However, the MIC values for staphylococci typically are higher than for gram-negative bacteria, and staphylococcal resistance to fluoroquinolones has been a problem in human patients. Methicillin-resistant strains of staphylococci (MRSA) may be resistant to fluoroquinolones.

The use of the newest generation of fluoroquinolones has not yet been reported in veterinary medicine, except in experimental studies (Caputo et al. 1997; Watts et al. 1997). These drugs, such as grepafloxacin, trovafloxacin, and premafloxacin, have

Na = Data not available or not applicable.
Nd = Not determined.
$t_{1/2}$ = Half-life of the terminal portion of the plasma concentration vs. time curve.
Vd = Apparent volume of distribution (area method).
AUC = Area under the curve of the plasma concentration vs. time curve.
C_{max} = Maximum plasma concentration after administration of oral or IM dose.
%*F* = Percentage of oral or IM administered dose absorbed (determined from comparison of IV dose).

[a] Half-life, Vd, and AUC are from an IV dose unless otherwise noted.

[b] Assay type = Assay using HPLC is able to distinguish between enrofloxacin and ciprofloxacin, and values shown in table represent enrofloxacin. Assays performed by bioassay represent the parent drug and active metabolites. Bioassay may include concentrations of ciprofloxacin.

[c] Registered dose with the FDA in the United States. In some European countries doses may vary or may not include the flexible range. In most cases, when treating non-*Pseudomonas* infections, the lowest dose in the range listed is used.

[d] After multiple dosing with ciprofloxacin, the C_{max} was 1.18 mg/mL and the 12 hr AUC was 9.58 mg/hr/mL.

[e] Oral absorption of ciprofloxacin estimated from a comparison of independent oral and IV studies.

[f] These parameters determined after administration of 5.8 mg/kg of enrofloxacin.

Topoisomerase IV has been found in staphylococci with high-level resistance (Ferrero et al. 1995), a mutation in the outer membrane protein, OmpF, can lead to lack of accumulation of these drugs in bacteria, and other mutations can cause drug efflux (e.g., *mex R, nfx B*).

Resistance can occur through a multistep process (Everett et al. 1996). A single mutation can increase the MIC slightly (perhaps one dilution), and each subsequent mutation produces a progressively higher level resistance in a stepwise fashion. For example, resistant strains of *E. coli* with MIC >8 µg/mL usually have at least 3 mutations for the target genes and may also show enhanced drug efflux. Unlike plasmid-mediated bacterial resistance, in which resistance may disappear after selective antibiotic pressure is removed, chromosomal (mutational) resistance is usually maintained in bacteria after drug administration is discontinued. Plasmid-mediated resistance has been found in *E. coli* and *Klebsiella* organisms, but the clinical significance of plasmid-mediated resistance has not been identified (Martinez-Martinez et al. 1998). Chromosomal mutations, rather than plasmid-mediated resistance, is overwhelmingly the most important mechanism of clinical resistance.

Clinical Resistance Problems. Resistance to fluoroquinolones has become a problem in human medicine that some investigators have attributed to increased prescribing of these drugs. Resistance to fluoroquinolones by *E. coli, Staphylococcus aureus,* and *Streptococcus pneumoniae* has been documented (Chen et al. 1999; Murphy et al. 1997; Sanders et al. 1995; Neu 1992; Peña et al. 1995; Perea et al. 1999; Everett et al. 1996). Clinical resistance in human hospitals among staphylococci appeared relatively quickly after introduction of ciprofloxacin (Neu 1992; Sanders et al. 1995; Hedin and Hambreus 1991). These investigators suggest that increased antibiotic pressure owing to increased prescribing has selected for resistant bacteria. Resistant bacteria also have been identified in companion animals. Resistance in small animals has been documented for *E. coli, P. aeruginosa, Enterobacter, Proteus,* and other gram-negative bacteria. Resistance by staphylococci has also been documented, with a prevalence of 0.9% (Lloyd et al. 1999). In a study of bacteria causing chronic otitis in dogs, 14% of *Staphylococcus intermedius* from the middle ear were resistant to enrofloxacin (Cole et al. 1998).

Pseudomonas organisms have been particularly troublesome because single-step mutations are common for this bacteria, and except for the fluoroquinolones, there are no other oral drugs with which to treat infections caused by *Pseudomonas* organisms. Resistance is primarily caused by a *gyrA* mutation, but an additional mutation in *parC* could cause a high-level resistance (Jalal and Wretlind 1998). Strains with both mutations were significantly more resistant than strains with one mutation. Factors leading to resistant *P. aeruginosa* are an inadequate dosage, low oral absorption, and extended treatment at low doses. From the horizontal and middle ear of dogs with chronic otitis, 87 and 65%, respectively, of the pseudomonads cultured were resistant to enrofloxacin (Cole et al. 1998).

Human Health Risks. Infectious disease experts have warned that frequent usage of fluoroquinolones may lead to increased resistance in animals (World Health Organization 1997). Transfer of fluoroquinolone resistance from animals to people has been suggested to occur for *Campylobacter* species (Endtz et al. 1991) and *Salmonella typhimurium* type DT-104 (Threlfall et al. 1995; Threlfall et al. 1997; Griggs et al. 1994). An increase in the incidence of resistant *Campylobacter jejuni* infecting people was linked to consumption of *Campylobacter*-contaminated chicken. The increased resistance occurred primarily after 1995, which coincides with the time that fluoroquinolones were approved for use in poultry as an additive to drinking water (Smith et al. 1999). Investigators have associated resistance in salmonellae with veterinary use of fluoroquinolones in livestock (Piddock et al. 1998). Resistant strains of *Salmonella typhimurium* may have occurred spontaneously because some of the resistant salmonellae have come from farms in which fluoroquinolones were not administered to animals (Griggs et al. 1994). Nevertheless, some scientists have warned that continued use of fluoroquinolones in livestock is a public health risk because it can potentially lead to resistant mutants of salmonellae being passed on to humans through the food chain. Because of these concerns, there have been limited approvals of fluoroquinolones for food-producing animals, and the extra-label use of fluoroquinolones is prohibited in food-producing animals in the United States.

PHARMACOKINETICS. Pharmacokinetic characteristics such as elimination half-life ($t_{1/2}$), Vd, and oral absorption (*%F*) are listed in Table 45.1. Mammals are relatively consistent in elimination half-life and Vd. Reptiles with lower renal clearance generally demonstrate longer half-lives—as long as 55 and 36 hours for enrofloxacin in alligators and Monitor lizards, respectively (Papich 1999). It has been demonstrated that there are allometric relationships in pharmacokinetic parameters among mammals ranging in size from mice to cattle (Bregante et al. 1999). The allometric relationship was improved considerably when the pharmacokinetic parameters were corrected for the percentage of protein-unbound enrofloxacin in the plasma. In particular, for enrofloxacin the Vd was the most directly proportional to animal body weight, with the animals with largest body weight having the largest Vd.

Among the drugs, there are differences in the pharmacokinetic parameters within species (Table 45.1). Whether or not these differences translate to clinical differences, however, has not been shown, because there are no comparative studies. For example, it does not appear that differences in half-life can account for different clinical results for skin infection treatment in

Hidden page

trations occur because fluoroquinolones are sufficiently lipid soluble to cross the cell membrane, or there may be active mechanisms to transport these drugs into cells. Fluoroquinolones also have a slower efflux from these cells. In humans, ciprofloxacin has an intracellular half-life of 6.7 hours in neutrophils versus 3.7 hours in serum (Easmon et al. 1986).

The high intracellular distribution in leukocytes may account for higher drug concentrations of fluoroquinolones in infected tissue compared to healthy tissue. Leukocytes, attracted via chemotaxis, may transport active drug to the site of infection. Dogs with superficial and deep pyoderma had significantly higher enrofloxacin concentrations in affected skin compared to healthy skin from control dogs (DeManuelle et al. 1998). Skin from dogs with deep pyoderma had higher enrofloxacin concentrations than skin from dogs with superficial pyoderma and there was significant correlation between dermal inflammation (dermal inflammatory cell count) and drug concentration.

Concentrations in urine have been several times higher than plasma concentrations. Concentrations of enrofloxacin, marbofloxacin, and orbifloxacin in urine of dogs are listed by the manufacturer to be 43, 40, and 84.5 μg/mL, respectively. One exception to the high urine excretion is difloxacin, of which, according to the manufacturer, less than 5% of the dose is cleared in the urine. Fluoroquinolones are among the few drugs that adequately penetrate the prostate gland in sufficient concentrations to treat infection. Enrofloxacin concentration (determined by bioassay) in the prostatic fluid and prostate tissue exceeded serum concentration at all times after administration (Dorfman et al. 1995). But, there were no differences in tissue concentrations when infected prostate was compared to healthy tissue. Concentrations of other fluoroquinolones in prostate tissue have been reported by the manufacturers to be 3.36, 5.6, and 1.35 μg/gram for difloxacin, marbofloxacin, and orbifloxacin, respectively.

PHARMACODYNAMICS. MIC values for bacteria are listed in Table 45.2. Even though there are differences in potency among the currently available fluoroquinolones, a pattern is apparent: *Pasteurella*, such as the strains found in skin wounds, are the most susceptible; the gram-negative enteric bacilli (e.g., *E. coli* and *Klebsiella*) also have low MIC values. The gram-positive cocci such as the common skin pathogen *Staphylococcus intermedius* have MIC values at a somewhat higher range, and *P. aeruginosa*, if sensitive at all, has MIC values that are among the highest for susceptible bacteria. Although not listed in Table 45.2, streptococci, enterococci, and anaerobic bacteria typically have MIC values high enough that they are usually in the resistant category.

The best pharmacokinetic-pharmacodynamic marker to predict efficacy has been debated for the fluoroquinolones. Most of the evidence suggests that fluoroquinolones are bactericidal and that they act in a concentration-dependent manner rather than a time-dependent manner. The exposure to the bacteria has been measured by using the maximum peak concentration (C_{max}) in relation to the bacteria MIC and expressed as the C_{max}:MIC ratio. Alternatively, the AUC for a 24-hour dose interval in relation to the MIC, expressed as the AUC:MIC ratio, or AUIC, has been used. A C_{max}:MIC ratio that is at least 8–10 (i.e., a peak concentration that is 8–10 times the MIC) or a AUC:MIC ratio of 125–250 has been associated with the optimum antibacterial effect (Lode et al. 1998; Hyatt et al. 1995; Dudley 1991; Nicolau et al. 1995).

These targeted C_{max}:MIC and AUC:MIC ratios were based on in vitro or in vivo studies performed with immunosuppressed laboratory animals or on clinical studies involving people with serious illness (Forrest et al. 1993; Blaser et al. 1987; Sullivan et al. 1993). A study in neutropenic mice showed that the optimum therapeutic effect was attained when the C_{max}:MIC ratio was greater than 10, but at lower drug doses when the C_{max}:MIC ratio was less than 10, the AUC:MIC was better linked to outcome (Drusano et al. 1993). A C_{max}:MIC ratio of at least 8–10 has been associated with a lower incidence of development of resistance (Blaser et al. 1987). When lower ratios were achieved, the mutant strains that occur spontaneously were not suppressed, and resistance was allowed to emerge because these mutant strains have MIC values that are at least 4–8 times that of the parent (wild-type) strain (Drusano et al. 1993). Veterinary studies also have supported a high C_{max}:MIC or AUC:MIC ratio to predict efficacy (Meinen et al. 1995).

Our clinical observations in veterinary patients reveal that we often achieve a cure using standard doses even though we may not achieve these targeted ratios. For example, if one compares the C_{max} or AUC in Table 45.1 to representative MIC values from Table 45.2, an AUC:MIC ratio of 50–60 in some patients appears adequate (Cester et al. 1996). In one model of skin infection in dogs caused by *Staphylococcus intermedius* (MIC 0.5 μg/mL), infections were prevented with C_{max}:MIC ratios of only 3–5.5 μg/mL of marbofloxacin (Gruet et al. 1997). Perhaps a competent immune system or less serious infection accounts for this discrepancy between laboratory studies and clinical observations in veterinary medicine.

FLEXIBLE DOSE RANGES. Despite our uncertainty as to the best pharmacokinetic-pharmacodynamic parameter to use to predict therapeutic efficacy, we usually design dosage regimens to attain a targeted C_{max}:MIC so that we decrease the chance of resistant mutants arising from an infection. Calculated doses listed in Tables 45.1 and 45.4 are based on attaining a C_{max}:MIC ratio of at least 8–10. The basis for the flexible doses listed in Table 45.1 is the wide MIC range among susceptible bacteria, from as low as 0.03 μg/mL, to as high as 1.0 μg/mL. (The flexible dose

TABLE 45.4—Dose recommendations for enrofloxacin in exotic animals

Animal	Dose	Route	Interval	Reference
Alligator	5 mg/kg	IV, oral	Every 96 hr	Helmick et al. 1997
Savanna monitor	5 mg/kg (10 mg/kg for *Pseudomonas* spp.)	IM, oral	Every 96 hr	Hungerford et al. 1997
Burmese python	5 mg/kg (higher doses for *Pseudomonas* spp.)	IM	Every 48 hr	Young et al. 1997
Indian star tortoise	5 mg/kg	IM	Every 24 hr	Raphael et al. 1994
Red-eared slider	5 mg/kg	oral, IM	Every 72 hr (oral), every 48 hr (IM)	James et al. forthcoming
Gopher tortoise	5 mg/kg	IM	Every 24–48 hr	Prezant et al. 1994
Bottlenose dolphin	5 mg/kg	oral	Every 24 hr	Linnehan et al. 1999.
Parrot and cockatoo	7.5–15 mg/kg	oral	Every 12 hr	Flammer 1998
Fish (ornamental)	5 mg/kg	IM, oral, or IP	Every 48 hr	Lewbart 1998

Note: These recommendations are based on an analysis of pharmacokinetic data and limited clinical experience. There have been no well-controlled efficacy studies or safety studies in these animals.

ranges specified by the manufacturers are noted by the superscript "c" in Table 45.1.) The upper dose is limited by safety (such as gastrointestinal effects); the lower dose is determined by efficacy. There is no advantage to frequent dosing (multiple times/day) as long as a sufficiently high C_{max}:MIC or the same AUC:MIC is achieved; therefore, the doses discussed for mammals and listed in Table 45.1 are intended for once-daily administration.

The flexible dose allows relatively low doses of fluoroquinolones to be administered to treat the most susceptible organisms. That is, for susceptible *E. coli* or *Pasteurella* organisms, the lowest approved dose can be administered. To achieve the necessary concentration for some *Staphylococcus* or gram-positive bacteria that have higher MIC values, a higher dose may be needed, e.g., a dose in the middle of the dose range in Table 45.1. When the MIC values are high for organisms such as *P. aeruginosa*, the highest safe dose should be considered (Walker et al. 1992; Meinen et al. 1995).

CLINICAL USE

Dogs and Cats. The administration of fluoroquinolones to dogs and cats constitutes the largest application of these drugs for veterinary medicine. They have been used extensively during the past 10 years for infections of the skin, soft tissue, oral cavity, urinary tract, prostate, external and middle ear, wounds, respiratory tract, and bone (Paradis et al. 1990; Ihrke and DeManuelle 1999; Ihrke 1996; Carlotti et al. 1999; Griffin 1993; Hawkins et al. 1998; Dorfman et al. 1995; Cotard et al. 1995). There has been a decade of experience with enrofloxacin, and veterinarians now have experience with marbofloxacin, orbifloxacin, and difloxacin. The efficacy of the fluoroquinolones has been accepted by virtue of approval by the US Food and Drug Administration (FDA) for the treatment of skin and urinary tract infections (all current drugs) and respiratory infections (enrofloxacin only). In the United States, enrofloxacin and orbifloxacin are approved for dogs and cats; marbofloxacin and difloxacin are registered for dogs only. According to each drug's FOI summary available through the FDA, enrofloxacin, orbifloxacin, marbofloxacin, and difloxacin are efficacious for skin infections and urinary tract infections in dogs at the lowest label dosage.

The efficacy of enrofloxacin and marbofloxacin has been demonstrated specifically for canine pyoderma through published reports (Ihrke and DeManuelle 1999; Ihrke 1996; Paradis et al. 1990; Carlotti et al. 1999). One disease in particular for which enrofloxacin's efficacy has been demonstrated is German Shepherd dog pyoderma when the drug is administered orally once daily at a dose rate of 5–10 mg/kg (Ihrke and DeManuelle 1999; Koch and Peters 1996). The effectiveness of enrofloxacin in the management of this syndrome also may be partially explained by beneficial anti-inflammatory properties (Ihrke and DeManuelle 1999). Quinolones have been shown to diminish tumor necrosis factor production and suppress induced leukotriene generation from neutrophils, lymphocytes, monocytes, and basophils (Bailly et al. 1990; Knöller et al. 1989). German Shepherd dog pyoderma may be associated with a predilection for an exaggerated tissue response to staphylococcal bacteria characterized by an inappropriate release of cytokines and other mediators of inflammation.

In addition to treatment of infections in these common sites, fluoroquinolones also have been used to treat rickettsial infections (Breitschwerdt et al. 1990, 1999) and have been examined for treating *Bartonella* infections in cats (Kordick et al. 1997). Against *Rickettsia rickettsii,* enrofloxacin is equally as effective as doxycycline or chloramphenicol (Breitschwerdt et al. 1990), but the success for eliminating *Bartonella* in cats has been equivocal (Kordick et al. 1997). Enrofloxacin has been used successfully to treat acute ehrlichiosis in dogs caused by *E. canis* and *E. platys* at a dosage of 5 mg/kg once daily for 15 days (Kontos and Athanasiou 1998). However, success in treating chronic ehrlichiosis has not been demonstrated. Fluoroquinolones also have been used to treat infections caused by *Mycoplasma* and *Mycobacteria*. Although the activity against *Mycoplasma* can be variable (Hannan et al. 1997), it has been effective for some opportunistic mycobacterial infections in cats (Studdert and Hughes 1992). Enrofloxacin and danofloxacin were consistently more active against veterinary *Mycoplasma* isolates than flumequine (Hannan et al. 1997).

Small Mammals. Enrofloxacin and other fluoroquinolone antibiotics are used frequently in small mammals such as rabbits, mice, rats, and exotic species for skin and visceral infections (Göbel 1999; Cabanes et al. 1992; Broome and Brooks 1991). One of the reasons fluoroquinolones are popular for treatment in small mammals is the potent activity against gram-negative pathogens affecting these animals and the excellent oral absorption. Another important advantage is the good safety record of the fluoroquinolones in small mammals. Oral tablets of fluoroquinolones have been administered directly or crushed to make a suspension that can be conveniently administered orally to the small mammals mixed with water, fruit, or some other palatable flavoring. Small mammals such as rodents and rabbits are prone to gastrointestinal disturbances and enteritis caused by overgrowth of bacteria, especially *Clostridium* organisms after administration of β-lactam and macrolide antibiotics. Because fluoroquinolones are not active against the anaerobic bacteria that compete with *Clostridium* organisms, bacterial overgrowth of pathogenic opportunistic bacteria has not been a problem as it has with other drugs, such as penicillins or macrolides.

Of the available drugs, enrofloxacin has been the most extensively studied. The doses listed in textbooks and review articles for mice, gerbils, hamsters, rats, and guinea pigs are 2.5–5.0 mg/kg up to 10–20 mg/kg IM, SC, or orally administered twice daily. The pharmacokinetics has been reported (Table 45.1), and there is some experience with the drug's efficacy. In rabbits, e.g., enrofloxacin, after a dose of 5 mg/kg, has been effective for improving clinical signs associated with pasteurellosis. The recommended dose of enrofloxacin for rabbits is 5 mg/kg IM, SC, or oral. Although it does not completely eradicate the bacteria in pasteurellosis in rabbits, it is considered the drug of choice (Göbel 1999; Broome and Brooks 1991).

Reptiles. The use of fluoroquinolones in reptiles has become popular because of their activity, safety, and convenience of administration (Papich 1999; Jacobson 1999; Rosenthal 1999). The only fluoroquinolone studied extensively is enrofloxacin. It is active against gram-negative organisms often implicated in serious infection of reptiles, including *Salmonella* spp., *Aeromonas hydrophilia*, *Klebsiella* spp., and *P. aeruginosa*, and its pharmacokinetics has been summarized in a review (Papich 1999). It shows remarkable differences among the reptiles, but generally the elimination is longer than in mammals or birds, which allows long dose intervals—as long as every 96 hours in some species. The elimination rate of drugs in reptiles varies with the animal's body temperature, because it affects metabolic rate. When enrofloxacin is administered, there is variable metabolism to the active metabolite ciprofloxacin among the reptiles. Elimination half-life ranged from 55 hours in alligators to 5.1 hours in tortoises (Young et al. 1997; Raphael et al. 1994; Helmick et al. 1997; Hungerford et al. 1997; Prezant et al. 1994; James et al. forthcoming). Monitor lizards, pythons, and turtles had half-lives of 36, 17.6, and 6.4 hours, respectively. Analysis of pharmacokinetic data and appraisal of clinical experience (Jacobson 1999; Papich 1999) suggest a range of doses (Table 45.4), but safety and efficacy studies have not been performed.

Pharmacokinetic studies have shown good absorption of enrofloxacin from IM administration, and this route may prolong the half-life, probably because of delayed absorption from the injection site. Although some authors have suggested that oral administration should be avoided in reptiles because of unreliable absorption, absorption was good after oral administration to alligators, lizards, and turtles (Helmick et al. 1997; Hungerford et al. 1997; James et al. forthcoming). Because of slow gastrointestinal transit time, oral absorption may prolong the half-life.

Birds. The fluoroquinolones are an important group of antibiotics for pet birds and poultry. Administration is via drinking water for bacterial infections in poultry and by injection or orally for pet birds. Fluoroquinolones have the advantage of good activity against bacterial pathogens important to birds, including *E. coli*, *Klebsiella* spp., *Pseudomonas* spp., *Staphylococcus* spp., and *Chlamydia* spp. Resistance is possible for *E. coli* and *Pseudomonas* spp., however, and activity against gram-positive cocci (e.g., streptococci and enterococci) is low. Although there is in vitro susceptibility of *Chlamydia* to fluoroquinolones, experience suggests that enrofloxacin can decrease clinical signs but not eliminate the infections (Flammer 1998). Therefore, fluoroquinolones are not recommended for mass medication of pet birds, and doxycycline is still the choice for this indication.

For pet birds, the dose is higher than for mammals because the clearance is faster. Pharmacokinetics of enrofloxacin has been studied in some birds (Table 45.1), and from these studies a dose of 15 mg/kg IM or orally every 12 hours has been recommended (Flammer 1998; Flammer et al. 1991). One advantage of enrofloxacin for treating birds is that it has been possible to add it to the drinking water of pet birds so they can be conveniently medicated. Enrofloxacin added to drinking water at a concentration of 0.3–0.5 mg/mL has been used to treat highly susceptible bacteria (Flammer et al. 1990). Enrofloxacin is well absorbed via this route, and as long as the bird is drinking, effective plasma concentrations can be attained. One concern with the IM injection is that it can produce irritation at the site of injection, which is problematic

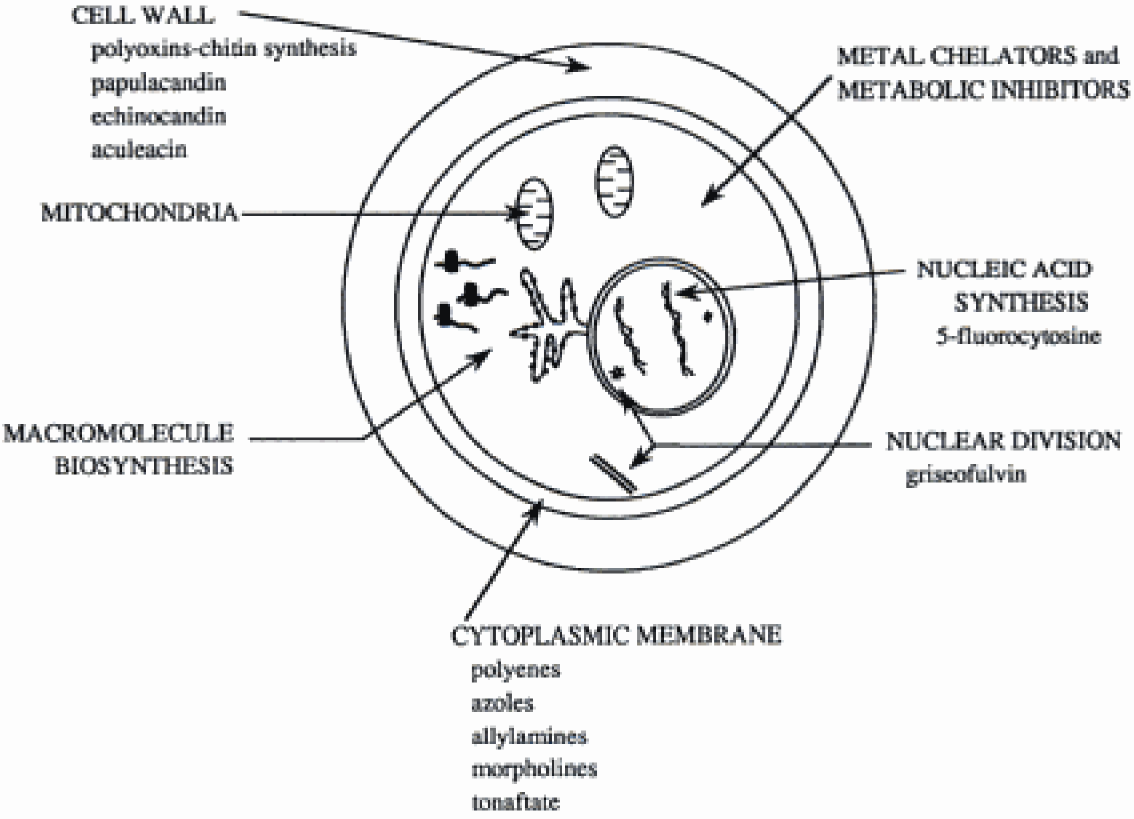

FIG. 46.1—Schematic anatomy of a fungal cell and potential sites where antifungal drugs act.

dures (Galgiani 1990; Graybill 1992). Without readily available susceptibility tests in veterinary medicine, most of the therapeutic choices are empirically based.

The diagnosis of mycotic infection is difficult because clinical signs mimic those of other disease processes, and often clinicians do not initially consider fungal etiologic agents. Definitive diagnosis is difficult owing to the slow and fastidious nature of fungal growth. Additionally, obtaining suitable and sufficient numbers of fungal specimens may be impossible for some of the systemic fungi because the infection may occur in an anatomic location difficult to sample (e.g., central nervous system [CNS] and eye). But advances in immunodiagnosis of systemic mycoses have dramatically improved the ability to diagnose some mycotic diseases (Jackson 1986).

DISEASES CAUSED BY FUNGI. Superficial infections are associated with dermatophytosis and onychomycosis (*Trichophyton, Microsporum*) and thrush (oral candidiasis). Also, yeast infections caused by *Malassezia pachydermatis* (formerly called *Pityrosporum*) are recognized as an important skin infection in dogs.

Subcutaneous or regional lesions are associated with draining sinuses or invasion of bone. These may be introduced traumatically or iatrogenically and can become disseminated. Examples of these infections are mycetomas, chromomycosis, zygomycosis, phycomycosis, sporotrichosis, and rhinosporidiosis.

Systemic fungal infections are often associated with immunocompromised patients, although they may occur in immunocompetent hosts under optimum circumstances. These diseases are serious and often life threatening due to the organ involved and the refractoriness to therapy. These diseases may follow a chronic granulomatous course (e.g., blastomycosis, histoplasmosis, coccidiomycosis, cryptococcosis, aspergillosis) and are often challenging to treat because of the need for potent systemic drugs.

ANTIFUNGAL DRUGS

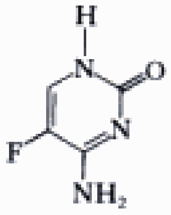
Griseofulvin. *Griseofulvin*, USP (Fulvicin U/F, Fulvicin P/G, Grifulvin V, Grisactin, Grisactin ultra) (Fig. 46.2), is a fungistatic antibiotic produced by *Penicillium griseofulvin dierckx*. It is colorless, slightly bitter, and virtually insoluble in water. Its selective toxicity is based on an energy-dependent uptake into susceptible fungi that occurs preferentially to uptake into mammalian cells. Once into the cell, griseofulvin disrupts the mitotic spindle by interacting with polymerized microtubules, thus causing mitotic arrest in metaphase. Grossly this may appear as shortened and less branched fungal hyphae, known as the "curling" phenomenon. Griseofulvin may also interfere with cytoplasmic

more practical, than an equal dose of the microsized preparation (Hiddleston 1973). A dose rate of 1 g/100 kg has been recommended for pigs for a duration of 30–40 days (Kielstein and Gottschalk 1970). Griseofulvin at 30 g/day/animal was reported to be effective in curbing a mycotic abortion outbreak due to *Aspergillus fumigatus* and *Cryptococcus neoformans* in buffalo heifers. Considering the concomitant use of intrauterine infusions, these results are difficult to interpret (Shehata 1991).

OTHER SPECIES. Case reports exist of griseofulvin's successful use in the prevention of mycotic dermatitis in ostriches (Onderka and Doornenbal 1992) and in the treatment of *Trichophyton* in small ruminants (Abdel-Halim et al. 1988). In the first report, griseofulvin was added to the drinking water, whereas in the latter it was used as a feed supplement. Griseofulvin was also used as a food supplement at a dose of 7.5 mg/kg to treat an outbreak of ringworm in a flock of 250 housed ewes. The animals were treated for 7 days while all were in their second third of gestation. Lesions resolved within 20 days and were microscopically and culturally negative, and parturition and offspring were normal (McKellar et al. 1987). Griseofulvin was unsuccessful in treating *Trichophyton mentagrophytes* in a commercial rabbitry as a water additive, whereas individual therapy, although potentially effective, was considered impractical and uneconomical (Franklin et al. 1991).

Flucytosine. Flucytosine (*5-Fluorocytosine*, 5-FC, Ancobon) (Fig. 46.3) is a synthetic antifungal agent originally intended as an anticancer agent (Dushchinsky et al. 1957). It was ineffective against tumors, but further screening revealed it possessed antifungal activity in vitro (Berger and Duschinsky 1962). An oral preparation became available in the United States in 1972. To have cytotoxic effects, 5-FC must first be converted to 5-fluorouracil (5-FU). Uptake into the fungal cell is governed by cytosine permeate. Once in the cell, it is converted to the active form by a fungal cytosine deaminase enzyme. Then 5-FU either is incorporated into RNA, disrupting protein synthesis, or is converted to a related compound which inhibits DNA synthesis. The mammalian cell's deficiency in cytosine deaminase is the basis for the selective toxicity of this compound; however, conversion to 5-FU may occur by microbes in the gastrointestinal (GI) tract. 5-FU is not readily absorbed by fungal cells but is toxic to mammalian cells and may lead to anemia, leukopenia, and thrombocytopenia (Bennett 1990).

Flucytosine is active against *Cryptococcus neoformans* and certain species and strains of *Candida*. The majority of *Aspergillus* species are resistant. It has little effect in vitro against *Sporothrix schenckii, Blastomyces dermatitidis, Histoplasma capsulatum, Coccidioides immitis*, and *Rhizopus*. Resistance to flucytosine has developed both in vitro and during therapy, which limits its use as the sole antifungal agent in a therapeutic protocol. This resistance is thought to be due to fungal mutations resulting in either decreased permease or decreased deaminase activity.



Flucytosine

FIG. 46.3

Flucytosine is used infrequently in veterinary medicine and there is little information available to guide dosing or clinical use. Since few pharmacokinetic data are available, the pharmacokinetics of flucytosine must be inferred from human studies. 5-FC is rapidly and completely absorbed from the (GI) tract. It is minimally bound to plasma proteins such that its volume of distribution approximates total body water. It is present in the cerebrospinal fluid (CSF) at concentrations approximately 65–90% of those in plasma and also appears to penetrate into aqueous humor. The penetration into the CNS has expanded its use to treat CNS fungal infections. Its half-life is between 3 and 6 hours but may be as long as 200 hours in patients in renal failure, as approximately 80% of a dose is excreted unchanged in urine by glomerular filtration.

Due to its previously mentioned limitations, the therapeutic indications for flucytosine are limited to adjunct therapy with amphotericin B in systemic infections caused by *Candida* or *Cryptococcus neoformans*. Synergy between these two medications has been demonstrated, and combination therapy has been successful, particularly in the treatment of cryptococcal meningitis (Utz et al. 1975; Bennet et al. 1979). Flucytosine was shown to be effective in a domestic cat for treating phaeohyphomycosis due to an *Exophiala spinifera* infection that was refractory to both griseofulvin and ketoconazole (Kettlewell et al. 1989). But caution is recommended because combination therapy of flucytosine and ketoconazole was found to be toxic in cats for treatment of this same disease (Pukay and Dion 1984).

Amphotericin B. Amphotericin B (Fungizone) (Fig. 46.4) is a polyene antibiotic first isolated from rotting vegetation in Venezuela in 1956 (Gold et al. 1956). Both amphotericin A and B are natural fermentation products of the actinomycete *Streptomyces nodosus*. Although both forms possess antifungal characteristics, amphotericin B was developed, and current preparations are almost devoid of amphotericin A (less than 2%). As its name implies, it is an amphoteric compound whose molecular structure consists of a large macrolide ring with a hydrophobic conjugated double-bond chain and a hydrophilic hydroxylated carbon

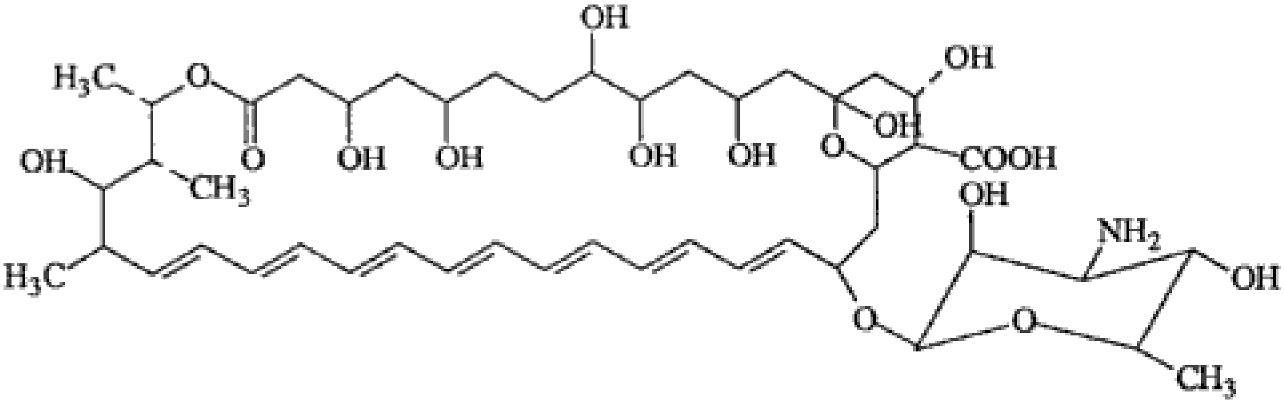


FIG. 46.4—Amphotericin B.

chain and attached sugar (Mechlinsk et al. 1970). It is prepared as a yellowish powder which is insoluble in water and somewhat unstable (Bennett 1990). When reconstituted in a vial, the commercial formulation (Fungizone) is a micellar complex of amphotericin B and a bile salt (sodium dexoxycholate).

MECHANISM OF ACTION. The action of amphotericin B on fungal cells may involve more than one mechanism (Brajtburg et al. 1990). A major action of amphotericin B is to bind ergosterol in the fungal plasma cell membrane, thereby making the membrane more permeable. Increased permeability results, among other actions, in leakage of cell electrolytes, resulting in cell death. At high concentrations, amphotericin B is thought to cause oxidative damage to the fungal cell (Warnock 1991) or disruption of fungal cell enzymes. The selective toxicity of amphotericin B is based on its decreased binding to the major cell membrane sterol of mammalian cells (cholesterol) as compared to that of fungal cells (ergosterol).

SPECTRUM OF ACTIVITY. The growth of strains of most veterinary fungal pathogens is inhibited in vitro at amphotericin B concentrations between 0.05 and 1.0 µg/mL. Sensitive fungi include *H. capsulatum, C. neoformans, C. immitis, B dermatitidis, Candida* spp., and many strains of *Aspergillus*. Amphotericin B has been indicated for treatment of mucormycosis, sporotrichosis, and phycomycosis (Drouhet and Dupont 1987). Most strains of *Pseudallescheria boydii* as well as some agents causing chromoblastomycosis and phaeohyphomycosis have minimum inhibitory concentration (MIC) values greater than 2.0 µg/mL and are therefore considered resistant. Although MIC values are not typically measured for clinically isolated fungi, there is good correlation between the MIC values and clinical response to amphotericin B (O'Day et al. 1987). Clinical fungal resistance to amphotericin B, either primary or acquired, does not appear to occur commonly, although resistant strains occur in vitro. In most cases, these resistant strains contain decreased levels of membrane ergosterol (Pierce et al. 1978); increased catalase levels may allow these fungi to be resistant to oxidative dependent damage (Sokol-Anderson et al. 1988). Treatment failure due to fungal resistance has rarely been reported in humans; however, MIC concentrations were found to be increased in certain patient populations, such as neutropenic patients (Dick et al. 1980), transplant patients (Powderly et al. 1988), and patients undergoing cytotoxic therapy.

CHEMICAL PROPERTIES AND PHARMACOKINETICS. Despite its long history of use, much is still unknown concerning the pharmacokinetics of amphotericin B, especially in the veterinary population. It is poorly absorbed from the GI tract and not administered orally except for local treatment of oral yeast infections. Whether binding in the GI tract, failure to cross the intestinal mucosa, or first-pass hepatic metabolism is responsible for poor systemic absorption is uncertain. Amphotericin B must be given intravenously or intrathecally.

To achieve solubility for injection, current preparations contain sodium deoxycholate, which forms a suspension. This form should not be admixed with electrolytes in solutions or inactivation will occur. Following infusion, amphotericin B separates from the deoxycholate and binds extensively (~95%) to serum proteins, mainly β lipoprotein (Bennett 1977). Much of the drug is thought to leave the vascular space and bind to cholesterol-containing membranes. The highest concentrations are found in liver, spleen, kidney, and lungs, with little accumulation in either muscle or adipose tissue. Concentrations of amphotericin B in fluids from inflamed pleura, peritoneum, and synovium and in aqueous humor are about two-thirds of those in serum. Amphotericin B readily crosses the human placenta. Penetration into normal or inflamed meninges, vitreous humor, and normal amniotic fluid is poor. This differential distribution may explain treatment failures for infections in some tissues. Although amphotericin B binds ergosterol with higher affinity than cholesterol, it was suggested that because there are more binding sites

The liposomal complex of amphotericin B (AmBisome) is a unilamellar liposomal formulation. This was the first liposomal formulation available. When reconstituted, it produces small vesicles of encapsulated amphotericin B. This formulation has been used safely and effectively in some dogs for blastomycosis (Plotnick 2000). This liposomal complex of amphotericin B was used in another study of 13 dogs for treatment of *Leishmania infantum* at a dose of 3–3.3 mg/kg. Although there was rapid clinical improvement, dogs remained positive for *Leishmania* (Oliva et al. 1995).

The advantage of these lipid-based formulations of amphotericin B is that in comparison to the conventional formulation of amphotericin B (amphotericin B deoxycholate), they can be given at higher doses to produce greater efficacy with less toxicity (Hiemenz and Walsh 1996). Doses of lipid complex formulations of amphotericin B have been 3 mg or more per kilogram (compared to 0.25–0.5 mg/kg of the conventional formulation) (Walsh et al. 1999; Ringden et al. 1991; Graybill et al. 1982; Hostetler et al. 1992). Decreased toxicity is attributed to a selective transfer of the lipid complex amphotericin B, releasing the drug directly to the fungal cell membrane and sparing the mammalian cell membranes. Reduced drug concentrations in the kidneys and diminished release of inflammatory cytokines from amphotericin lipid complex compared to the conventional formulation also may prevent adverse reactions. It is possible that doses used for veterinary patients have been too conservative, and based on experience in people, higher doses may be tolerated.

Azole Antifungal Drugs. The azole antifungal drugs include the imidazoles and triazoles. They are broad-spectrum antifungal agents that also show some activity against gram-positive bacteria (although they are never used therapeutically for treating bacterial infections in animals). In the early 1970s, the first imidazole compound with antifungal activity, clotrimazole, was discovered. Unfortunately, autoinduction of hepatic degrading enzymes caused undetectable plasma concentrations after several days of therapy. In 1977 miconazole, also an azole compound, was introduced and was found to be effective against some fungi refractive to amphotericin B. Rapid clearance and poor oral absorption necessitate frequent IV infusions during hospitalization. In addition, the solubilizing agent in the parenteral form induces histamine-related toxic side effects, making its use hazardous. The current uses of both clotrimazole and miconazole have been primarily restricted to topical treatment of localized superficial infections. The first orally active imidazole antifungal, approved for use in 1979, was ketoconazole. More recently the introduction of two triazoles, fluconazole and itraconazole, has presented the clinician with several safe, effective alternatives to amphotericin B for the treatment of serious fungal infections.

MECHANISM OF ACTION. All azoles exert their antifungal effect on the cell membrane of the fungus by inhibiting synthesis of primary sterol of the fungal cell membrane, ergosterol. Inhibition of the P-450-dependent lanosterol C_{14}-demethylase enzyme results in depletion of ergosterol and accumulation of C_{14}-methyl sterols in the cytoplasmic membrane (Fig. 46.5). Inhibition of the P-450 enzyme occurs via binding of the nitrogen (N_3 of imidazoles and N_4 of azoles) to the heme iron atom of ferric cytochrome P-450. This prevents the formation of the superoxide Fe^{+++} complex ($Fe^{+++}O^-$) needed for hydroxylation of methyl sterols. The result is an inability to demethylate C_{14}-methyl sterols and reduced synthesis of ergosterol. Incorporation into the membrane of sterols that are less planar than ergosterol changes membrane fluidity and interferes with the barrier function of the membrane and with membrane-bound enzymes.

Azole drugs are generally fungistatic at concentrations achieved clinically. Fungicidal action can occur via direct interaction with the cell membrane barrier (miconazole) and accumulation of toxic peroxides resulting from alterations in oxidative metabolism and inhibition of cellular respiration (Polak 1990).

PHARMACODYNAMICS. The potency of each azole drug is related to its affinity for binding the P-450 enzyme. The selective toxicity of each compound is directly dependent upon its specificity for binding fungal P-450 more readily than mammalian P-450. Imidazoles are less specific than triazoles and produce side effects in animals attributed to inhibition of P-450 enzymes such as synthesis of cortisol and reproductive steroid hormones. Azoles may decrease cholesterol, cortisol, androgen, and testosterone biosynthesis and may interfere with several liver enzymes necessary for inactivation of toxic and carcinogenic agents (Polak 1990).

KETOCONAZOLE. Ketoconazole (Nizoral) (Fig. 46.6), one of the imidazoles, became available in 1979, with results of its successful use in veterinary medicine being published shortly thereafter (Legendre et al. 1982; Medleau et al. 1985). Ketoconazole is most effective against yeast and dimorphic fungi such as *Candida, Malassezia (Pityrosporum) pachydermatis, C. immitis, H. capsulatum, B. dermatitidis,* as well as most dermatophytes with MIC values less than 0.5 μg/mL. It is less effective against *C. neoformans, S. schenckii,* and *Aspergillus* spp., with MIC values varying from 6 to >100 μg/mL (Hume and Kerkering 1983).

PHARMACOKINETICS. The advantages over older azole compounds include increased solubility in an acid environment, good tissue distribution, and reasonably long half-life (Daneshmend and Warnock 1988). Ketoconazole is well absorbed from an acid environment and when given with a meal. Ketoconazole is highly protein bound (>98%) and therefore does not penetrate into the cerebrospinal, seminal, or ocular fluid to a significant degree; however, it is found in

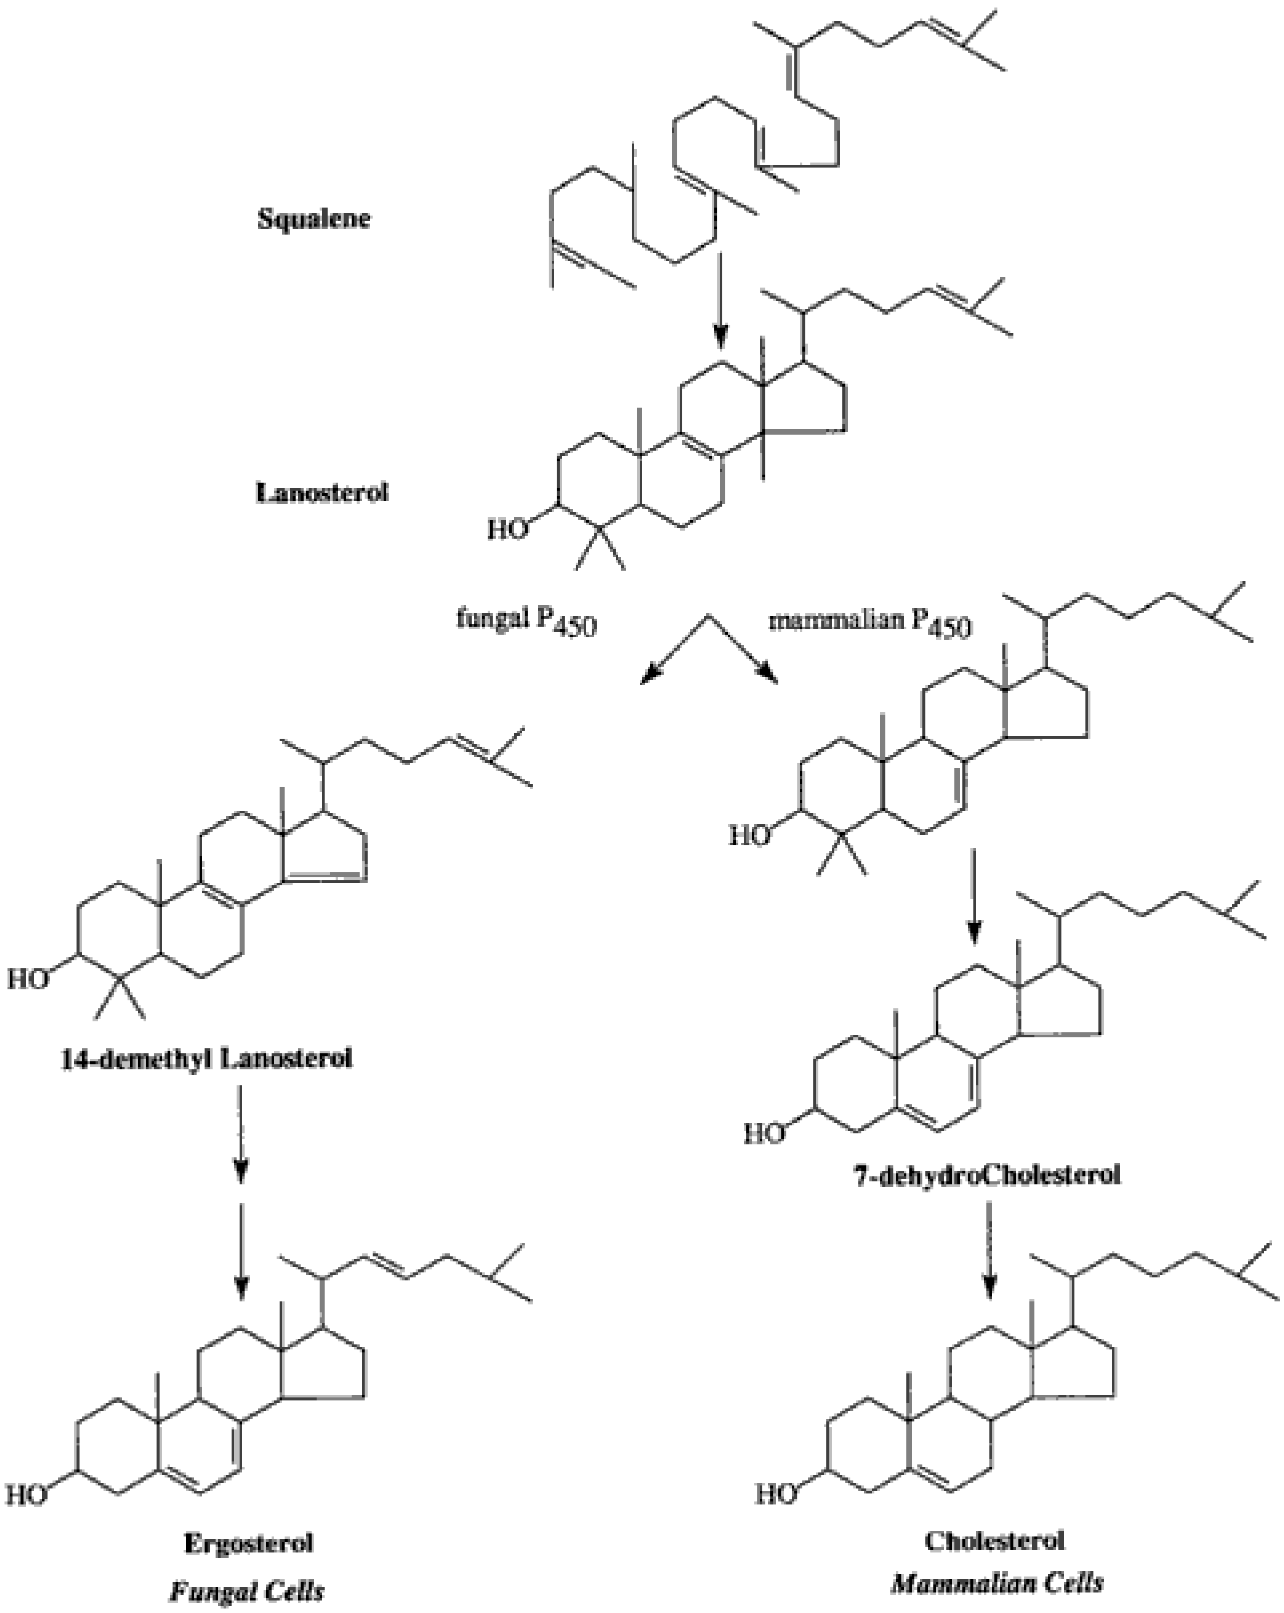

FIG. 46.5—Simplified scheme of fungal and mammalian biosynthesis of the major sterol in the cell membrane. The affinity with which an azole antifungal binds to each P-450 enzyme determines its potency and selective toxicity.

fulvin and ketoconazole, and in two subcutaneous dermatophyte infections (pseudomycetoma) in cats (Mundell 1990).

In dogs, the most extensive study has been for treatment of blastomycosis (Legendre et al. 1996). In a study of 112 dogs, 5 mg/kg/day was as effective as 10 mg/kg/day. With a 60-day course of therapy, 54% of dogs were cured.

Itraconazole has been used to treat ocular and systemic blastomycosis in dogs. When given 5 mg/kg itraconazole twice a day for 60 days, 76% of eyes with posterior segment disease other than optic neuritis and 18% and 13% of eyes with anterior uveitis or endophthalmitis, respectively, recovered (Brooks et al. 1992).

Itraconazole has been successfully used in both the prevention and the treatment of aspergillosis in caged birds. A dose of 20 mg/kg daily for at least 30 days was used to successfully treat 5 of 12 presumed cases of *Aspergillus* infections in penguins. This same author suggests its prophylactic use in penguin chicks (Shannon 1992). A different treatment protocol was recommended for aspergillosis in raptors. Birds are treated with 10 mg/kg twice daily in combination with amphotericin B nebulization three times a day for 20 minutes. Treatment for some cases lasted as long as 6 weeks. These authors also recommend the prophylactic use of itraconazole whenever the clinician expects increased risk for the disease (Forbes et al. 1992).

DOSES. Dosages used in dogs have been 2.5–5 mg/kg/day and as high as 5–10 mg/kg/day for the treatment of blastomycosis. The most commonly recommended dose is 5 mg/kg/day (Legendre 1995) and may be as effective as high doses with less toxicity. In cats it has been used to treat dermatophytosis at a dose of 10 mg/kg once daily (Moriello and DeBoer 1995), but 3 mg/kg once daily may be just as effective. Itraconazole is available as 100 mg capsules. The granules in these capsules may be added to food for convenience. It also is available as a 10 mg/mL cherry-flavored oral liquid formulation.

ADVERSE EFFECTS. Itraconazole is probably better tolerated in dogs and cats than ketoconazole. Nevertheless, toxic reactions are still possible. Since most adverse effects are dose related, one is advised to lower the dose in animals in which adverse effects are observed. According to Legendre (1995) about 10% of dogs receiving recommended doses develop hepatic toxicosis. Liver enzyme elevations may occur in 10–15% of dogs. Hepatic toxicosis is also possible in cats. Anorexia may occur as a complication of treatment, especially with high doses and high serum concentrations. It usually develops in the second month of therapy in dogs. In cats there seem to be dose-related GI effects of anorexia and vomiting (Mancianti et al. 1998).

Dogs chronically administered itraconazole (2.5, 10, or 40 mg/kg daily for 3 months) had no significant alterations in mortality rate, behavior, appearance, food consumption, body weight, hematologic values, serum and urine chemistry, or gross pathology (VanCauteren et al. 1987b). Subacute toxicity studies in rats revealed increased adrenal gland weight and the accumulation of proteinaceous material in the mononuclear phagocyte system at doses of 40 and 160 mg/kg. Since the mononuclear phagocyte system is responsible for ridding the body of a fungal infection, the clinical importance of this toxic effect remains to be seen. Although not teratogenic at 10 mg/kg, maternal toxicity, embryo toxicity, and teratogenicity were observed at 40 and 160 mg/kg in rats (VanCauteren et al. 1987b); therefore, its use in pregnant animals is not recommended. Itraconazole has been well tolerated by clinically ill cats, although one case of fatal drug-induced hepatitis has been reported (Medleau 1990).

Itraconazole exhibits the highest affinity and selectivity for the fungal cytochrome P-450 enzyme of all known azoles. It is up to 125 times more selective for fungal P-450 systems than mammalian liver enzymes in certain in vitro preparations (Vanden Bossche 1987). Not only is itraconazole efficacious in vitro, but it also does not inhibit P-450 systems in the testis, adrenal, or liver in vivo (Vanden Bossche et al. 1990). In clinical studies, 100 mg of itraconazole given to humans each day for 30 days had no effect on serum testosterone or cortisol levels (DeCoster et al. 1987). Similarly, there were no changes in testosterone and cortisol concentrations in rats and dogs receiving daily itraconazole for at least 1 month.

The biochemical basis for the specificity of itraconazole toward fungal P-450 is thought to be dependent upon the hydrophobic nonligand portion of the molecule and its affinity for the apoprotein portion of the cytochrome molecule (Vanden Bossche et al. 1990). The resulting lack of significant inhibition of liver microsomal enzymes results in itraconazole's inability to affect other drugs' metabolism. Although the clinical significance is as yet unknown, drugs that can inhibit or stimulate liver degradative enzymes are able to alter the pharmacokinetics of itraconazole. Even though itraconazole is primarily cleared by hepatic metabolism, there appears to be no need for dosage adjustments in patients with liver disease (Heykants et al. 1987). As with ketoconazole, itraconazole's oral absorption is pH dependent; therefore, dosage adjustments may be necessary when gastric pH is increased.

DRUG INTERACTIONS. Like ketoconazole, itraconazole absorption is decreased when the stomach is less acidic. Do not administer with antacids, H_2 blockers, or omeprazole. Oral capsules of itraconazole should be taken with food to increase absorption. The oral solution (10 mg/mL Sporanox solution), on the other hand, is absorbed better on an empty stomach. In a study in cats, itraconazole oral solution appeared to be much better absorbed than a capsule, but cats were fed with each medication.

Some cytochrome P-450 inhibition occurs (CYP3A4) and itraconazole may increase concentrations of cyclosporine, digoxin, and cisapride, when used concurrently. However, enzyme inhibition is much less in comparison to ketoconazole.

FLUCONAZOLE. Like itraconazole, fluconazole (Diflucan) has replaced ketoconazole in small animals and birds for many indications. Fluconazole (Fig. 46.9) is a synthetic bistriazole that was licensed in the United States by the Food and Drug Administration in January 1990 for use in human cryptococcal and candidial infections.

In attempts to overcome some of the deficiencies seen with earlier imidazole compounds, it was found that replacing the imidazole ring with a triazole ring increased in vivo activity despite being four times less potent in vitro than the original imidazole. This suggested that due to the triazole ring's decreased nucleophilicity, it possessed an increased resistance to metabolic attack. Addition of a second triazole group resulted in in vivo potencies 100 times that of ketoconazole and in relatively low lipophilicity. Aqueous solubility dramatically increased (from <1 mg/mL to 8 mg/mL) (Richardson et al. 1990) by replacing the dichlorophenyl substituent in ketoconazole with a difluorophenyl group. The resulting compound has good efficacy in animal models and pharmacokinetics differing from previous azole antifungals.

Fluconazole has been shown to be effective in animal models of *Blastomyces, Candida, Coccidioides, Cryptococcus,* and *Histoplasma* infections and variably effective against *Aspergillus* infection.

PHARMACOKINETICS. Fluconazole has different solubility characteristics than ketoconazole and itraconazole and is absorbed well regardless of the circumstances. Feeding or formulation (liquid vs. tablet) does not affect absorption. Fluconazole absorption is complete in animals. Fluconazole tablets (Diflucan) and oral suspension (10 mg/mL) are absorbed well, and the oral dose is similar to the IV dose.

Fluconazole demonstrates linear absorption kinetics, with bioavailability greater than 90% (Brammer et al. 1990); thus, oral and IV dosages are identical. Maximum fluconazole concentrations are reached 1–4 hours after an oral dose. Unlike other azole antifungals, fluconazole is not highly protein bound. Humphrey et al. (1985) found plasma protein binding to be between 10 and 12% at concentrations of 0.1 and 1 mg/L in mice, rats, dogs, and humans. Fluconazole's low molecular weight, water solubility, and high unbound fraction allow it to be readily distributed throughout the body, including pharmacokinetically privileged spaces. Drug concentrations in saliva, sputum, skin, nails, blister fluid, and vaginal tissue and secretions were found to be similar to plasma concentrations. The advantages of fluconazole lie in its ability to produce higher CSF concentrations than ketoconazole or itraconazole, and therefore, it may be useful for treating mycotic meningitis (Kowalsky and Dixon 1991). Fluconazole CSF/plasma or serum concentration ratios range from 0.5 to 0.9 in humans (Brammer et al. 1990), rabbits (Perfect et al. 1986), and rhesus monkeys (Arndt et al. 1988). Fluconazole has a volume of distribution that approximates total body water, ≈0.7 L/kg (Humphrey et al. 1985).

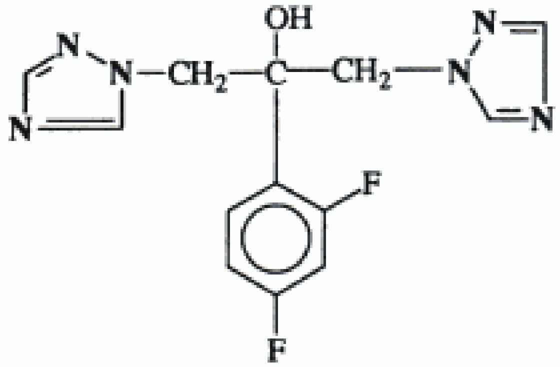

FIG. 46.9—Fluconazole.

Due to its polarity, low molecular weight, and metabolic stability, fluconazole is eliminated principally by the kidney. A unique feature of fluconazole is that this drug is the only one of the azoles that is water soluble and excreted in the urine in an active form. Therefore, it may be one of the few drugs useful for treating fungal cystitis. Approximately 80% of the dose is excreted as active drug in the urine. Estimates of renally excreted metabolites range from 4 to 11%, whereas fecal excretion was negligible in the dog but composed 10 and 2% of the dose in mice and humans, respectively. Half-lives were 4–5 hours in mice and rats, ≈14 hours in dogs and cats (Craig et al. 1993), and 22–30 hours in humans. The disparity between renal fluconazole clearance and creatinine clearance suggests that net tubular reabsorption is responsible for the extended half-life. Steady-state levels are achieved in 5–7 days; thus, the manufacturer suggests a two times loading dose during the first 12–24 hours (Dudley 1990). The lack of significant hepatic metabolism allows for linear elimination kinetics; i.e., half-life is independent of dose.

In cats, fluconazole has a long half-life of 25 hours, with good absorption and distribution to the CSF and aqueous humor (Vaden et al. 1997). The volume of distribution was determined to be ~1 L/kg. Based on these results the authors suggest a cat would require 100 mg fluconazole per day, as a single dose or divided, to produce an effective clinical response (Craig et al. 1993).

The pharmacokinetics of fluconazole was investigated in horses recently (author's unpublished data). Briefly, fluconazole administered orally to horses was well absorbed with bioavailability of 100%. The long half-life of 36 hours and good distribution (1 L/kg) indicate the potential utility of this drug in treating fungal infections. Concentrations in the CSF, synovial joint fluid, and aqueous humor of horses in this study were 96, 90, and 73%, respectively, of plasma concentrations. Based on results of this study, a dose of 5 mg/kg once daily orally was calculated.

CLINICAL USE. Extensive experimentation has been done in vitro and in various animal models using various species of fungi (for reviews, see Saag and Dismukes 1988; Troke 1987; Graybill 1987). Based on fluconazole's tissue distribution, certain predictions can be made regarding its clinical applications both in human and in veterinary medicine. High CSF/serum ratios provide a promising alternative to intrathecal use of other antifungals (Foulds et al. 1988). Encouraging results have been seen with fluconazole's use in cryptococcal meningitis either in acute management or in prevention of recurrence in AIDS patients. High penetration into sputum suggests that high enough concentrations exist in pulmonary secretions to be effective against pulmonary mycotic infections. Fluconazole has been used in pulmonary or disseminated coccidioidomycosis with a favorable response in 86% of patients; it had variable success with fungal pneumonia caused by *Aspergillus* spp. (Cantazaro et al. 1990). Penetration into skin and vaginal tissue allow for fluconazole's use in dermatophytosis and vulvovaginal candidiasis. Since the drug is renally excreted, urinary concentrations are approximately 10 times that in serum, suggesting its use for fungal urinary tract infections.

Fluconazole has been used in the treatment of an abdominal eumycetoma caused by *Madurella mycetomatis*. Following surgical excision of the main mass, a 7-month course of fluconazole was initiated. Three weeks into therapy, celiotomy and ultrasonography confirmed no regrowth of the mass, but smaller granulomas were present. Seven months after diagnosis these granulomas had increased in size and number, and the dog was euthanized (Lambrechts et al. 1991).

Fluconazole has also been used to treat canine nasal aspergillosis and penicilliosis. Ten affected dogs were treated with 2.5–5 mg/kg fluconazole orally for 8 weeks. Six dogs became free of disease 2–4 weeks after cessation of therapy and remained free of disease for at least 6 months. Serum alkaline phosphatase and alanine transaminase activity remained within normal ranges throughout the treatment period, and adverse side effects were not noted (Sharp 1991).

Fluconazole was used to control an outbreak of coccidioidomycosis in Japanese Macaque monkeys in the South Texas Primate Observatory. Previous success was seen with liposomal amphotericin B; however, it required anesthesia of the animals. Fluconazole was administered by placing 25 (for juveniles) or 50 mg (for adults) in caramel candies. Of 14 animals treated, 8 improved rapidly while the others had no response. Discontinuation of therapy resulted in relapse of signs in 4 of the surviving monkeys. The authors conclude that fluconazole has a role in the treatment of coccidioidomycosis; however, the dose may exceed the 2–3 mg/kg used in this outbreak, and a protracted duration of therapy may be necessary for fungal eradication (Graybill et al. 1990).

DOSES. For cats with systemic cryptococcosis, clinical studies have shown a benefit from a dose of 100 mg/cat/day in one or two divided doses. Other reported doses are 2.5–5 mg/kg once a day (Hill et al. 1995). Pharmacokinetic studies support a dose of 50 mg/cat per day (Vaden et al. 1997). In dogs the dose is 10–12 mg/kg/day orally. Fluconazole is available in tablets, oral suspension, and IV injection. Oral absorption in horses has been studied; 5 mg/kg q24h in horses produces sufficient concentrations in plasma and tissues.

ADVERSE EFFECTS. Fluconazole has been generally well tolerated, with mild adverse effects being reported in 5–30% of cases. The GI tract was most frequently involved, followed by the CNS and skin. Mild elevations in hepatic enzymes are sometimes seen, and two cases of hepatic necrosis and death occurred in association with fluconazole therapy (Kowalsky and Dixon 1991). There seems to be little evidence of testosterone or other steroid biosynthesis inhibition in vitro (Shaw et al. 1987) or in human or animal patients (VanCauteren et al. 1987). Hematologic abnormalities, including anemia, leukopenia, neutropenia, and thrombocytopenia, have been reported (AHFS Drug Information 1992). In subacute toxicity studies in dogs the highest dose tested (30 mg/kg) caused slight increases in liver weight, hepatic fat, and plasma transaminase activity. Although there is no evidence of mutagenicity or carcinogenicity, its use in pregnant patients is not recommended.

INTERACTIONS WITH OTHER DRUGS OR DISEASES. Unlike ketoconazole or itraconazole, fluconazole's aqueous solubility is acid independent; hence, drugs that raise gastric pH were not found to have any significant effects on fluconazole pharmacokinetics. As can be expected with a renally excreted drug, renal dysfunction affects fluconazole's elimination such that dose adjustments are necessary. When patients with normal renal function were compared with those with severe renal insufficiency, fluconazole's elimination half-life nearly tripled (from 30.1 hr to 84.5 hr) (Dudley 1990). Reduced dosages as well as extended dosing intervals have been recommended in renal insufficiency.

Terbinafine. Terbinafine (Lamisil®) is reported to be a highly fungicidal antifungal agent. It is a synthetic drug of the allylamine class. A closely related drug of the same class is naftifine (Naftin®), which is used as a topical cream for dermatophyte infections in people. Terbinafine inhibits squalene epoxidase to decrease synthesis of ergosterol. Fungal cell death results from disruption of cell membrane (Balfour and Faulds 1992).

ACTIVITY. Terbinafine is active against yeasts and a wide range of dermatophytes. It is fungicidal against

TABLE 46.1—Suggested antifungal drugs and dosages for treating systemic fungal infections in the dog and cat

		Daily dose (mg/kg)			
Disease	Treatment	Dog	Cat	Frequency	Comment
Blastomycosis[a]	Am B initially	0.5	0.25	3 times/week	For life- threatening disease
	then KTZ	10–15	10	12–24 hr	
	ITZ[b]	5	5	12 hr	For non-life-threatening disease
Histoplasmosis[c]	KTZ	10–15	50	12–24 hr	
	Concurrent Am B	0.25–0.5	0.25-0.5	48 hr	Drugs started together; KTZ given alone after condition improves
	and KTZ	10–15	50	12–24 hr	
Cryptococcosis	Am B	0.25–0.5	0.1–0.5	3 times/week	For CNS infections initially
	5–FC	30	30	6 hr	For CNS infections initially
		50	50	8 hr	
		75	75	12 hr	
	FLZ[d]	10–20	10–20	12–24 hr	For CNS infections initially
	KTZ	5–30	5–20	12–24 hr	For maintenance
	FLZ	5–10	5–10	12 hr	For maintenance
Coccidioidomycosis	KTZ	5–10	50	8–24 hr	Not useful in meningitis
	Am B	0.4–0.5		48–72 hr	If CNS is involved
	FLZ	5–10	5–10	12 hr	
	ITZ	5	5	12 hr	
Aspergillosis[e]	FLZ	5–10	5–10	12 hr	For systemic disease
	Enilconazole	10		12 hr	Topical-direct infusion at infection site
Candidiasis	KTZ	5–11	50–100	12–24 hr	For systemic disease
	ITZ	5–7	5–7	12 hr	For systemic disease
	Nystatin				For local mucocutaneous disease
	Miconazole				Applied topically
	Clotimazole				Applied topically
	Am B cream				Applied topically

Note: Am B = amphotericin B; ITZ = itraconazole; KTZ = ketoconazole; FLZ = fluconazole; 5–FC = fluorocytosine.

[a] Fluconazole not effective, not recommended.

[b] Itraconazole may replace ketoconazole therapy.

[c] Human studies suggest itraconazole and fluconazole to be as effective as ketoconazole-amphotericin B combination therapy.

[d] More rapid cerebrospinal fluid sterilization occurs with amphotericin B-5-fluorocytosine therapy than with fluconazole.

[e] Itraconazole not effective in nasal aspergillosis.

specific treatment of viral diseases in human patients (Crumpacker 1989). In addition, at no other time in history has more emphasis and support been placed on development of antiviral compounds, the result of the epidemic of an invariably fatal infection, HIV.

The treatment of viral disease in the veterinary population is made somewhat problematic due to the infrequency with which definitive diagnosis of a disease attributed to a specific viral agent is made. Viral cultures are not routinely performed and, when done, take a long time, so results are often obtained after the disease has taken its course. Many of the antiviral drugs are toxic and may worsen the condition of an already debilitated infected individual. In chronic viral infections, such as those caused by the feline leukemia or the feline immunodeficiency virus, the ability of the virus to become latent makes eradication of the disease virtually impossible (Huraux et al. 1990). All of the presently available antiviral drugs are virostatic. Thus, an intact immune system is required to maintain the suppression of many viral infections (an additional problem in FeLV and FIV infection). It would appear that the clinicians' best defense against viral disease remains preventing infection (vaccination) rather than attempting to specifically treat an already existing viral infection.

The following discussion of antiviral drugs considers all compounds available, but greater emphasis is placed on those with veterinary significance. An overview of the physiology and biochemistry involved in viral replication is necessary to identify target sites at which antiviral agents are directed. The viral replicative cycle can be divided into eight steps (Fig. 46.10):

1. *Attachment:* The virus particle must attach to the host cell membrane, often to a specific protein receptor.
2. *Penetration:* The virus particle penetrates the host cell membrane.
3. *Uncoating:* The viral protein coat is broken, releasing the viral genetic material into the host cell cytoplasm.
4. *Transcription:* A mRNA strand is made from the viral genetic material.
5. *Translation:* Viral mRNA attaches to host ribosomes, and nucleic acids are translated into viral proteins.
6. *Replication:* Duplicate strands of genetic material are produced from the original viral template.

cell often requires the specific interaction of viral coat proteins with "receptor" proteins of the host cell membrane. Strategies for coating specific viral attachment proteins with monoclonal antibody to prevent attachment are limited by the fact that antibody must coat virus prior to infection and hence requires knowledge of exposure or prophylactic use. Analog viral binding proteins can bind host cell receptor proteins, thereby competing with actual viral particle binding. Unfortunately, the host cell proteins often have other physiologic functions which preclude this approach. Host cell protein receptor analogs which attach to the viral coat protein have been conjugated to compounds which enhance opsonization and phagocytosis by macrophages, thereby preventing viral replication.

TRANSCRIPTION

Idoxuridine and Trifluridine. *Idoxuridine,* USP (5-iodo-2′-deoxyuridine, Herplex, Stoxil) (Fig. 46.11A), and *Trifluridine,* USP (5-trifluoromethyl-2′-deoxyuridine, Viroptic) (Fig. 46.11B), are thymidine analogs and therefore are only active against DNA viruses, primarily herpesvirus and poxvirus. The compound is phosphorylated inside the host cell and is then incorporated into growing mammalian and viral strands. This DNA is thought to be more susceptible to breakage and results in faulty proteins if transcribed. The fluorinated compound (trifluridine) is thought to have higher affinity for viral DNA than mammalian, as well as being more active. Both compounds are used topically in the treatment of herpetic keratitis. Given the cost of these medications, idoxuridine should be used initially, and if no response is seen within 1 week, trifluridine therapy should be initiated (Martin 1990). Toxic side effects, including leukopenia, hepatotoxicity, and GI signs, have precluded their systemic use.

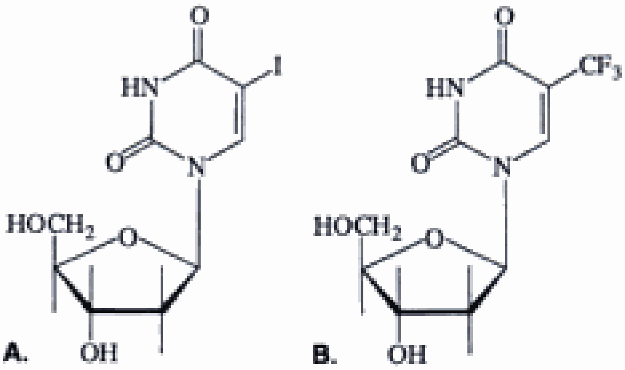

FIG. 46.11—(A) Idoxuridine; (B) trifluridine.

Cytarabine and Vidarabine. *Cytarabine,* USP (cytosine arabinoside 1-β-D-arabinofuranosylcytosine, Ara-C) (Fig. 46.12A), and *Vidarabine,* USP (adenine arabinoside, 9-β-D-arabinofuranosyladenine, Ara-A) (Fig. 46.12B), are nucleoside analogs of cytosine and adenine, respectively. They have in vitro activity against certain DNA viruses, including herpesviruses, poxviruses, vaccinia, rabies, cytomegalovirus, and probably hepatitis B virus. Cellular enzymes convert these compounds to the triphosphate form, which then act as competitive inhibitors of DNA polymerase. Herpes-induced DNA polymerase seems to be more sensitive to this inhibition than the mammalian cellular counterpart.

Vidarabine is poorly soluble so must be given intravenously in large fluid volumes over 12 hours. Vidarabine and its active metabolite, hypoxanthine arabinoside, are widely distributed in body fluids and tissues, including the brain and cerebrospinal fluid. Cytarabine is biotransformed to an inactive metabolite and is therefore less effective than vidarabine. Major side effects include GI, neurologic, and hematologic toxicity and teratogenicity.

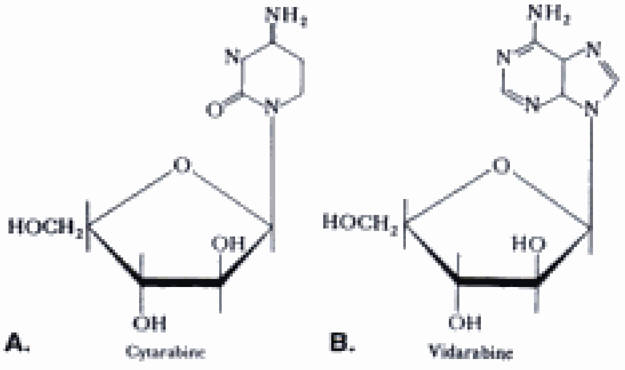

FIG. 46.12

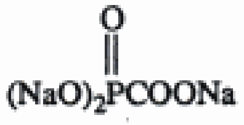
These compounds have been used topically in the treatment of herpes keratitis and systemically in herpes simplex encephalitis. In human medicine, vidarabine's role has been suggested to be as a "backup" drug for resistant infections of herpes simplex virus and varicella-zoster virus (Hirsch and Schooley 1989). Vidarabine demonstrated significant antiviral activity in vitro against the feline infectious peritonitis virus. However, this effect was only seen if the compound was used as a pre- or cotreatment with viral inoculation (Barlough and Scott 1990).

Ribavirin. Ribavirin (Virazole) (Fig. 46.13) is a triazole purine nucleoside analog that inhibits the replication of a wide range of RNA and DNA viruses in vitro. Its strongest antiviral activity is against RNA respiratory viruses (influenza A and B) and herpesviruses but also includes myxoviruses, paramyxoviruses, arenaviruses, bunyaviruses, retroviruses, adenoviruses, and poxviruses. Ribavirin is thought to have multiple sites of action. After being monophosphorylated to ribavirin 5′-monophosphate (RMP) by adenosine kinase, it is able to indirectly inhibit synthesis of guanine nucleotides. Further phosphorylation to RTP allows it



$(NaO)_2\overset{\overset{O}{\|}}{P}COONa$

FIG. 46.16—Foscarnet.

Foscarnet. Foscarnet (trisodium phosphonoformate hexahydrate; PFA) (Fig. 46.16) is a pyrophosphate analog which exhibits antiviral activity against a variety of DNA and RNA viruses. It inhibits DNA and RNA polymerases as well as reverse transcriptase. The mechanism of foscarnet differs from those of the preceding antiviral agents in that it inhibits these enzymes by binding at the pyrophosphate binding site rather than at a base binding site. Thus, inhibition is noncompetitive rather than competitive (Oberg 1989). Because phosphorylation by viral kinases is unnecessary for antiviral activity, it has potential for use in thymidine kinase-deficient herpesvirus infections (Teich et al. 1992). Viruses inhibited include avian myeloblastosis, Moloney murine leukemia, Rauscher leukemia, visna, influenza, bovine leukemia, African swine fever, baboon endogenous, simian sarcoma, human herpes, and human immunodeficiency viruses (Swenson et al. 1991).

Although viral replication has been shown to be inhibited at concentrations achievable in plasma, these concentrations often vary widely. In addition, variable interindividual pharmacokinetics in humans make optimal dosage regimes difficult to identify (Lietman 1992). The pharmacokinetics of PFA have been investigated in the cat (Straw et al. 1992). PFA was only 8% bioavailable, was found to have a terminal half-life of ~3 hours, and was not metabolized, resulting in a total clearance of 1.88 mL/min/kg. The related compound thiofoscarnet (thiophosphonoformate, TPFA) had greater bioavailability (22–44%) and a shorter plasma half-life (42 minutes) and was metabolized to the active PFA, suggesting its possible use as a prodrug. The percutaneous absorption of PFA was studied in rabbits and dogs to ensure its safe topical use in herpetic mucocutaneous conditions. Systemic absorption after vaginal application was found to be 14% in the rabbit and 34% in the dog, whereas 12% (rabbit) and 3% (dog) of the dose entered the systemic circulation after topical administration (Hussain and Ritschel 1989).

Foscarnet is more effective than vidarabine in the treatment of acyclovir-resistant herpes simplex virus infections. It is as effective as ganciclovir for treating CMV retinitis in AIDS patients. It has the advantage of having intrinsic anti-HIV activity, and it is better tolerated than ganciclovir when given in combination with AZT (Jacobson et al. 1991; Palestine et al. 1991). Foscarnet therapy may result in renal impairment, and lifelong intermittent therapy may be necessary to prevent recurrent CMV infection, but myelosuppressive toxicity is avoided. For these reasons, it may replace ganciclovir in this application (Minor and Baltz 1991) except in patients with decreased renal function (SOCA 1992). The prophylactic and therapeutic use of PFA has been suggested in the cat (Swenson et al. 1991). It is suggested that long-term PFA administration to FeLV-infected cats may limit spread of infection within and between hosts via extracellular inactivation of newly produced virus particles. The authors also suggest PFA may have a role as a viral disinfectant for blood, blood products, supplies, and equipment.

ASSEMBLY

Amantadine and Rimantadine. *Amantadine hydrochloride,* USP (1-adamantanamine hydrochloride, Symmetrel) (Fig. 46.17A), and *Rimantadine* (Flumadine) (Fig. 46.17B) are water-soluble cyclic amines with antiviral activity against a narrow range of RNA viruses, including myxoviruses, paramyxoviruses, togaviruses, and most strains of influenza A virus. Rimantadine has approximately 3–4 times greater in vitro activity against influenza A than amantadine (Betts 1991). The mechanism of these two related compounds has been debated. They were thought at one time to prevent viral penetration and uncoating (Hoffman et al. 1965), but this has been refuted more recently (Couch and Six 1986). Their antiviral activity is now thought to involve inhibition of late-stage assembly of the virus.

Both compounds are absorbed well from the human GI tract. Serum concentrations of amantadine are greater than those of rimantadine, but the latter achieves greater concentrations in secretions (Hayden et al. 1985). The volume of distribution of amantadine is significantly less than that of rimantadine. Amantadine is excreted unchanged in urine, with an elimination half-life of ~16 hours, whereas rimantadine is 85% metabolized and eliminated with a 24–36 hour half-life. Neither agent has bone marrow, renal, or hepatic side effects, but amantadine may be neurotoxic, causing jitters, difficulty in concentrating, and seizures in certain patient populations. CNS side effects are less

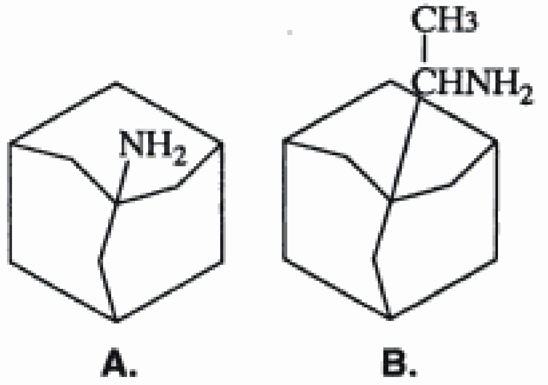


FIG. 46.17—(A) Amantadine; (B) rimantadine.

frequent with rimantadine. The combination of greater in vitro efficacy, greater distribution and terminal half-life, and less toxicity suggests rimantadine has greater clinical potential. Both compounds are equally effective in the prophylactic prevention of respiratory infections caused by influenza A virus, although not as effective as vaccination. They have also been used to treat flu outbreaks, resulting in shorter duration fever and more rapid resolution of symptoms (VanVoris et al. 1981). Experimentally infected chicks that received amantadine via the drinking water were one-half as likely to die as untreated controls (Obrosova-Serova et al. 1976). Amantadine had no inhibitory effect on FIP virus replication in vitro at the highest concentration tested (Barlough and Scott 1990).

HOST RESISTANCE

Interferon. A complete discussion of the biochemistry, physiology, and immunological function of interferon-$\alpha_{2a,2b}$ (Roferon-A, Intron A) is beyond the scope of this chapter. Interferons are glycopolypeptide molecules produced by certain mammalian cells in response to viral infections as well as other stimuli. They are potent cytokines that possess antiviral, immunomodulating, and anticancer properties (Pestka et al. 1987). Three classes of interferons exist: alpha, beta, and gamma, with the last being produced solely by T lymphocytes. Interferons affect RNA and DNA viral replication via multiple mechanisms which act at different stages of the viral replicative cycle. They bind specific cell-surface receptors, inhibiting binding, and may prevent penetration and uncoating. Interferon can inhibit synthesis or methylation of mRNA, translation, and viral assembly and release (Whitaker-Dowling and Younger 1987). Interferons are thought to inhibit viral protein synthesis indirectly by inducing an enzyme that indirectly activates a ribonuclease that degrades mRNA. They may also induce a protein kinase that phosphorylates and inactivates a viral initiation protein (Douglas 1990).

Being peptides, interferons are orally inactive and must be given parenterally. Peak plasma concentrations occur 4–8 hours following subcutaneous or intramuscular injection. Distribution half-life is 40 minutes and the terminal half-life is ~4–5 hours; however, biologic half-life is extended (24 hours). Penetration into the cerebrospinal fluid, brain, and eye is poor (Cantell and Pyhala 1976).

Interferon therapy has shown efficacy in many human clinical situations, including viral infections caused by influenza virus, rhinovirus, herpesvirus, and papilloma virus. Treatment of FeLV with interferon has had mixed results. Although shown to inhibit replication in vitro (Jameson and Essex 1983), this did not carry over to in vivo (Beck 1985). When given at the same time as experimental FeLV virus challenge, interferon-α ameliorated the clinical course and improved survival rates, although it did not affect viremia (Cummins et al. 1989). In contrast to these results, interferon had no protective effect against FeLV challenge unless given in combination with AZT (Zeidner et al. 1989). Bovine interferon-α_1 was able to inhibit replication of the transmissible gastroenteritis virus in vitro but, due to GI instability, was unable to prevent infection in vivo (MacLachlan and Anderson 1986). Human leukocyte interferon-α has been used for prophylactic treatment of bovine herpesvirus type I–associated shipping fever (Baker 1990).

OTHER COMPOUNDS. As previously mentioned, the research and development of antiviral compounds is occurring at an unprecedented pace. Many compounds that, at the time of printing, are only experimental may become available for clinical use.

2′-3′-dideoxyinosine (ddI) and 2′-3′-dideoxycytidine (ddC) are nucleoside analogs under development for the treatment of AIDS. Incorporation of the triphosphate form of these molecules is thought to result in termination of chain elongation and interruption of DNA synthesis. The ability of these compounds to interfere with FeLV infection in vitro and in vivo has been studied (Tavares et al. 1989). The intravenous pharmacokinetics of ddI were found to be nonlinear in the dog (Kaul et al. 1991).

The acyclic purine nucleoside analog 9-2(phosphonomethoxyethyl)adenine (PMEA) has been studied in the treatment of both FeLV and FIV infections in cats. PMEA was found to inhibit replication of FeLV in vitro and prevented the development of persistent antiginemia and the induction of the immunodeficiency disease in cats exposed to the virus (Hoover et al. 1991). PMEA exhibited similar effects against FIV infection. Seropositive cats with symptoms of opportunistic infection showed improvement of clinical signs during PMEA therapy at 5 mg/kg/day (Egberink et al. 1990).

Ribozymes have recently been added to the antiviral armamentarium. Ribozymes are small, single-stranded catalytic RNAs which are capable of destroying specific RNA target sequences. These antisense molecules have the ability to interfere with the virus at an early step in its replicative cycle and have adequate specificity such that host metabolic processes may be spared (Sarver 1991). Aspects of ribozymes currently under investigation include target accessibility, stability, methods for delivery, and intracellular localization (Rossi et al. 1991).

Dextran sulfate is a glucose homopolymer with a molecular weight of 7000–8000 and contains 17–20% sulfur in the form of sulfate. It has been shown to inhibit replication of the HIV virus and other retroviruses in vitro, including the FIV (Tanabe-Tochikura et al. 1992) and the FeLV virus. Dextran sulfate was unable to prevent FeLV infection and development of persistent viremia in challenged cats at a dosage that did not cause toxicity. Toxicity of dextran sulfate at 24 mg/kg/day was seen as GI ulceration, anemia, and death (Mathes et al. 1991).

TABLE 46.2—Antiviral drugs of potential veterinary importance (in most cases doses are experimental, necessitating further clinical study)

Drug	Preparation	Brand (manufacturer)	Route	Dosage	Interval (hr)
Idoxuridine	0.1% ophthalmic solution	Herplex Liquifilm (Allergen); Stoxil (SKF)	Ocular, topical	1 drop	5–6
	0.5% ophthalmic ointment	Stoxil (SKF)	Ocular, topical	Ointment	1–2
Trifluridine	1% ophthalmic solution	Viroptic (Burroughs Wellcome)	Topical	1 drop	2
			IV	1.5, 2.9 mg (humans)	4–8, 4
Vidarabine	3% ophthalmic ointment	Vira-A (Parke-Davis)	Ocular, topical	1 cm ointment	5–6
	200 mg/mL suspension for injection		IV	10–30 mg/kg	24 as a continuous drip for 12–24 hr
Ribavirin	6 g/100 mL vial powder	Virazole (ICN Pharmaceuticals)	Inhalation	Using SPAG-2 nebulizer only	8–18 hr period daily
Acyclovir	5% cutaneous ointment	Zovirax (Burroughs Wellcome)	Topical	Cover lesion adequately	3 hr, 6 times/day
	200 mg capsules or tablets		PO	200 mg (humans)	4 hr, 5 times/day
	200 mg/5 mL suspension 500 mg/vial powder		IV	250–500 mg/m^2	8 (infused over at least 1 hr)
	1 g/vial powder			5–10 mg/kg (humans)	8
Ganciclovir	500 mg/vial powder	Cytovene (Syntex)	IV	2–5 (humans)	8–12
Zidovudine	100 mg capsules	Retrovir (Burroughs Wellcome)	PO	100–200 mg (humans) 10–20 mg/kg	4
	Syrup 10 mg/mL		PO	200 mg (humans)	4
	10 mg/mL single-use vial		IV	1–2 mg/kg	Infused over 1 hr
Foscarnet			IV	60 mg/kg	8 (CMV initiation therapy)
				90–120 mg/kg	24 (CMV maintenance therapy)
				40 mg/kg	8 (for HSV and VZV infections)
Amantadine	100, 500 mg capsules	Symmetrel (Dupont)	PO	100 mg total (humans)	12–24
	Syrup 10 mg/mL		PO	100 mg total (juveniles)	24
Rimantadine		Flumadine	PO	200–300 mg total (humans)	24
				100–200 mg total (juveniles)	24
Interferon-α_{2a}	3×10^6 IU/vial	Roferon-A (Roche)	SC, IM	3×10^6 IU (humans)	24
Interferon-α_{2b}	3×10^6 IU/vial	Intron A (Schering)	SC, IM	3×10^6 IU (humans)	24

Other potential antiviral agents include glycoprotein-processing inhibitors (Elbein 1991), viral protease inhibitors (Kleina and Grubman 1992), and even neurotransmitter antagonists (Tsiang et al. 1991). The future use of these and other compounds remains to be seen. Table 46.2 lists potentially useful antiviral agents in veterinary medicine. In most cases, doses are experimental and require further clinical trials to verify.

against lungworms can be achieved with a single dose of 25 mg/kg fenbendazole. Albendazole is also effective against swine lungworms. Better efficacy is obtained when this drug is administered in the feed (10 ppm) for 5 days rather than by single dosing.

As the previous examples suggest, BZDs generally are more effective when given at lower dosages for several days rather than as larger, single doses. For example, single doses of thiophanate at 50–100 mg/kg are quite effective against adult and larval stages of *Oesophagostomum, Trichuris, Hyostrongylus,* and *Strongyloides* in pigs and against all major GI nematodes of ruminants. When given in feed over several days, however, thiophanate maintains efficacy against these species and is additionally effective against ascarids in pigs (6 mg/kg/day for 14 days) and against inhibited larvae of *Ostertagia ostertagi* in cattle (20 mg/kg/day for 5 days).

It is difficult to assess the comparative values of BZDs against the larval and immature fifth stages of the GI parasites of swine because many reports on efficacy do not include this information. In general, however, efficacy against these stages parallels activity against adult forms. None of the BZDs claims efficacy against spirurid stomach worms or *Macracanthorhynchus hirudinaceus.*

DOGS AND CATS. The activities of mebendazole and fenbendazole have been evaluated extensively in dogs and cats. Mebendazole is approved for use in dogs against adult hookworms, ascarids, and whipworms. Nematodes are satisfactorily expelled by a 3-day course of 22 mg/kg/day. Mebendazole has similar activity against similar parasites of cats but is not approved in this host species.

Fenbendazole also has excellent activity for the same parasites of dogs and cats. It is administered as granular, powder, or suspension formulations at a dosage of 50 mg/kg/day for 3 days for common nematodes. It currently has FDA approval for dogs but not cats. Additionally, administration of fenbendazole at 50 mg/kg daily from the 40th day of pregnancy through the 14th day after whelping provides excellent reduction of hookworm (>99%) and ascarid (>90%) burdens of pups that were infected lactogenically or prenatally, respectively (Burke and Roberson 1983). Albendazole and oxfendazole are apparently effective against somatic ascarid and hookworm larvae when similarly used in infected bitches during the last third of pregnancy (Stoye 1992). Digestion of musculature from dogs, rats, and mice somatically infected with these parasites suggests that fenbendazole kills larval forms of canine ascarids and hookworms. Controlled studies in dogs suggest greater than 94% effectiveness in reducing developing third- and fourth-stage larvae of canine ascarids (*T. canis* and *T. leonina*) following a 30-day regimen at 50 mg/kg/day (Fisher et al. 1993).

The efficacy of albendazole against common GI nematodes of dogs and cats has not been investigated thoroughly. Albendazole's activity for canine ascarids (70%), hookworms (18%), and whipworms (8%) is limited when given as a single dose of 15 mg/kg. A higher, single dose (20 or 25 mg/kg) is 100% effective for *T. canis* but still limited (66–73%) against *Ancylostoma caninum.* Daily dosing (3 days at 15 mg/kg/day) is 100% effective for both *T. canis* and *A. caninum.*

Albendazole apparently is active against some of the less common nematode parasites such as *Filaroides hirthi* and *Capillaria plica.* In dogs with clinical signs (hematuria, dysuria, pollakiuria) associated with *C. plica* infection, a prolonged, high-dose regimen of albendazole (50 mg/kg orally every 12 hr for 12–14 days) is required to achieve efficacy. Anorexia may occur 5–10 days after initiation of treatment. Fenbendazole is reportedly effective against this parasite at its regular therapeutic dosage (50 mg/kg for 3 days) and has no side effects.

Albendazole (25–50 mg/kg every 12 hr for 5 days) is apparently almost totally effective in treating *F. hirthi.* Tracheal infections of *Filaroides osleri* in dogs have been treated by repeated use of oxfendazole (10 mg/kg/day for 28 days) or TBZ (70 mg/kg/day for 2 days, then 140 mg/kg/day for 21 days). Albendazole or fenbendazole may be effective against this parasite with less demanding regimens. Fenbendazole appears to be particularly suited for treatment of the cat lungworm (*Aelurostrongylus abstrusus*) as well as the stomach worm (*Ollulanus tricuspis*). Treatment regimens are 20–50 mg/kg/day for 5 days or 3 days, respectively.

Interested readers are referred to earlier editions of this text for detailed discussions of the activity of BZDs against *Strongyloides stercoralis* infections in dogs (Courtney and Roberson 1995).

A combination of oxibendazole and diethylcarbamazine (Filaribits Plus) is administered daily to dogs for prevention of hookworm and heartworm and for removal of whipworms and ascarids.

BIRDS. Mebendazole and fenbendazole can be used effectively against parasites of the GI and respiratory tracts of birds. Mebendazole in a single dose of 50 mg/kg or fenbendazole at 8 mg/kg/day in feed for 6 consecutive days effectively eliminates ascarid and capillarid infections of birds. Turkeys require fenbendazole at 45 ppm in feed for 6 days to effect 100% removal of ascarids, *Heterakis,* and *Capillaria obsignata.* Single treatments with fenbendazole at 350 mg/kg are fully effective against ascarids. Parbendazole is effective against both ascarids and heterakids at a single dose of 30 mg/kg or as a 0.05% preparation in food for 2 days. Treatment with parbendazole is not recommended during the laying period.

Treatment of zoo birds is generally accomplished with lower daily dosages over a long period to ensure safety and compliance. Mebendazole is used in feed at 60 ppm for 7 days in chickens, turkeys, and guinea fowl and at 120 ppm for 14 days in pheasants, partridges, geese, and ducks. Fenbendazole is used at 60 ppm for 6 days in all these species.

apeutic dose or in 9 repeated administrations of 5 times the therapeutic dose at approximately 1-week intervals. Similar levels of oxibendazole are also safe for cattle, sheep, and dogs. Mebendazole is tolerated in horses when given as a single dose equal to 40 times the therapeutic dose or as daily, 6-times doses for 15 days. Parbendazole may cause transient diarrhea in horses treated at doses as low as 2.5 mg/kg but is tolerated well in pigs at 10,000 mg/kg. Mebendazole is tolerated in chickens at 2000 mg/kg. In dogs, treatment with this drug at therapeutic doses occasionally results in acute hepatic necrosis with jaundice.

Acute and chronic LD$_{50}$ values have not been established for the BZDs in some domestic animals. A single 200 mg/kg dose of albendazole is lethal for cattle, as parbendazole (600 mg/kg) occasionally is for sheep. The LD$_{50}$ for mebendazole in dogs, cats, and guinea pigs is 640 mg/kg; its LD$_{50}$ in horses is not known, but daily treatment of horses with a standard dose of 5 g mebendazole for 19–74 days had no ill effects. Mebendazole in standard-size particles (10–20 μm) has an LD$_{50}$ of 3.56 g/kg for mice, but in smaller particles (3–5 μm) it is five times more toxic for mice (LD$_{50}$ = 0.62 g/kg). Acute LD$_{50}$ values of oxfendazole are greater than 1600 mg/kg for dogs and greater than 6400 mg/kg for both mice and rats. The LD$_{50}$ value of flubendazole in mice, rats, and guinea pigs exceeds 2560 mg/kg. Attempts to cause fatalities by poisoning small laboratory animals with fenbendazole or oxibendazole have been unsuccessful because rats and mice tolerate the maximum quantities (10,000 mg/kg) that physically can be administered.

Contraindications. Because of the potential for tissue and milk residues, slaughter clearance times are required, and milk of treated animals may not be used for human consumption. A notable exception is fenbendazole in dairy cattle, which requires no milk withdrawal following treatment with 5 mg/kg. A 10-day withdrawal time is recommended for both cattle and sheep following treatment with oxfendazole. Persons administering anthelmintics to food-producing animals should consult the label instructions concerning withdrawal requirements and contraindications.

Another major contraindication for use of some of the substituted BZDs is early pregnancy. Parbendazole and cambendazole exert teratogenic effects when given to pregnant ewes during the second to fourth weeks of gestation. The period of greatest teratogenic potential coincides with the time that normal embryonic limb development begins (i.e., around the 20th day of pregnancy). Principal reported malformations include rotational and flexural deformities of the limbs, overflexion of the carpal joints, and abnormalities of posture and gait. Incidences of malformed lambs born to ewes treated on the 21st and 24th days of gestation were 27 and 47%, respectively. No abnormalities occur if the drugs are administered as early as the 10th or 14th days of pregnancy, but treatment at this time reduces the lambing rate (67% for drug-treated ewes vs. 84% for nontreated controls). There is no restriction on use of cambendazole in ewes following the fourth week of pregnancy.

Although cambendazole is no longer marketed in the USA, its use was reported to cause occasional congenital limb deformities in foals. Interested readers are referred to earlier editions of this text for further details of teratogenic effects of BZD anthelmintics.

There are no known teratogenic effects of mebendazole, fenbendazole, flubendazole, oxibendazole, or thiophanate, and repeated, multiple therapeutic doses of fenbendazole have not caused adverse effects in pregnant ewes, cows, mares, bitches, or laboratory animals.

All BZDs are compatible with other drugs administered simultaneously except that oxfendazole and fenbendazole should not be administered concurrently with bromsalan flukicides. This combination has produced abortions in some cattle and deaths in sheep.

Dosage and Administration. BZDs are almost always administered orally, generally as a paste or suspension for drenching or as a powder or granules for administration in feed or incorporation in a salt- or feed-block carrier. Controlled-release devices (intraruminal bolus) have been developed for sheep and cattle, and oxfendazole can be injected directly into the rumen through the left paralumbar fossa of cattle.

PROBENZIMIDAZOLES. Two probenzimidazole compounds, netobimin and febantel, are converted in the GI tract to albendazole and fenbendazole, respectively, and their subsequent sulfone and sulfoxide metabolites. The parent probenzimidazole compounds have no apparent anthelmintic activity in vivo and are effective only after metabolic conversion. Worms resistant to other BZDs are resistant to the probenzimidazoles as well.

Netobimin. *Netobimin* (Hapadex) is a broad-spectrum probenzimidazole anthelmintic having nematocidal activity in horses and ruminants as well as cestocidal and fasciolicidal activity in ruminants. Netobimin is found only briefly in the GI tract following administration, being replaced by albendazole and albendazole sulfoxide, which are thought to account for its anthelmintic activity. Netobimin is effective against the common GI nematodes (including hypobiotic larvae of *Ostertagia ostertagi*), lungworms, and *Fasciola hepatica*. In horses, it is effective against ascarids as well as large strongyles and cyathostomes.

Febantel. *Febantel* (Rintal) is a broad-spectrum probenzimidazole anthelmintic that has FDA approval for use in horses, dogs, and cats and has broad-spectrum efficacy against nematodes of ruminants, swine, and a variety of species of zoo animals. Febantel is found only briefly in the GI tract following administration, being replaced by fenbendazole and its sulfoxide, oxfendazole, which are thought to account for febantel's anthelmintic activity. Febantel (Rintal Tabs) is

to treat dogs for whipworm (*Trichuris vulpis*) and hookworm (*Ancylostoma caninum*) infections. It is no longer marketed in the USA. Interested readers are referred to earlier editions of this text (Courtney and Roberson 1995) for additional information about butamisole.

Levamisole. *Levamisole,* INN (Levasole, Tramisol, Totalon), is an antinematodal drug with a broad range of activity in numerous host species (sheep, cattle, swine, horses, chickens, dogs). It is approved and marketed in the USA only for use in cattle, sheep, and swine. Major advantages of levamisole are its efficacy against nematodes of the lungs and GI tract, and optional routes of administration (oral, parenteral, or topical).

CHEMISTRY AND RELATION TO *dl*-TETRAMISOLE. Levamisole is the *l* isomer of *dl*-tetramisole. The latter drug was introduced as an anthelmintic in 1966 and is a racemic mixture of two optical isomers: *s*(−)tetramisole (= *l*-tetramisole = levamisole) rotates plane polarized light to the left; *R*(+)tetramisole (= *d*-tetramisole) rotates light to the right. The mixture of isomers, known as *Tetramisole,* INN, or *dl*-tetramisole (Nemicide, Nilverm, Ripercol), was marketed throughout the world as an anthelmintic for sheep, cattle, and various other hosts.

Following approval of the racemic mixture, pharmaceutical scientists were able to develop a process for separating the *dl*-tetramisole into its two isomers. Upon testing the separated components, it was found that the anthelmintic activity of the mixture was attributable almost solely to the *l* isomer. Thus it was determined that using the *l* isomer alone could reduce the dosage by 50%. Reducing the dosage also increased the safety margin since both components of tetramisole are similarly toxic. The compound currently available in the USA and in many other countries is levamisole rather than the parent tetramisole. Most of the following discussion addresses the *l* isomer.

The chemical name of levamisole is (−)-2,3,5,6-tetrahydro-6-phenylimidazo[2,1-*b*]thiazole. The marketed form is either the hydrochloride (bolus, drench, or paste) or phosphate (injectable) salt. Levamisole hydrochloride, a white crystalline compound, is highly soluble in water. This solubility facilitates the formulation of an injectable solution and a stable drench.

MODE OF ACTION. Levamisole hydrochloride is a direct cholinergic and paralyzes nematodes by sustained muscle contraction. Levamisole acts as a ganglionic stimulant (cholinomimetic). This conclusion is supported by the fact that levamisole-induced contractions of *Ascaris suum* are blocked by the autonomic ganglion-blocking agents mecamylamine and pempidine.

PHARMACOKINETICS. Absorption and excretion of levamisole are rapid following oral administration of the radioactive-labeled drug to rats at a dose of 15 mg/kg. Approximately 40% is excreted in urine within 12 hours. Thereafter, urinary excretion decreases and only another 8% is eliminated over the next 8 days. Elimination in feces over an 8-day period accounts for approximately 41% of the dose, the bulk of which passes in 12–24 hours. A small amount is expelled in respired gases (i.e., 0.2% of the dose during a 48-hour period immediately following dosing).

Tissue residues of the drug are not appreciable. Approximately 0.9% of the initial dose is found in tissues (principally degradative and excretory organs like the liver and kidney) at 12–24 hours after dosing. By 7 days after dosing, levamisole is not detectable in muscle, liver, kidney, fat, blood, or urine of rats or other animals tested. On this basis, a 2- to 11-day slaughter clearance time is mandated, depending on the formulation used. The identified metabolites of levamisole are much less toxic than the parent compound, so the parent drug is sought in analysis of tissue samples.

The pharmacodynamic actions of levamisole (or tetramisole) in the host suggest that the drug exerts both muscarinic and nicotinic effects. Signs of levamisole intoxication (salivation, defecation, and respiratory distress from smooth muscle contraction) are like those of organophosphate poisoning. Indeed, evidence suggests that some of the toxicity of this drug may be concerned with cholinesterase inhibition, leading to manifestations of the muscarinic action of acetylcholine (ACh) (i.e., constriction of pupils and respiratory bronchioles, acceleration of motility of the digestive tract, slowing of the heart rate, and other autonomic actions).

It is suggested that levamisole additionally produces effects consistent with the nicotinic action of ACh (i.e., initial stimulation but subsequent blocking of ganglionic and skeletal neuromuscular transmission). Clinical signs of pronounced nicotinic action of ACh are an initial rise in blood pressure followed by a fall in arterial pressure and simultaneous respiratory paralysis. These nicotinic manifestations are only slightly represented in levamisole toxicosis; the muscarinic manifestations of the drug markedly predominate.

MODULATION OF THE HOST IMMUNE SYSTEM. In addition to its anthelmintic activity, levamisole also apparently enhances immune responsiveness. This characteristic has caused considerable excitement in both veterinary and human medicine. For a discussion of these properties, interested readers are referred to the 7th edition of this text (Courtney and Roberson 1995).

FORMULATIONS AND ADMINISTRATION. Levamisole is administered as a bolus, drench, feed additive, subcutaneous (SC) injectable solution, or topical pour-on. The drug for drenching ruminants is marketed in powder form to which water can be added. Drench solution is quite stable and can be held for as long as 12 days without loss of anthelmintic activity.

Two formulations of levamisole hydrochloride are prepared for administration in feed of ruminants. One incorporates the drug in a pelleted, ready-to-use, dehydrated alfalfa carrier (the pellets should be mixed with one-half the regular daily ration and fed at one time). The second, a medicated premix containing 50% levamisole, is for use by feed mills in manufacturing a deworming supplement (0.8% levamisole) for cattle and sheep. Feed should be withheld overnight. The following morning the medicated supplement can be mixed with one-half the daily ration.

Administration of levamisole in drinking water is used routinely only for swine and poultry. The drug intended for this use is marketed as a powder to be added to water and consumed at the rate of 3.8 L/45.4 kg in a 24-hour period. After mixing, the solution is stable up to 3 months if stored in a tightly capped bottle. For poultry, the medicated drinking water is prepared by calculating the total amount of tetramisole needed to provide a dose of 40 mg/kg. This quantity is used to prepare a 0.01% (approximate) solution that should be consumed by the birds within 12 hours.

Levamisole has wide appeal as an injectable anthelmintic for cattle. The original, aqueous solution of levamisole hydrochloride was administered by intramuscular (IM) or SC injection. The hydrochloride, however, proved to be irritating to tissues, and IM injection resulted in moderate to severe reactions at the injection site. The monobasic phosphoric acid salt of levamisole was found to be less irritating to tissues; thus, levamisole phosphate is now regularly used for SC injections.

The pour-on formulation contains 10% levamisole as base, which is readily absorbed through the skin following application to the midline of the back. Blood levels of levamisole following pour-on application are similar to those obtained after either SC or oral administration. Ease of administration by this method makes treatment more practical than by conventional methods.

ANTHELMINTIC SPECTRUM

CATTLE AND SHEEP. The efficacy of levamisole in ruminants is essentially equal regardless of whether the bolus, drench, pellet, injectable, or pour-on formulations are used. The pour-on formulation appears to be slightly less effective than other preparations of the drug, which seems to be a common characteristic of other anthelmintics as well. Adult stages of the major ruminant parasites of the abomasum (*Haemonchus, Ostertagia*), small intestine (*Cooperia, Trichostrongylus, Bunostomum*), large intestine (*Oesophagostomum*), and lungs (*Dictyocaulus*) are satisfactorily removed by this broad-spectrum drug. Activity against whipworms is poor or inconsistent. Levamisole is 98% effective for both mature and immature lungworms of ruminants.

Larval and immature stages of the GI parasites of ruminants are effectively removed by levamisole. More than 87% of the lumen-dwelling late fourth-stage and immature adults of *Ostertagia* and *Haemonchus* are removed from treated cattle. Immature adults of *Cooperia* are completely eliminated. Studies using cattle with natural *Ostertagia* infections reported an average 56% reduction in inhibited fourth-stage larvae following treatment with levamisole.

Levamisole also has been successful in treating eyeworms (*Thelazia*) of cattle.

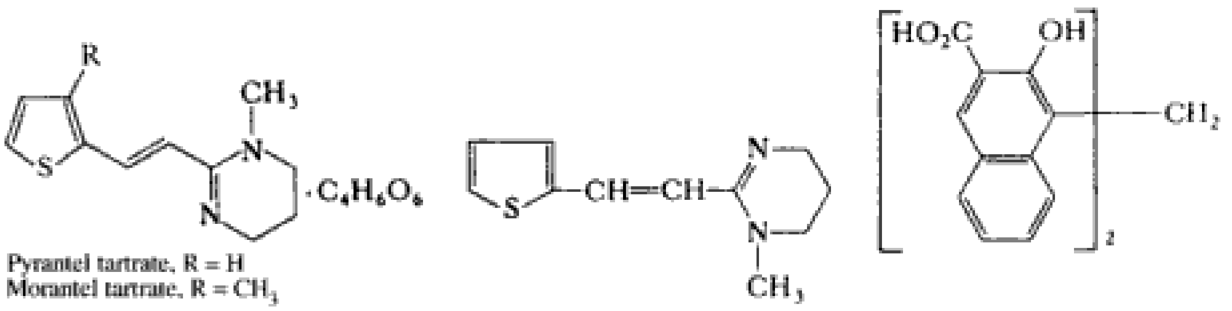
SWINE. The convenient and most widely used method for deworming swine with levamisole is to add the drug to the drinking water or feed. When administered orally, efficacies for levamisole approach 99% for ascarids (*Ascaris suum*), threadworms (*Strongyloides ransomi*), and lungworms (*Metastrongylus* spp.). The nodular worm (*Oesophagostomum dentatum*) is also effectively expelled, but efficacies in separate studies range from 72 to 99%; kidney worms (*Stephanurus dentatus*) are removed from the urinary tract, but larval stages in other parts of the body are not affected. Levamisole is approved in the USA only for the above parasites of swine. Activity of levamisole for swine whipworms is variable, but higher efficacy can be obtained with the injectable formulation (95%) than with oral medication in feed (40%).

Larval stages of certain swine parasites are readily eliminated by levamisole. More than 90% of the third, fourth, and immature adult stages of *Metastrongylus* spp. and the fourth stage and immature adults of *Oesophagostomum* spp. and *Ascaris* spp. are destroyed by the drug. Less than 65% of the third stage of the latter two parasites are eliminated.

POULTRY. Levamisole can be administered to chickens in half the daily consumption of drinking water at either 36 or 48 mg/kg. This dose clears more than 95% of adult forms of *Ascaridia galli, Heterakis gallinarum*, and *Capillaria obsignata* and apparently eliminates a high percentage of the immature adults and larval stages of these parasites as well. At this dosage, the drug is palatable and without toxic signs in birds. Oral administration of levamisole via drinking water is also an effective means of eliminating the fowl eyeworm (*Oxyspirura mansoni*). Application of several drops of a 10% solution directly to the eye is nonirritating to the bird, yet completely and rapidly effective in killing the parasites.

Tetramisole is effective against the gapeworm (*Syngamus trachea*). Practically all worms will be expelled from the mouths of turkeys about 16 hours after they have access to medicated water. The water should provide 3.6 mg tetramisole/kg/day and treatment should be continued for 3 days.

DOGS. Although levamisole is not approved for use in dogs, oral treatment with 10 mg tetramisole/kg/day for 2 days removed more than 95% of ascarids (*Toxocara, Toxascaris*) and hookworms (*Ancylostoma, Uncinaria*). Levamisole is not effective against canine whipworms (*Trichuris vulpis*).



Pyrantel tartrate, R = H
Morantel tartrate, R = CH_3

Pyrantel pamoate

FIG. 47.2

for commercial use as the tartrate (Banminth, Strongid, Strongid C) or pamoate salt (*Pyrantel Pamoate*, USP, Strongid Paste, Pyraminth, Nemex-2, Anthelban). The structural formulas of the tartrate and pamoate salts of pyrantel and the methyl-substituted analog morantel are given in Fig. 47.2.

Pyrantel salts are relatively stable in the solid phase; aqueous solutions, however, are subject to photoisomerization upon exposure to light, with resultant loss of potency. It is recommended that drench suspensions be used immediately after preparation.

PHARMACOKINETICS. Following oral administration, pyrantel tartrate is well absorbed in the pig, dog, and rat. There is less absorption of the drug by ruminants. Concentrations of radioactivity from labeled drug are maximal in plasma of the dog and pig at 2–3 hours after dosing but are highly variable in ruminants. The dog achieves the highest plasma levels (4.3 μg/mL). The drug is quickly metabolized in the body, little surviving intact by the time it is excreted.

Urinary excretion of pyrantel accounts for about 40% of the dose in the dog and 34% in the pig, most of which is excreted as metabolites. The dog is the only species excreting more of the drug or its metabolites in urine than in feces. In ruminants, urinary excretion accounts for about 25% of the original dose, much of the remainder passing unchanged in feces. In rats, urinary excretion of the drug is minor; bile is the major route of excretion of metabolites of the absorbed drug.

The pamoate salt of pyrantel is poorly soluble in water, which offers the advantage of reduced absorption from the gut. This allows the drug to reach the lower end of the intestine and to exert activity against parasites in that locale, such as pinworms. Formulations of pyrantel pamoate are beneficial for use against pinworm infections of humans and horses.

Pharmacologic effects of pyrantel tartrate on the host are similar to effects of levamisole, diethylcarbamazine citrate, and morantel tartrate. All of these anthelmintics share biologic properties with ACh and act essentially by mimicking the effects of excessive amounts of this natural neurotransmitter. In physiologic amounts, ACh serves as a neurotransmitter by stimulating all autonomic ganglia, the adrenal medullas, the chemoreceptors of the carotid and aortic bodies, and the neuromuscular junction. With excess amounts of ACh, however, these sites are paralyzed. Pyrantel, morantel, levamisole, and diethylcarbamazine mimic this paralytic action. It is similar to the paralytic effect caused by nicotine; thus the action of these anthelmintics is referred to as nicotine-like. In anesthetized dogs, use of these anthelmintics results in a precipitous pressor response and enhancement of rate and depth of respiration. These effects are antagonized by hexamethonium, and the pressor responses are nullified by the adrenergic blocking agent phentolamine.

MODE OF ACTION. Pyrantel tartrate is a depolarizing neuromuscular blocking agent in nematode parasites and the vertebrate host. The drug probably produces paralysis of worms by causing contracture of the musculature similar to the action of ACh. Pyrantel and morantel are 100 times more potent than ACh, although slower in initiating contraction. The effect of ACh is easily reversible; that of pyrantel or morantel is not.

FORMULATIONS AND ADMINISTRATION. Both the tartrate and pamoate salts of pyrantel are used for treating horses. Pyrantel tartrate is generally administered as a top-dressed pellet. The amount of pellet formulation necessary to yield a single dose of 12.5 mg/kg is mixed in an amount of feed normally consumed at one feeding. Pyrantel tartrate as Strongid C is formulated for continuous, daily administration over prolonged periods of parasite exposure. The medicated alfalfa/molasses pellets are fed once a day with the grain ration to effect a daily dosage of 2.64 mg/kg body weight.

Pyrantel pamoate can be administered in suspension or paste formulations, as well as by mixing with feed. Regardless of the method of administration, a dose of 6.6 mg pyrantel base/kg should be used. The compound contains 34.6% base activity.

A powdered premix formulation containing 10.6% pyrantel tartrate is available for treating parasitic infections of swine via medicated feed. A dosage of 22 mg/kg is used for a single therapeutic treatment. It is recommended that a sufficient quantity (i.e., 0.88 g/40

been determined, however, that the therapeutic dose of 25 mg/kg is more than 99% effective against 7-day-old, 81% effective against 14-day-old, and 94% effective against 21-day-old stages of *T. colubriformis* in sheep. It is less effective against these same stages in cattle. The drug is 100% effective for *N. battus*, whether the parasites are 7, 14, or 21 days of age.

For *Ostertagia* infections, pyrantel is highly effective against mature worms and any immature stages that dwell in the lumen. Nevertheless, pyrantel has low activity (42%) against 7-day-old histotrophic stages of *Ostertagia* spp. in sheep and is even less effective against the same stage in cattle.

In addition to its therapeutic use, pyrantel can be used prophylactically in sheep at a dosage of 3 mg/kg/day. Approximately 97% fewer GI worms occurred in medicated sheep than in untreated controls examined after a 50-day period.

DOGS AND CATS. Pyrantel pamoate is effective (95%) against the common hookworms (*Ancylostoma caninum, Uncinaria stenocephala*) and ascarids (*Toxocara canis, Toxascaris leonina*) of dogs at single doses of 5 mg base/kg. Efficacy is inconsistent in pups, so a higher dose (15 mg/kg) is recommended 30 minutes after a light meal. Pups can be treated while suckling (e.g., 2, 4, 6, and 8 weeks of age) to control parasites acquired prenatally or lactogenically.

Pyrantel pamoate has limited efficacy against canine whipworms and no activity against tapeworms or heartworms. By combining pyrantel pamoate with praziquantel and febantel (Drontal Plus), tapeworms as well as whipworms can be eliminated from dogs, in addition to hookworms and ascarids. Drontal Plus is approved for use in dogs as young as 3 weeks of age. Treatment can be repeated at 2-week intervals during exposure to infective stages of parasites from the bitch or environment.

In cats, pyrantel pamoate at 20 mg/kg is effective against the common hookworm (*Ancylostoma tubaeforme*) and ascarid (*T. cati*) and is clinically safe in 4- to 6-week-old kittens at 100 mg/kg for 3 consecutive days. Pyrantel pamoate (20 mg/kg) is combined with praziquantel (5 mg/kg) in tablet form (Drontal) to control hookworm, ascarid, and tapeworm infections in cats.

SAFETY AND TOXICITY. In general, the salts of pyrantel are free of toxic effects in all hosts at doses up to approximately 7 times the therapeutic dose. The oral LD_{50} of pyrantel tartrate is 175 mg/kg in mice and 170 mg/kg in rats. In dogs, the acute oral LD_{50} for pyrantel pamoate is greater than 690 mg/kg (138 times the therapeutic dose). In chronic toxicity studies, dogs showed ill effects when administered pyrantel tartrate at 50 or more mg/kg/day for 3 months but no adverse effects when the dosage was reduced to 20 mg/kg/day for the same period.

Pyrantel is safe for horses and ponies of all ages, including sucklings, weanlings, pregnant mares, and stallions. At 20 times the recommended dose in horses, ponies, and foals, pyrantel pamoate shows no adverse clinical effects or changes in blood cell values or serum chemistry parameters.

Pyrantel tartrate is slightly less tolerated in horses than the pamoate salt. The tartrate salt (100 mg/kg) produced death in one of three horses. Toxic signs preceding death included a marked increase in respiration rate, profuse sweating, and incoordination. No signs of toxicosis occurred following administration of 75 mg/kg. Ataxia is seen in some cattle treated with a high dose of pyrantel tartrate (200 mg/kg). The toxic dose of the drug in pigs is not known.

CONTRAINDICATIONS. Pyrantel is not recommended for use in severely debilitated animals, presumably because its pharmacologic action (cholinergic) may be more pronounced in these hosts.

Withdrawal periods exist for swine and ruminants designated for slaughter. Because of lack of metabolism data in horses, the drug should not be used in horses intended for human consumption.

Despite its cholinergic properties, there is no clinical evidence that simultaneous use of organophosphates increases toxicity. Thus labeling for pyrantel products indicates safety for simultaneous use with insecticides, tranquilizers, muscle relaxants, and central nervous system (CNS) depressants.

DOSAGE. Dosages for Pyrantel tartrate are as follows:
Horses: single therapeutic dose, 12.5 mg/kg; continuous dosing, 2.64 mg/kg/day
Swine: 22 mg/kg; maximum of 2 g/animal
Sheep, cattle, goats: 25 mg/kg
Dosages for Pyrantel pamoate are as follows:
Horses: 6.6 mg base/kg
Dogs: suspension and chewable form, 5 mg base/kg; tablets, 5 mg/kg for dogs over 2.2 kg but 10–15 mg/kg for dogs less than 2.2 kg (with a light meal)

Morantel. *Morantel,* INN (Banminth II), is the methyl ester analog of pyrantel; it is primarily formulated as the tartrate salt for veterinary anthelmintic use. The structural formula of morantel tartrate is presented in Fig. 47.2.

The salts of morantel have greater anthelmintic activity than the parent compound, pyrantel; but their pharmacologic properties are similar. Efficacy of the tartrate salt is quite good against adult and immature stages of *Haemonchus, Ostertagia, Trichostrongylus, Cooperia,* and *Nematodirus* organisms of ruminants. In the USA, morantel tartrate is marketed as a type A medicated premix (Morantel Premix-88) containing 88 g morantel/lb. Sufficient premix is added to a ration to provide from 0.44 to 4.4 g per pound of complete feed, which is fed to deliver 0.44 g/100 lb body weight. Slaughter withdrawal periods are 14 and 30 days for cattle and goats, respectively.

A sustained-release bolus of morantel tartrate (Paratect Flex Diffuser) for both dairy and beef cattle is widely used in Europe and has been approved in the USA. The drug (11.8 g morantel base) is packaged in a cylindrical trilaminate cartridge, which is administered orally by a special delivery device and is retained in the rumen/reticulum. The permeable wall allows continuous release of morantel tartrate (approximately 150 mg/day) into the rumen/reticulum fluid for at least 90 days. Administration of the cartridge is recommended at the beginning of the grazing season so that as overwintered larvae are acquired from pasture, they will be prevented from establishing patent infections in cattle. Existing adult worm burdens in cattle are also eliminated. The ultimate effect is marked reduction in pasture contamination for a prolonged period, e.g., 90 days of drug release and benefits that extend for another 90 days. Numerous field studies in Europe, the UK, Canada, and the USA have demonstrated significantly greater weight gains and less parasite-induced production loss in cattle during their first and second grazing seasons than in nontreated controls. Inhibited *Ostertagia* larvae are not killed by this method of treatment, but lowered pasture contamination helps prevent development of type II ostertagosis.

Pharmacologically, morantel tartrate is a safer drug than pyrantel tartrate. The oral LD_{50} of pyrantel for mice is only 170 mg/kg while that of morantel is 5 g/kg. Chronic toxicity studies indicate that doses up to 4 times the therapeutic dose for sheep for 60 days and 2.5 times that for cattle for 20 days produce no toxic signs. Following a single therapeutic dose (10 mg/kg) via medicated feed (Rumatel), the drug is barely detectable (<0.05 mg/mL) in plasma or milk of lactating cattle and goats. That which is absorbed from the abomasum and proximal small intestine is quickly metabolized, presumably in the liver, and excreted in the urine within 96 hours; the remainder of the dose is excreted in feces.

Negligible or absent levels of morantel tartrate in plasma and milk following single or sustained administration allow use of this drug in lactating dairy animals without a milk withdrawal restriction.

ORGANOPHOSPHATE COMPOUNDS. In general, organophosphate compounds had their origins as pesticides and only subsequently found use as anthelmintics. Six such compounds have been used as anthelmintics in domestic animals: dichlorvos, trichlorfon, haloxon, coumaphos, naphthalophos, and crufomate. The first two were used primarily in horses, and the latter four in ruminants.

Mode of Action. The main effect of organophosphate compounds on nematode parasites is inhibition of acetylcholinesterase (AChE), leading to interference with neuromuscular transmission and subsequent paralysis. Nematodes utilize ACh as a neurotransmitter, and the enzyme acetylcholinesterase (AChE) serves to terminate transmission by destroying ACh. In very dilute amounts, organophosphate drugs are able to bind the AChE of nematodes. In the absence of functional AChE, the neurotransmission initiated by ACh persists, and coordinated feeding activities cease. These assumptions are made because a direct correlation is known to exist between inhibition of AChE of certain parasites by organophosphate drugs and toxicity of the same drug for the parasite. Knowles and Casida (1966) tested a large number of organophosphates in *Ascaris*. Drugs that were poisonous to the parasite also inhibited parasite AChE. Conversely, drugs that did not inhibit AChE were not toxic.

Acetylcholinesterases of host and parasite and of different species of parasites vary in their affinity for, and susceptibility to, organophosphate drugs. For example, AChE of *Haemonchus contortus* forms an irreversible complex with the organophosphate haloxon, which results in toxicity to the worm and eventual expulsion from treated cattle. Conversely, AChE of ascarids is not as susceptible to haloxon as that of *Haemonchus*. Ascarid AChE is bound by haloxon, but it is a reversible complex, and the ascarid enzymatic activity recovers to near pretreatment levels within 32 hours after treatment with haloxon. Nevertheless, this is sufficient time for worms to be expelled effectively by peristalsis. Even shorter periods of incapacitation result when the drug is used against *Nematodirus* and *Oesophagostomum columbianum*, and the efficacy of haloxon for these parasites is generally poor.

The relative safety of various organophosphates is probably correlated to lack of binding susceptibility of host AChE for the drug. The complex formed between sheep erythrocyte AChE and haloxon, for example, is quickly reversible, which may account for the lack of toxicity of therapeutic doses in sheep. Conversely, haloxon is very toxic to geese; indeed, the brain AChE of geese is found to be irreversibly complexed by the drug. These findings illustrate that the AChE enzymes differ among vertebrate hosts and certainly between hosts and their nematode parasites. An attempt has been made to exploit this information in the development of organophosphate anthelmintics in order to produce compounds with maximum anthelmintic efficacy but minimal host toxicity.

General Efficacy. Organophosphate compounds generally remove the principal parasites of horses, pigs, and dogs but are somewhat deficient in their activity against parasites of ruminants. In cattle and sheep, the organophosphates generally have satisfactory efficacy for nematode parasites of the abomasum (especially *Haemonchus*) and small intestine but lack satisfactory efficacy for parasites of the large intestine (*Oesophagostomum, Chabertia*). Where the latter infections are prevalent, it is recommended that cattle or sheep be treated with a nonorganophosphate, broad-spectrum anthelmintic after two consecutive treatments with organophosphate compounds (e.g., haloxon or naphthalophos). It is also advisable to alternate organophosphate anthelmintics with dewormers of other classes to prevent development of organophosphate resistance by target parasites.

Safety and Toxicity. Certain precautions should be followed when using organophosphate anthelmintics. Animals should not be treated simultaneously (or

argues that if dose titration studies had been designed appropriately, side-resistance between ivermectin and moxidectin would have been apparent.

Avermectins

IVERMECTIN. The avermectins are a group of chemically related macrocyclic lactones produced by fermentation of the actinomycete *Streptomyces avermitilis*. Avermectin is a complex of eight such fermentation products, each having nematocidal activity but lacking significant antibacterial or antifungal properties. Ivermectin (Cardomec, Double Impact, Equimectrin, Eqvalan, Heartgard-30, Ivomec, Mectizan, Oramec, Rotectin 1, Topline, Ultramectrin, Zimecterin) is a semisynthetic derivative of avermectin that has a broad spectrum of activity against a wide variety of arthropods and nematodes of domestic animals and humans.

CHEMISTRY. Avermectin is a mixture of four major components (avermectin A_{1a}, A_{2a}, B_{1a}, and B_{2a}) and four minor components recovered in smaller quantities (avermectin A_{1b}, A_{2b}, B_{1b}, and B_{2b}). Of these, the B_{1a} component is recovered in greatest quantity along with its B_{1b} minor homolog. Ivermectin, derived from this mixture of B_1 avermectins by saturation of the double bond between C-22 and C-23, consists of not less than 80% 22,23-dihydroavermectin B_{1a} and not more than 20% 22,23-dihydroavermectin B_{1b} (Fig. 47.3). Ivermectin (as its major component, 22,23-dihydroavermectin B_{1a}) is an off-white powder that is highly lipophilic and hydrophobic. It dissolves in most organic solvents but is poorly soluble in water. It is stable at room temperature in nonacidic solutions but is degraded by ultraviolet light.

PHARMACOKINETICS. Pharmacokinetic studies with ivermectin were summarized by Fink and Porras (1989). The pharmacokinetics of ivermectin is affected by the specific formulation used, the route of administration, and the animal species to which it is administered. The biological half-life ($t_{1/2}$) of ivermectin in plasma following IV administration of 300 µg/kg to cattle is 2.8 days. IV administration to sheep gives a similar biological half-life (2.7 days) but a lower plasma concentration due to a greater volume of distribution in sheep than in cattle (1.9 vs. 4.6 L/kg). Ivermectin is eliminated more rapidly in dogs ($t_{1/2}$ = 1.6–1.8 days).

SC administration of the commercial formulation of ivermectin to cattle at a dosage of 200 µg/kg results in a longer biological half-life ($t_{1/2}$ = 8 days) than IV administration, due to slow absorption from the injection site. A peak plasma concentration (C_p) of 44 ng/mL occurs at 2 days (T_p) after SC injection. Clinically significant anthelmintic efficacy persists for approximately 2 weeks after SC injection, depending upon parasite species. Oral dosing in sheep results in a $t_{1/2}$ of 3–5 days and T_p within 1 day. Oral dosing of dogs (100 µg/kg as a tablet) resulted in a C_p of 40 ng/mL within 2–4 hours. In a comparative bioavailability study, oral dosing of dogs with ivermectin (6 µg/kg) as a chewable tablet, either alone or in combination with pyrantel pamoate, resulted in an essentially identical C_p of about 2.4 ng/mL. Area under the plasma concentration versus time curve (AUC) was about 71 ng-hr/g, although the T_p was significantly longer for the ivermectin–pyrantel pamoate combination than for ivermectin alone (7.6 vs. 5.2 hr) (Clark et al. 1992). Studies in swine show that plasma concentrations peaked faster after oral (oral T_p = 0.5 days) than after SC (SC T_p = 2 days) administration. However, SC injection results in greater bioavailability than oral administration; the AUC for oral administration was only 41% of that for SC administration. Similarly, a pronounced difference in bioavailability was seen in horses between oral administration of a paste and an aqueous micelle formulation. The micelle attained a more rapid peak

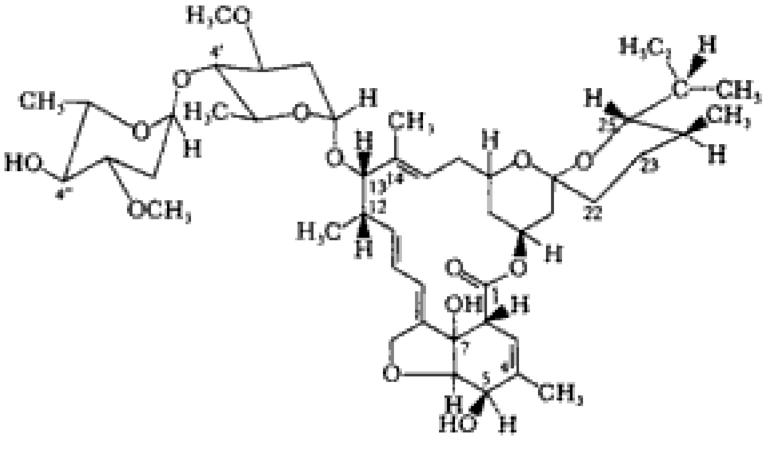


FIG. 47.3—Structure of 22,23-dihydroavermectin B_{1a}, the major component of ivermectin. Ivermectin also contains not more than 20% 22,23-dihydroavermectin B_{1b}, which is identical except that the substituent in the 25 position is *iso* propyl instead of *sec* butyl. Abamectin consists of two components identical to those of ivermectin except the bond between C-22 and C-23 in each abamectin component is not saturated.

concentration (micelle T_p = 4–5 hr; paste T_p = 15 hr) and greater bioavailability than the paste (AUC 20% greater for the micelle).

Following administration, ivermectin residues are lowest in brain and highest in liver, bile, and fat (Chiu and Lu 1989). Depletion half-lives were 4.8 and 7.6 days for liver and fat, respectively, in cattle. Tissue redistribution patterns are similar for sheep, swine, and rats, but depletion half-lives for liver and fat are shorter in sheep and rats than in cattle or swine. Tissue redistribution is not affected by route of administration (SC, intrarumenal, or oral) in cattle. The parent drug is the major liver residue for 3, 5, 7, and 14 days after dosing in rats, sheep, swine, and cattle, respectively. This pattern is identical for fat except that the parent drug is the major metabolite for only 3 days in sheep. In cattle, sheep, and rats, the major liver metabolites are 24-hydroxy-methyl-22,23-dihydroavermectin-B_{1a} and its monosaccharide and B_{1b} equivalents. The major metabolites in swine, 3″-*O*-desmethyl derivatives of 22,23-dihydroavermectin-B_{1a} and -B_{1b}, are identical in liver and fat. Fecal excretion is the main route of elimination, accounting for more than 98% of excreted ivermectin, with the remainder appearing in the urine. In lactating females, up to 5% of the dose may be excreted in milk.

MODE OF ACTION. See the previous general discussion on mode of action of macrocyclic lactones.

FORMULATIONS. Various regulatory agencies have approved ivermectin for use in humans, horses, cattle, sheep, pigs, dogs, cats, reindeer, bison, and camels. Additionally, extensive extra-label use is made of ivermectin in various minor domestic species as well as in captive and free-ranging wildlife.

Ivomec Injection (Double Impact; Ultramectrin) is a sterile solution containing 1% ivermectin (*w/v*) in an organic vehicle containing 60% propylene glycol and 40% glycerol formal for administration by SC injection to cattle, sheep, and swine. A 0.27% (*w/v*) injectable formulation is used in young pigs. Ivomec (or Oramec) oral solution for sheep contains 0.08% ivermectin (*w/v*) in an aqueous micelle used as a drench. An intraruminal bolus (Ivomec SR Bolus for Cattle) contains 1.72 g ivermectin in a wax vehicle that is extruded by an osmotic pump mechanism at a rate of 12 mg/day of ivermectin for 135 days. Eqvalan (Phoenectin) liquid contains 1% ivermectin (*w/v*) in an aqueous micelle for administration to horses either as an oral drench or by nasogastric tube. Eqvalan paste (Zimecterin; Equimectrin; Rotectin 1) contains 1.87% ivermectin (*w/v*) in a vehicle of 79% propylene glycol plus inert binders for oral use in horses. Ivomec Pour-On for Cattle (Topline; Ultramectrin) contains 0.5% ivermectin (*w/v*) in an 80% isopropyl alcohol vehicle for topical administration. Ivermectin Type A Medicated Feed Article contains 0.6% ivermectin (*w/w*) and is mixed to a final maximum ivermectin concentration of 1.8 g/ton in a type C medicated feed for swine. Heartgard-30 tablets and Heartgard-30 Chewables (chewable cubes) for dogs contain either 68, 136, or 272 µg of ivermectin. Heartgard for Cats chewables contain either 55 or 165 µg of ivermectin. Heartgard-30 Plus Chewables (chewable cubes) for dogs contain either 68, 136, or 272 µg of ivermectin and 57, 114, or 227 mg of pyrantel pamoate, respectively.

ANTHELMINTIC SPECTRUM. Extremely small quantities (less than 1 mg/kg) of ivermectin are sufficient for anthelmintic activity by either the oral or the parenteral route of administration. Confirmation tests with ivermectin have indicated a wide range of efficacy against nematodes and many arthropods (Campbell and Benz 1984). The following parasites are eliminated by ivermectin: all major GI and lung nematodes and certain ectoparasites of cattle, sheep, horses, and swine; intestinal nematodes, ear mites, and sarcoptic mange of dogs; infective-stage heartworm and microfilariae of dogs; and certain GI nematodes and ectoparasites of chickens.

Cattle and Sheep. Ivermectin is administered at dosages of 0.2 mg/kg to sheep (orally) and cattle (orally or subcutaneously) or 0.5 mg/kg to cattle (topically). These regimens provide efficacies of 97–100% against adult and fourth-stage larvae of respective species of *Haemonchus, Ostertagia* (including inhibited EL_4 in cattle), *Cooperia, Trichostrongylus* (including *T. axei*), *Strongyloides, Bunostomum, Nematodirus, Trichuris, Oesophagostomum, Dictyocaulus,* and *Chabertia ovina.* Arthropod parasites controlled by this dosage of ivermectin include oestrid larvae (*Hypoderma bovis, H. lineatum, Oestrus ovis*), mites (*Sarcoptes bovis, Psoroptes ovis*), and sucking lice (*Linognathus vituli, Hematopinus eurysternus,* and *L. pedalis*). It is slightly less effective in controlling chewing lice (*Damalinia* spp.) and the sheep ked (*Melophagus ovinus*). Similar high efficacies for nematodes and arthropods have been found when cattle are treated with an intraruminal sustained-release bolus designed to release 12 mg ivermectin daily for 135 days.

Ivermectin has substantial activity against ticks and dung-breeding flies. It does not result in prompt death or detachment of ticks but does interrupt feeding, molting, and egg production, thereby reducing the ticks' reproductive potential. This is especially true of ticks when they are experimentally applied to animals within a 5-day period before a single 0.2 mg/kg SC treatment or during daily low-level (0.01 mg/kg) treatment. Some degree of control of dung-breeding flies is also provided by a single SC treatment at 0.2 mg/kg. For 9 days after treatment of cattle, feces of treated animals failed to support larval development of face flies, *Musca autumnalis*. For a further 5 days, the propagation of the fly is greatly reduced through abnormal pupation and diminished maturation of adults. Development of the horn fly (*Haematobia irritans*) is similarly diminished for 4 weeks after treatment at this dosage.

not been recorded, however, when Collies were given the heartworm preventive dosage (0.006–0.012 mg/kg) or even 10 times the preventive dose monthly for 1 year. For dogs, the efficacy and safety of formulations designed for other species should not be assumed.

Ivermectin is safe for use in breeding and pregnant animals (Campbell and Benz 1984). In general, twofold increase in dosage and multiple dosing have not adversely affected spermatogenesis, conception, longevity of gestation, or fetal development.

Transient pruritus and cutaneous edema may occur in horses following IM or oral treatment. These signs can be attributed to death of microfilariae of *Onchocerca cervicalis* and usually resolve within 3–4 days.

DOSAGE AND ADMINISTRATION. Single-treatment dosages are given below:

Cattle: Pour-on, 0.5 mg/kg; SC or oral, 0.2 mg/kg
Sheep: Oral, 0.2 mg/kg
Horses: Oral, 0.2 mg/kg
Swine: SC, 0.3 mg/kg
Dogs: Oral, 0.006–0.012 mg/kg
Cats: Oral, 0.024–0.048 mg/kg

ABAMECTIN. Abamectin (Avomec) is a naturally occurring fermentation product of *Streptomyces avermitilis*. Abamectin is used in cattle to control adult and larval GI nematodes, lungworms, sucking lice, and ticks, and in horses to control large and small strongyles, ascarids, pinworms, and other nematode internal parasites. Abamectin is also sold as a pesticide under other brand names (Affirm, Agri-Mek, Avid, Vertimec). Abamectin has a broad range of activity against insect and mite pests of horticultural and agronomic crops as well as the imported fire ant.

CHEMISTRY. Abamectin consists of a mixture of not less than 80% avermectin B_{1a} and not more than 20% avermectin B_{1b}. It differs from ivermectin (Fig. 47.3) in that the double bond between C-22 and C-23 is not saturated in abamectin. Abamectin (as its major component, avermectin B_{1a}) is an off-white powder that is highly lipophilic. It dissolves in most organic solvents but is poorly soluble in water. It is stable at room temperature in nonacidic solutions but is degraded by ultraviolet light.

MODE OF ACTION. See the previous general discussion on mode of action of macrocyclic lactones.

FORMULATIONS. Avomec injectable is a sterile solution of 1.0% *w/v* abamectin. It is administered SC to cattle, immediately in front of or behind the shoulder, at a dosage of 200 μg abamectin/kg body weight (1 mL/50 kg).

ANTHELMINTIC SPECTRUM. Abamectin is an endectocide with activity against both nematode and arthropod parasites of cattle (reviewed by Benz and Cox 1989). At the recommended dosage of 200 μg/kg SC in cattle, abamectin is greater than 99% effective against adults and developing fourth-stage larvae of *Ostertagia ostertagi, Haemonchus placei, Cooperia* spp., and *Dictyocaulus viviparus*. Abamectin is similarly effective against hypobiotic larvae of *O. ostertagi* and against adult *Trichostrongylus axei*. Abamectin prevents reinfection with *Ostertagia* spp., *H. placei, Cooperia* spp., and *O. radiatum* for at least 7 days after treatment, and with *D. viviparus* for at least 14 days after treatment. Cattle treated with abamectin remain free of sucking lice (*Linognathus vituli*) for at least 56 days after administration. Abamectin reduces the number of engorged female *Boophilus microplus* ticks from cattle for at least 21 days following treatment, and egg production is reduced in any surviving female ticks.

Abamectin is also effective against larvae of some dung-breeding Diptera. Feces collected from cattle for up to 21 days after SC injection with 200 μg/kg of abamectin would not suport development of the buffalo fly (*Haematobia irritans exigua*).

SAFETY AND TOXICITY. Clinical signs of toxicity include tremors and/or coma in most species, mydriasis in dogs, and emesis in monkeys. Abamectin is slightly more toxic than ivermectin, with an oral LD_{50} in mice of 14–24 mg/kg (vs. 25–40 mg/kg for ivermectin) and a minimum-effect level in dogs of 0.5 mg/kg/day (vs. 1.0 mg/kg/day for ivermectin). Cleft palates are seen at or near maternotoxic doses in developmental toxicology studies with both drugs. The no-effect level for abamectin fed to dogs in 1-year oral toxicity studies was 0.25 mg/kg/day. Two-year carcinogenicity studies at the maximum tolerated dosage in rats and mice demonstrated a lack of carcinogenicity, as did the lack of genotoxic activity in microbial and mammalian genetic toxicity assays.

Cattle tolerate a maximum dose of 1.0 mg/kg abamectin by SC injection. Lethargy and ataxia are early signs of toxicity. At higher doses (2 to >8 mg/kg), cattle show signs of ataxia that progress to paresis, recumbency, decreased lip and tongue tone, drooling, mydriasis, coma, and death. Reproductive safety studies in cows and bulls with 300 μg/kg abamectin showed no negative effects. Adverse reactions, some of which were related to overdosing, have been reported in calves aged 1 week to 4 months; thus the label warns against treating calves under 4 months of age. In Australia, idiosyncratic toxic reactions were reported in one herd of Murray Grey cattle, which may be analogous to idiosyncratic toxicity with ivermectin in Collies.

The avermectins are largely excreted in the feces, and these excreted products have been shown to suppress larvae of some dung-breeding Diptera. Thus, there has been concern about their potential for damage to pasture populations of beneficial dung-destroying insects. Fecal residues resulting from a single SC injection of 200 μg/kg of abamectin apparently have little effect on adult dung beetles (*Onthophagus gazella*). However, dung beetle larvae failed to develop in feces collected for up to 21 days after treatment, although development was unaffected in feces collected 28 days after treatment (reviewed by Roncalli 1989). Similar experiments with a second species of dung beetle (*O. binodis*) again showed no effect on adults although the development and survival of immature beetles were affected in feces collected up to 4 weeks following treatment. Adverse effects on dung beetle populations could result if abamectin were used intensively and simultaneously over a wide geographical area. However, the use of abamectin at infrequent intervals in individual herds should not significantly affect dung beetle populations, because only part of one generation of beetles will be affected and considerable recruitment of beetles will take place from neighboring pastures grazed by untreated herds.

In the environment, abamectin is quickly degraded (half-life of 4–21 hr) by oxidative and photo-oxidative mechanisms when exposed to light in water, on soil particles, or as a thin film on biological surfaces such as leaves. Abamectin is essentially an immobile pesticide that strongly binds to soil particles. When protected from light within the soil, its major component, avermectin B_{1a}, is degraded by aerobic microbial metabolism and has a half-life of 20–47 days, depending on soil type. Abamectin does not bioconcentrate in individual organisms nor does it bioaccumulate in the local food chain, whether terrestrial or aquatic.

DORAMECTIN. Doramectin (Dectomax) is a novel avermectin prepared by mutational biosynthesis. It has a broad range of activity against GI nematodes, lungworms, eyeworms, sucking lice, grubs, ticks, mites, and screwworms in cattle. Doramectin's efficacy against the agents of myiasis is unique among the macrocyclic lactones. In swine, doramectin has excellent efficacy against ascarids, nodular worms, lungworms, sucking lice, and sarcoptic mange mites. Much of the following information is summarized from a review of doramectin edited by Vercruysse (1993).

CHEMISTRY. The structure of doramectin is given in Fig. 47.4. It differs from ivermectin and abamectin in having a cyclohexyl substituent in the C-25 position.

PHARMACOKINETICS. When administered intravenously as an aqueous micelle, plasma concentrations of doramectin were approximately 2-fold higher than those of a similar formulation of dihydroavermectin B_{1a}, the principal component of ivermectin. Also, the plasma half-life with this formulation of doramectin was approximately twice that of the dihydroavermectin B_{1a}. A vehicle formulation consisting of 90:10 (*v/v*) sesame oil/ethyl oleate was subsequently found to improve efficacy by reducing the rate of absorption of doramectin following SC administration. This resulted in prolonged plasma concentrations and a higher AUC for doramectin during the first 12 days after injection. SC injection of doramectin in the sesame oil–ethyl oleate vehicle results in clinically significant plasma levels of doramectin for at least 12 days following injection. Efficacy against reinfection persists for at least 12 days for *Cooperia oncophora*, 21 days for *Ostertagia ostertagi*, and for up to 35 days for highly sensitive parasites such as *Dermatobia hominis*.

The identical doramectin injectable formulation is also labeled for IM use in swine.

MODE OF ACTION. See the previous general discussion on mode of action of macrocyclic lactones.

FORMULATIONS. Dectomax is a sterile 1% solution of doramectin in a sesame oil–ethyl oleate (90:10 *v/v*) vehicle. It is administered to cattle at a dosage of 200 μg/kg by SC injection and to swine at a dosage

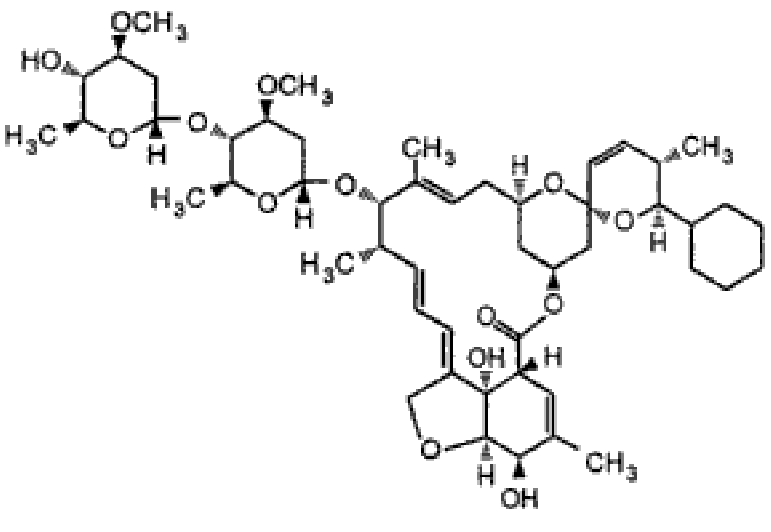

FIG. 47.4—Doramectin.

of 300 µg/kg by IM injection. Dectomax Pour-on is a topical 5% solution in a nonaqueous base and is administered at a dose of 0.5 mg/kg.

ANTHELMINTIC SPECTRUM. In controlled studies in Europe, North America, and South America, doramectin was shown to be greater than 99% effective against mature and immature stages of *Ostertagia ostertagi* (including hypobiotic larvae), *O. lyrata*, *Haemonchus placei* (including hypobiotic larvae), *H. contortus*, *H. similis*, *Trichostrongylus axei* (including hypobiotic larvae), *T. colubriformis*, *Cooperia oncophora* (including hypobiotic larvae), *C. punctata*, *C. pectinata*, *C. spatulata*, *C. surnabada*, *Bunostomum phlebotomum*, *Strongyloides papillosus*, and *Oesophagostomum radiatum* (including hypobiotic larvae). Efficacy was inconsistent against *Trichostrongylus longispicularis;* greater than 93% in one study, but greater than 99% in a second. Doramectin was less effective against *Trichuris* spp. (92.3–94.6%) and *Nematodirus spathiger* (96.5%). *Nematodirus helvetianus* was the dose-limiting species, with efficacy against adult and fourth-stage larvae reported as 73.3% and 75.5%, respectively, in one study but 97.9% in a second trial. Doramectin treatment reduced experimentally administered and naturally acquired burdens of eyeworms (*Thelazia skrjabini* and *T. gulosa*) in calves by 100%.

Like ivermectin and moxidectin, doramectin persists in activity for several weeks following injection. Worm burdens in cattle experimentally challenged with larvae of *Cooperia oncophora* each day for 14 or 21 days following doramectin treatment were reduced by 99.2% and 90.7%, respectively. Reductions for *Ostertagia ostertagi* were 99.9 and 93.7% after daily challenge for 21 and 28 days, respectively, following treatment. Similarly, reductions for *Dictyocaulus viviparus* were 100% and 99.9% after 21 and 28 days, respectively. In natural-grazing experiments, doramectin delayed the appearance of worm eggs in feces of worm-free cattle turned out to graze pastures contaminated with larvae of *O. ostertagi* and *C. oncophora* by 19–22 days compared to untreated control calves.

Doramectin is also efficacious against a variety of arthropod parasites of cattle. Efficacy was 100% against naturally acquired *Psoroptes bovis*, *Sarcoptes scabiei*, *Hematopinus eurysternus*, *Linognathus vituli*, *Solenopotes capillatus*, *Hypoderma bovis* (first, second, and third instars), and *Dermatobia hominis*. Furthermore, cattle were protected from new infection with *D. hominis* for at least 35 days following doramectin treatment. As with the other avermectins, the efficacy of doramectin was reduced (82%) against chewing lice (*Damalinia bovis*). Unlike the other avermectins, doramectin is highly effective against the New World screwworm, *Cochliomyia hominivorax*. Doramectin was 100% effective in preventing experimental infections of calves with this parasite for at least 14 days following treatment.

In swine, doramectin has greater than 99% efficacy against *Ascaris suum*, nodular worms (*Oesophagostomum dentatum*), lungworms (*Metastrongylus* spp.), kidney worms (*Stephanurus dentatus*), as well as *Hyostrongylus rubidus* and *Strongyloides ransomi*. Efficacies were 100% against sucking lice (*Hematopinus suis*) and mange mites (*Sarcoptes scabiei* var. *suis*).

EPRINOMECTIN. Eprinomectin (Ivomec Eprinex) is a modified fermentation product of *Streptomyces avermitilis*. It is used in beef and dairy cattle to control most GI nematodes and lungworms and also is highly effective against biting and sucking lice, chorioptic mange mites, cattle grubs, and horn flies.

CHEMISTRY. Eprinomectin is a modified avermectin with an epi-acetylamino substitution at the 4″ position (Fig. 47.5). As marketed, eprinomectin is a racemic mixture of compounds that comprises not less than 90% of the major component (4″-*epi*-acetylamino-4″-deoxy-avermectin B_{1a}) (R = C_2H_5) and not more than 10% of the minor component (4″-*epi*-acetylamino-4″-deoxy-avermectin B_{1b}) (R = CH_3).

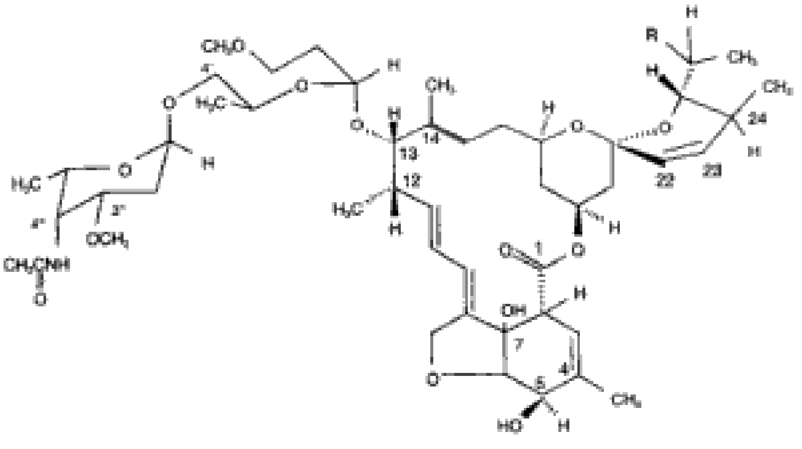

FIG. 47.5—Eprinomectin.

PHARMACOKINETICS AND METABOLISM. Eprinomectin is absorbed soon after topical administration, and achieves peak plasma concentrations of 22.5 ng/mL within 2–5 days after treatment. Plasma concentrations decline to 1 ng/mL within 21 days after administration. The majority of a topical dose is absorbed within 7–10 days.

Eprinomectin is not metabolized extensively, and parent compound makes up 90% of residues in tissues and more than 85% in feces. The major residue is eprinomectin B_{1a}, which is also the major component of the parent compound.

Eprinomectin has an extremely low milk-plasma coefficient, indicating greater partitioning of compound away from milk and into plasma. No meat or milk withdrawal periods are required after treatment with eprinomectin.

MODE OF ACTION. See the previous general discussion on mode of action of macrocyclic lactones.

FORMULATIONS. Eprinomectin has been marketed only as a 5% pour-on formulation (Ivomec Eprinex) for use on beef and dairy cattle. It is administered along the topline, from withers to tail head, as doses of 1 mL/10 kg body weight. The formulation is nonaqueous and very stable in various climatic conditions, including extremely heavy rainfall immediately after application.

ANTIPARASITIC SPECTRUM. Eprinomectin has greater than 99% efficacy against the common nematode genera in the bovine GI tract (including *Nematodirus helvetianus*, arrested early fourth-stage larvae of *Ostertagia ostertagi*, and *Dictyocaulus viviparus*) and greater than 97% efficacy against adult whipworms (*Trichuris* spp.). It exhibits persistent activity against reinfection with lungworms for 21 days after treatment. Eprinomectin has very high efficacy against chewing lice (*Bovicola bovis*), three genera of sucking lice (*Hematopinus, Solenopotes, Linognathus*), the mange mites *Chorioptes* and *Sarcoptes*, and both species of cattle grubs in North America (*Hypoderma bovis, H. lineatum*). Eprinomectin also controls horn flies (*Haematobia irritans*) and has residual activity against these pests for 7 days after administration.

SAFETY AND TOXICITY. The safety of eprinomectin was evaluated by treating 6 calves with a single administration of 10 times the recommended therapeutic dosage (i.e., 5000 μg/kg). The only adverse effect noted was mydriasis in 1 of the 6 calves from 4 to 7 days after the overdose.

Toxicity of eprinomectin was also evaluated by treating calves with up to 5 times the recommended dosage (i.e., 2500 μg/kg) on three occasions at 7-day intervals. No adverse effects were noted.

SELAMECTIN. Selamectin (Revolution) is derived by chemical modification of a precursor avermectin that is produced by fermentation of a new strain of *Streptomyces avermitilis*. Selamectin is used in dogs and cats to prevent heartworm, to kill fleas, and to treat and control a variety of ectoparasitic infections (Bruce et al., 1999). It is also effective against roundworm and hookworm infection in cats.

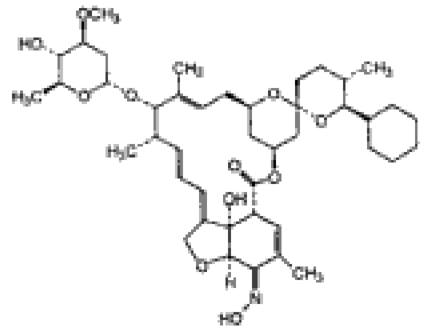

FIG. 47.6—Selamectin.

CHEMISTRY. Selamectin is a modified avermectin (Fig. 47.6) with the chemical name (5Z,25S)-25-cyclohexyl-4′-*O*-de(2,6-dideoxy-3-*O*-methyl-α*bino*-hexopyranosyl)-5-demethoxy-25-de(1-methylpropyl)-22,23-dihydro-5-hydroxyiminoavermectin A_{1a}.

PHARMACOKINETICS AND METABOLISM. Selamectin is absorbed fairly rapidly after administration and achieves peak plasma concentrations approximately 8 hours or 3 days after treatment by the oral or topical routes, respectively. The half-life of a single topical treatment of 24 mg/kg was approximately 11 days in dogs. Selamectin persists at clinically effective levels in dogs and cats for at least 30 days after a single topical treatment.

Following topical administration, selamectin is absorbed into the bloodstream and a portion of the compound is excreted into the intestinal tract. Substantial amounts of circulating selamectin are deposited in the sebaceous glands, which then act as reservoirs to provide persistent activity against various ectoparasitic infections.

MODE OF ACTION. See the general discussion on mode of action of macrocyclic lactones.

FORMULATIONS. Selamectin is marketed as a 6% or 12% topical formulation (Revolution) packaged for dogs and cats of various weight ranges. It is administered in a single spot at the base of the neck, cranial to the shoulder blades. The formulation is nonaqueous, and persistent efficacy is not compromised by bathing or wetting of the animal's haircoat.

ANTIPARASITIC SPECTRUM. Selamectin (6 mg/kg) had 100% efficacy against infective stages of heartworm (*Dirofilaria immitis*) for up to 60 days after exposure. A reduced dosage (3 mg/kg) was protective for up to 45 days. At label dosages (6 to 12 mg/kg) in cats, a single application of selamectin was 84.7% to 99.7% effective against *Ancylostoma tubaeforme* and 100% effective against *Toxocara cati*. Although selamectin demonstrated good efficacy against *Toxocara canis* infections in dogs, it is not currently labeled for that use.

SAFETY AND TOXICITY. The safety of selamectin was evaluated by treating kittens with up to 367.4 mg/kg and puppies with up to 114 mg/kg at 28-day intervals for a total of seven treatments. No adverse reactions were observed. Similarly, selamectin was shown to be safe in breeding cats and dogs, as well as in pregnant and lactating bitches and queens. When administered to dogs with *D. immitis* microfilaremia, selamectin caused no adverse reactions and resulted in a rapid and persistent reduction in microfilaria counts. Selamectin use was also safe in ivermectin-sensitive Collies.

Milbemycins

MILBEMYCIN OXIME. Milbemycin oxime (Interceptor, Sentinel) is a fermentation product of *Streptomyces hygroscopicus aureolacrimosus* and has activity against certain arthropods and nematodes. A second milbemycin, milbemycin D, was marketed in Japan for prophylaxis of canine heartworm (*Dirofilaria immitis*), but it was subsequently replaced by milbemycin oxime because the latter compound has a greater margin of safety in ivermectin-sensitive Collies and in microfilaremic dogs.

CHEMISTRY. As formulated in Interceptor, milbemycin oxime consists of a mixture of not less than 80% A_4 milbemycin oxime and not more than 20% A_3 milbemycin oxime (Fig. 47.7). The drug has low solubility in water.

PHARMACOKINETICS AND METABOLISM. Following oral administration, approximately 90–95% of the dose passes through the gut unchanged. The remaining 5–10% is absorbed and subsequently excreted in the bile. Nearly the entire dose is eliminated in feces.

MODE OF ACTION. See the previous general discussion on mode of action of macrocyclic lactones.

FORMULATIONS. Milbemycin oxime is sold as a chewable tablet (Interceptor Palatab) for dogs. Tablets come in four sizes, containing 2.3, 5.75, 11.5, or 23.0 mg of milbemycin oxime. Milbemycin oxime is also marketed as Interceptor Flavor Tabs for Cats in tablet sizes containing 5.75, 11.5, or 23.0 mg of active compound. Milbemycin oxime is administered orally once a month. The recommended dosages are 0.5–0.99 mg/kg for dogs and 2.0 mg/kg for cats.

Recently, milbemycin oxime has been combined with lufenuron in a chewable tablet formulation (Sentinel) that provides simultaneous prevention and control of flea infestations in addition to protection against heartworms and other internal nematodes. Sentinel tablets are available in four sizes, containing the following amounts of milbemycin oxime/lufenuron (all quantities in mg): 2.3/46, 5.75/115, 11.5/230, and 23.0/460.

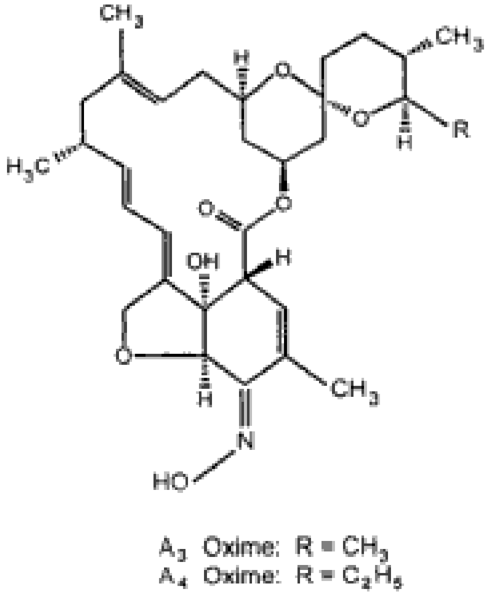

FIG. 47.7—Milbemycin oxime.

ANTHELMINTIC SPECTRUM. Milbemycin oxime is considered an endectocide, having activity against both internal parasites (nematodes) and external parasites (*Demodex canis*). It is effective against nematode parasites at a relatively low dosage (0.5 mg/kg or less). Developing larvae of the dog heartworm are susceptible to milbemycin oxime. It is marketed in Australia, Canada, Italy, Japan, New Zealand, and the USA for prevention of canine dirofilariasis and control of the intestinal nematodes *Toxocara canis*, *Trichuris vulpis*, and *Ancylostoma* spp. Despite its efficacy against hookworms of the genus *Ancylostoma*, milbemycin oxime does not reliably control hookworms of the genus *Uncinaria*. When administered to cats at 2.0 mg/kg at 30-day intervals, milbemycin prevents feline heartworm and removes *T. cati* and *A. tubaeforme* infections.

The efficacy of the milbemycin/lufenuron combination (Sentinel) against nematodes and fleas, respectively, is equivalent to that of the components used separately. Sentinel is administered to pups older than 4 weeks and heavier than 2 lb body weight at a dosage of 0.5–0.99 mg/kg milbemycin and 10–20 mg/kg lufenuron.

In dogs, a single oral dose of 0.5 mg/kg milbemycin oxime at 30 or 45 days after infection with third-stage larvae of *Dirofilaria immitis* completely prevents development of infection. A single treatment at 60 or 90 days after infection is not completely effective, but two or more monthly treatments beginning at 60 days after infection consistently prevent infection with *D. immitis* (Grieve et al. 1989). Cats treated monthly with

certain arthropod parasites of ruminants, and developing larvae of the dog heartworm are susceptible.

Ruminants. In cattle, moxidectin (as the injection or pour-on) is highly efficacious (>99%) against *Ostertagia ostertagi* adults and hypobiotic larvae, *O. lyrata* adults, *Haemonchus placei* adults, *Trichostrongylus axei* adults, *T. colubriformis* adults, *Trichuris discolor* adults, *Oesophagostomum radiatum* adults, *Bunostomum phlebotomum* adults and fourth-stage larvae, and *Dictyocaulus viviparus* adults. Moxidectin is slightly less efficacious against *Nematodirus helvetianus* adults (>95%) and *Cooperia* spp., with efficacies of 92–100% against adults and larvae of *Cooperia oncophora, C. punctata, C. pectinata,* and *C. mcmasteri* and against *C. spatulata* adults. Reinfection with nematodes of the genera *Ostertagia, Haemonchus, Trichostrongylus,* and *Oesophagostomum* is prevented for up to 28 days following a single injection or topical application of moxidectin, but such activity persists for no more than 7 days for *Nematodirus* and *Cooperia.* A single SC injection of moxidectin will completely eliminate mites of the genera *Sarcoptes* and *Psoroptes* and will markedly suppress, but not entirely eliminate, *Chorioptes* mites. A single topical application will eliminate mites of the genus *Psoroptes,* but data are not available for the other genera. *Boophilus microplus* tick populations are reduced by more than 95% following a single SC injection of moxidectin, and tick populations are suppressed for up to 32 days. Although both formulations control sucking lice (99–100% efficacious against *Haematopinus eurysternus, Linognathus vituli,* and *Solenopotes capillatus*) and cattle grubs (*Hypoderma lineatum*), the pour-on formulation provides much better control of the chewing louse (*Damalinia bovis*) than the injectable (Chick et al. 1993).

In sheep, orally administered moxidectin is highly efficacious (>99%) against adult and larval nematodes of the genera *Haemonchus, Ostertagia, Trichostrongylus, Cooperia, Oesophagostomum, Chabertia,* and *Dictyocaulus,* as well as adult *Nematodirus.* Additionally, good control is obtained for the sheep itch mite, *Psorergates ovis.*

In New Zealand, moxidectin pour-on is approved for use in ranch-raised deer, in which it is more than 99% effective against nematodes of the genera *Haemonchus, Ostertagia, Trichostrongylus, Oesophagostomum,* and *Dictyocaulus.*

Horses. Moxidectin is reported effective against the common internal parasites of the horse at a dose of 400 μg/kg, although its activity against bots may be erratic. At a dose of 300 μg/kg, an experimental gel formulation of moxidectin was more than 99% effective against adult and larval *Habronema muscae,* adult and larval *Parascaris equorum,* adult and larval *Oxyuris equi,* adult *Strongylus vulgaris* and *S. edentatus,* and adult *Triodontophorus* spp. Moxidectin removed more than 97% of adult and lumen-dwelling fourth-stage larval cyathostomes and was more than 79% effective against late third-stage and developing fourth-stage cyathostome larvae. In North American trials, moxidectin did not exhibit consistent efficacy against early third-stage cyathostome larvae. Efficacy against *Gasterophilus nasalis* is 100%, but efficacy against *G. intestinalis* is variable (57–100%) and apparently less than that of ivermectin (Xiao et al. 1993).

Dogs. Similar to milbemycin oxime, moxidectin is highly effective against *Ancylostoma caninum* but less effective against *Uncinaria stenocephala.* A single oral dose of 25 μg/kg will remove *Ancylostoma,* but a dose of at least 150 μg/kg is necessary for similar efficacy against *Uncinaria.* Whipworms are not controlled by doses up to 300 μg/kg (Supakorndej et al. 1993). Like ivermectin, moxidectin is an effective heartworm prophylactic at a remarkably low dose. Moxidectin is 100% effective against both 1- and 2-month-old larvae of *Dirofilaria immitis* at a dose of 3.0 μg/kg (McTier et al. 1992).

SAFETY AND TOXICITY. No adverse reactions occurred in sheep drenched at 2 or 5 times the recommended dose (0.4 or 1.0 mg/kg). Likewise, no adverse reactions occurred with repeated treatments at twice the normal dose. No deaths occurred when *Bos indicus* and *Bos taurus* cattle were injected SC with up to 10 times the recommended dose (2.0 mg/kg). However, extra care must be taken to use the correct dose in calves under 100 kg body weight because they may be susceptible to overdosing. No adverse reactions, either local or systemic, occurred when cattle were treated with up to 10 times the recommended dose (5.0 mg/kg) or when red deer fawns were treated with up to 5 times the recommended dose (2.5 mg/kg) of a pour-on formulation of moxidectin. The pour-on formulation likewise caused no damage to hides of cattle at the recommended dose (0.5 mg/kg). Known ivermectin-sensitive Collies and microfilaremic, *Dirofilaria immitis*–infected dogs tolerate at least 15 μg/kg moxidectin (5 times the recommended dose for heartworm prophylaxis) (Paul et al. 1992; Hendrix et al. 1992).

Moxidectin is safe in breeding animals. At 3 times the recommended dose (0.6 mg/kg), no adverse effects on reproductive performance of bulls and pregnant cows were observed. Up to 3 times the recommended dose (0.6 mg/kg) had no effect on reproductive performance of cows and heifers when injected during each trimester of pregnancy (Rae et al. 1994).

Residues excreted in feces of animals treated with moxidectin are less toxic to dung beetle larvae than those of animals treated with ivermectin and thus do not impact survival of dung beetles or their development to maturity.

HETEROCYCLIC COMPOUNDS

Phenothiazine. *Phenothiazine,* INN, was perhaps the first anthelmintic to demonstrate a fairly wide range of

little activity against immature pinworms. Retreatment within 3–4 weeks is recommended.

Piperazine compounds effectively remove cyathostomes. Piperazine also provides approximately 60% activity against *Strongylus vulgaris* and *Triodontophorus*, but there is no activity against the other *Strongylus* species or against stomach worms (*Habronema*).

Historically, piperazine was added to phenothiazine and thiabendazole to supplement their deficient activity against equine ascarids. In recent years, however, piperazine is most often combined with BZD drugs to increase activity against BZD-resistant cyathostomes that might survive treatment if a BZD were used alone.

SWINE. Piperazine compounds have been used extensively in swine because of their excellent efficacy against ascarids and nodular worms. Approximately 100% of the lumen-dwelling stages of both ascarids and nodular worms can be eliminated by a single treatment with piperazine. Retreatment 1–2 months later may be necessary to remove worms that were migrating through tissues during the initial treatment. Piperazine formulations can be administered to swine via drinking water or feed, either of which should be consumed in an 8- to 12-hour period.

RUMINANTS. Piperazine compounds are seldom used in cattle and sheep because their activity in these hosts is limited to nodular worms (*Oesophagostomum* spp.).

CHICKENS. *Ascaridia galli* is highly susceptible to piperazine, and citrate and adipate salts have been used most commonly to control this parasite in chickens. The cecal worm (*Heterakis gallinarum*) apparently is not susceptible to piperazine.

Piperazine compounds are usually administered to chickens in the feed (citrate or adipate salts) or drinking water (hexahydrate) over a 2-day period.

DOSAGE. Dosages are presented here by the amount of piperazine base. Product information should be consulted for specific information about various salts of piperazine.

Dogs and cats: 45–65 mg/kg
Horses: 110 mg/kg
Swine, cattle, sheep, goats: 110 mg/kg
Poultry: 32 mg/kg (approximately 0.3 g for each adult) given in each of 2 successive feedings or in drinking water for 2 days

Diethylcarbamazine Citrate. *Diethylcarbamazine Citrate*, USP, INN (Caricide, Dirocide, Filaribits, Filaricide), is a piperazine derivative. Diethylcarbamazine (DEC) is a colorless, odorless, crystalline solid that is highly soluble in water, alcohol, and chloroform but insoluble in most organic solvents. It is stable under varied conditions of climate and moisture.

FORMULATIONS AND ADMINISTRATION. DEC is formulated as tablets or chewables that are sold under several trade names as a preventive for heartworm disease in dogs. DEC should be administered daily throughout the mosquito vector season and continued for 2 months following. Young pups can begin a preventive program of daily DEC as soon as they are weaned and eating solid foods consistently.

In addition to heartworm prevention, a combination of DEC and oxibendazole (Filaribits Plus) also prevents the establishment of *Ancylostoma caninum* infections in dogs and removes or controls *Toxocara canis*, *Toxascaris leonina*, and *Trichuris vulpis*.

DEC apparently is active against *D. immitis* larvae only during 24- to 48-hour periods when they are molting. Thus, DEC kills developing larvae as they molt from the L_3 to the L_4 stage at approximately 2 weeks after infection and again at approximately 8 weeks after infection when the L_4 stage molts to the L_5. Because the latter event represents the last opportunity for DEC to prevent establishment, it is usually recommended that DEC prophylaxis be continued for 2 months after the local mosquito season ends.

DEC also has marked microfilaricidal properties, and dogs that are infected with heartworms must first be cleared of adult stages and microfilariae before DEC prophylaxis is instituted. The microfilaricidal activity often causes severe adverse reactions, especially in dogs with high numbers of circulating microfilariae at the time of treatment. These reactions develop rapidly and are frequently fatal. Consequently, use of DEC in microfilaria-positive dogs is strictly contraindicated.

DEC also can be used as a preventive for heartworms in sea lions and in ferrets. *Dirofilaria immitis* infections are common among captive sea lions, and DEC (7.7 mg/kg/day) in the food prevents infection and has no effect on host fertility. A dose of 2.75–5.5 mg DEC/kg/day is recommended as a preventive regimen for pet ferrets.

DOSAGE. Tablets or chewables used in prophylactic heartworm schedules are administered to dogs daily at 6.6 mg/kg.

PHARMACOKINETICS AND TOXICITY. DEC is absorbed rapidly from the gut. The peak concentration in blood occurs about 3 hours after oral administration and falls to zero within 48 hours. DEC is distributed to all organs and tissues except fat.

Excretion of DEC occurs almost entirely through urine; 70% of the dose is eliminated in this manner within 24 hours of administration. Only 10–25% of the drug is excreted unchanged; the remainder is excreted as one of four known metabolites, all of which contain an intact piperazine ring.

Rapid metabolism and excretion of DEC probably account for its low toxicity. Side effects rarely occur at the low dosage (6.6 mg/kg) used for heartworm prevention.

DEC apparently has no adverse effects on fertility of male dogs. Several studies in the USA to evaluate continued daily use in males have concluded that the drug causes no significant deterioration in quantity, morphology, motility, or viability of spermatozoa.

HEARTWORM ADULTICIDES. Adult stages of *Dirofilaria immitis* cause the major damage associated with heartworm infection in domestic dogs and other carnivores. Removal of adults is the key stage in heartworm therapy, but complete management includes elimination of microfilariae and prevention of new infections. Two compounds are currently approved as *Dirofilaria* adulticides, and both are organic arsenicals.

Thiacetarsamide Sodium. *Thiacetarsamide Sodium,* INN (Caparsolate sodium, Filaramide, Arsenamide), chemically consists of the disodium salt of *S,S*-diester of *p*-carbamoyldithiobenzenearsonous acid with mercaptoacetic acid.

ADMINISTRATION AND DOSAGE. Because thiacetarsamide sodium is hepatotoxic and nephrotoxic, normal kidney and liver function should be ascertained prior to initiating a therapeutic regimen.

Thiacetarsamide is administered intravenously because it is very irritating to tissues. Caution must be exercised to avoid perivascular leakage because extreme local swelling and possible sloughing of affected tissues can result. In the event of leakage or inadvertent perivascular administration, injecting steroids into the area helps to reduce the inflammatory reaction.

The recommended regimen of thiacetarsamide therapy is 2.2 mg/kg twice daily for 2 days. This dosage provides 0.44 mg of elemental arsenic/kg body weight and should not be reduced for large-breed dogs.

Feeding the patient about 1 hour before each treatment is recommended. Interest in eating provides some indication of the dog's general condition, and treatment may be continued if the dog is eating well. Treatment should be discontinued if the dog develops severe anorexia, persistent vomiting, or other indications of hepatic or renal disease.

Arsenic toxicity is manifested as persistent vomiting, icterus, and orange-colored urine. When arsenical treatment must be suspended, a 6-week rest period is recommended before initiating another thiacetarsamide regimen. Severe toxic reactions to thiacetarsamide can be treated with dimercaprol (8.8 mg/kg/day in 4 divided doses).

CLINICAL EFFICACY. Following the four therapeutic injections of thiacetarsamide, adult worms usually die within 5–7 days, but full efficacy may require 2 weeks. Arsenicals have no effect against circulating microfilariae. Dead or dying worms are swept out of the heart and lodge in the branches of the pulmonary arteries, especially those supplying the diaphragmatic lobes. Dead worms are resorbed from the pulmonary vasculature during the subsequent 2–3 months.

In the first 2 months following treatment, the embolic shower of whole or partially phagocytized worms poses a distinct threat to the animal. Absolute rest during the first 2 weeks (the most critical period) is necessary, and only limited exercise should be allowed during the subsequent 6 weeks. Increased body temperature and coughing indicate a pulmonary reaction to embolism.

The proportion of fatalities during or following thiacetarsamide therapy is directly related to the clinical severity of the patients' heartworm disease. Hundreds of asymptomatic dogs are treated without a single loss. Among mildly symptomatic patients, approximately 30% fatality is expected. The poorest risks are dogs in which advanced heartworm disease has resulted in cachexia and ascites; 50% mortality can be expected in this group during or immediately following therapy.

Cats are potential, but not ideal, hosts for *Dirofilaria immitis,* and the prevalence of feline infections is usually about 10% of that in the local dog population. Infections with adult heartworms are far more pathogenic in cats than in dogs. Nevertheless, adulticidal treatment of infected cats with thiacetarsamide cannot be recommended due to the frequency of fatal adverse reactions in treated cats.

Melarsomine. Melarsomine (Immiticide) is a trivalent arsenical of the melanonyl thioarsenite family with activity against adult and 4-month-old heartworms (*Dirofilaria immitis*) in dogs. Its structure is presented in Fig. 47.9.

ADMINISTRATION AND DOSAGE. Melarsomine is marketed as a sterile, lyophilized white powder containing the dihydrochloride salt. It must be reconstituted with 0.9% saline prior to use. Melarsomine is administered to dogs at 2.5 mg/kg (0.1 mL/kg) as two IM doses given 24 hours apart. Deep injections in the lumbar musculature are recommended; injections should be given in alternate sides of the animal on subsequent days. Adult and 4-month-old (L$_5$) worms appear to be equally sensitive to melarsomine.

A single, two-dose course of treatment kills all male worms and approximately 96% of female heartworms. Treatment completely clears all worms from 60–81% of treated dogs (Keister et al. 1992). When indicated in individual dogs by a lack of seroconversion and per-

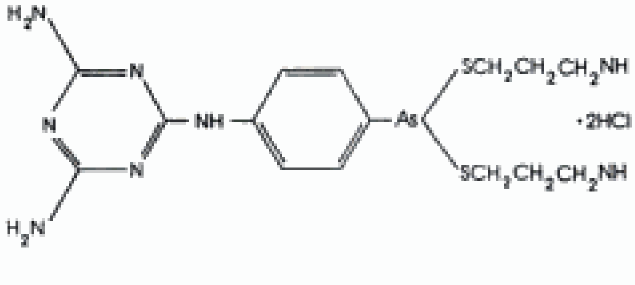

FIG. 47.9—Melarsomine dihydrochloride.

was widely used for treatment of common cestode infections in dogs and cats. Another compound, bunamidine hydroxynapththoate, was effective against *Moniezia* infections in small ruminants.

Although superior to its organic and inorganic natural precursors, bunamidine hydrochloride demonstrated inconsistent efficacy against *Dipylidium caninum* infections, required fasting before treatment (with emesis after treatment a frequent consequence), and occasionally caused fatal adverse reactions in large dogs. Modern cestocidal compounds with greater efficacy and milder side effects have displaced bunamidine, which is no longer marketed in the United States. A thorough discussion of bunamidine can be found in the previous edition of this text (Roberson and Courtney 1995).

NICLOSAMIDE. Niclosamide was widely used for treatment of cestode infections of dogs and cats from the 1960s to the 1980s. It was administered after a 12-hour fast and demonstrated inconsistent efficacy against *Dipylidium* spp. and cestodes other than *Taenia* spp. Like its contemporary, bunamidine, niclosamide has been replaced in small-animal practice by modern cestocides. Interested readers are referred to the previous edition of this text (Roberson and Courtney 1995) for a thorough discussion of the pharmaceutical and therapeutic properties of niclosamide.

DICHLOROPHEN. *Dichlorophen,* INN, has been used as a taeniacide in veterinary medicine for many years. For additional coverage of the chemical properties of dichlorophen, readers are referred to Roberson and Courtney 1995.

Dichlorophen is a taeniacide with efficacy against *Taenia* and *Dipylidium* spp. in the dog and cat, and with limited efficacy against *Moniezia expansa* in sheep. Despite certain disadvantages (frequent vomiting, colic, diarrhea, bulky dose), dichlorophen is still widely used in small-animal practice because it is combined with other antinematodal drugs to formulate several proprietary mixtures. Such mixtures are convenient because they treat both nematodes and cestodes simultaneously. Notable among these mixtures is the combination of dichlorophen with toluene (Vermiplex, Tri-Plex, Difolin) employed for dogs and cats. This combination removes 95% of ascarids, 82% of hookworms, 72% of *Taenia* organisms, and 85% of *Dipylidium* organisms.

HEXACHLOROPHENE. The antitrematodal properties of *hexachlorophene,* USP, will be discussed later in this chapter. In other countries, hexachlorophene enjoys minor use as a cestocide for sheep, cattle, dogs, and poultry. For further discussion of the anticestodal properties of hexachlorophene, readers are referred to Roberson and Courtney 1995.

RESORANTEL. *Resorantel,* INN (Terenol), is an anticestodal compound for ruminants that is now commercially available in parts of Europe. It is a hydroxybenzanilide, chemically named 4′-bromo-γ-resorcylanilide. Resorantel is highly effective (95–100%) against *Moniezia* spp. in both sheep and cattle and against *Thysaniezia giardi* and *Avitellina* spp. in sheep at a dosage of 65 mg/kg. Field trials with large numbers of lambs have demonstrated improved weight gains following removal of tapeworm burdens.

An additional advantage of resorantel is efficacy of approximately 90% against rumen flukes (*Paramphistomum* spp.) in sheep and cattle. Paramphistomosis is discussed later in this chapter.

Little is known about the pharmacodynamics of resorantel. It is excreted rapidly, and serum levels of the drug are undetectable at 48 hours after treatment. Within 3 days of treatment, the total body residue is less than 0.1% of the dose administered. Some minimal blood changes observed in sheep given a 3 times therapeutic dose are rapidly reversible. Side effects of therapeutic doses are limited to slight diarrhea in an occasional animal for 36 hours following treatment. Resorantel is well tolerated, even in ewes treated 2–3 days before lambing.

BITHIONOL. *Bithionol,* INN (Bithin, Lorothidol), is a phenolic compound that is used outside North America for treatment of tapeworm infections of dogs, cats, and poultry, and for tapeworm and rumen fluke infections of sheep, cattle, and goats. For a complete discussion of bithionol's pharmaceutical and therapeutic properties, see Roberson and Courtney 1995.

PRAZIQUANTEL. *Praziquantel,* INN (Droncit), is a novel anthelmintic with excellent activity against a wide spectrum of adult and larval cestodes of animals and humans and against all species of schistosome trematodes that are pathogenic to humans.

CHEMISTRY. Praziquantel is a synthetic isoquinolinepyrazine derivative with the chemical name 4*H*-pyrazino[2,1-a]isoquinolin-4-1,2-(cyclohexylcarbonyl)-1,2,3,6,7,11b-hexahydro-. Its structural formula is shown in Fig. 48.1. Praziquantel is a colorless, almost odorless crystalline compound with a bitter taste. It is soluble in most organic solvents and only sparingly soluble in water.

PHARMACOKINETICS. Praziquantel is quickly and almost completely absorbed from the alimentary tract following oral administration. Significant absorption occurs from the stomach of rats but primarily from the duodenum of mice. Maximum plasma concentrations are obtained after 5 minutes in the mouse, after 15–30 minutes in rats and hamsters, after 30–120 minutes in dogs, and after 2 hours in sheep. The drug is distributed to all organs, crossing the blood-brain barrier of rats (and presumably of other animals) and passing into bile of dogs. The ubiquitous distribution of praziquantel is an asset for activity against larval cestodes that can be located in various organs of the host (musculature, brain, viscera, peritoneal cavity).

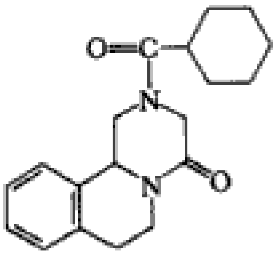

FIG. 48.1—Praziquantel.

Praziquantel is quickly metabolized into inactive forms within the liver. Following an oral dose of 300 mg/kg in rats, the mean drug concentration in portal blood was 21.2 μg/mL, while that in peripheral blood was 6.2 μg/mL. This difference suggests very quick metabolic inactivation of praziquantel by the liver. Plasma concentrations persist longer after intramuscular (IM) or subcutaneous (SC) injection than after oral administration of the same dose. About 80% of ^{14}C-labeled praziquantel administered intravenously to rats, dogs, and rhesus monkeys is eliminated as inactive metabolites, principally in urine, within 24 hours. The half-life of elimination of total radioactivity from the blood of dogs is 3 hours. Only trace amounts of the unchanged dose are excreted in urine and feces (0.3% in mice and dogs, 0.1% in sheep).

MODE OF ACTION. In both in vitro and in vivo studies, praziquantel was absorbed rapidly by cestodes and trematodes. The primary effect is instantaneous: tetanic contraction of parasite musculature and rapid vacuolization of the syncytial tegument. These effects occur within 30 seconds after in vitro contact with the drug at a concentration equivalent to therapeutic serum levels (about 0.3μg/mL) and occur within 15 minutes after in vivo dosing. Rapid contraction apparently is related to increased cell membrane permeability to calcium, with subsequent muscular paralysis.

Vacuolization of the tegument is restricted to the anterior region of the strobila of tapeworms but is scattered over the body surface of trematodes. Vacuoles start at the syncytial layer, increase in size with time, and result in visible blobs above the tegument surface. These burst and create lesions through which neutrophilic and eosinophilic granulocytes enter the parasite tissue and cause lysis within ~4 hours after treatment.

Although the phenomena of muscular contraction and tegument vacuolization appear to be calcium dependent, knowledge of the mode of action of praziquantel on a molecular level is still incomplete. See Andrews and Thomas 1983 for details of the pharmacokinetics of praziquantel.

DOSAGE AND ANTHELMINTIC SPECTRUM. Praziquantel is unique in having extremely high activity against adult stages of all species of tapeworms tested (Thomas and Andrews 1977; Thomas and Gonnert 1978); it also has good activity against larval cestodes (Thomas and Andrews 1977). The method of administration (oral, SC, or IM) affects efficacy slightly, and the SC route is least efficacious. In dogs, 1 mg/kg by any route is 100% effective against adult *Taenia pisiformis;* the same dosage in cats completely clears *Taenia (Hydatigera) taeniaeformis* and *Joyeauxiella pasqualei.* A single treatment of 2 mg/kg clears dogs of *T. hydatigena* and probably *T. ovis* and *T. multiceps,* but 2.5–5 mg/kg is required to completely eliminate *Dipylidium caninum.* A dosage of 5–10 mg/kg is required to obtain 100% removal of *Mesocestoides corti, Echinococcus granulosus,* and *E. multilocularis.* A dosage of 10 mg/kg is required for efficacy against juvenile forms of these parasites. The 5 mg/kg dosage, however, is generally recommended for elimination of the common cestode species of dogs and cats, except *Spirometra mansonoides* and *Diphyllobothrium erinacea,* which require 25 mg/kg on each of 2 consecutive days.

Lung fluke (*Paragonimus*) infections of dogs have been treated successfully with high doses of praziquantel (25 mg/kg) on each of 3 consecutive days. Praziquantel has no efficacy against nematodes but has been combined with febantel in a commercial paste (Vercom), with pyrantel pamoate in a tablet formulation (Drontal), and with both febantel and pyrantel pamoate in a tablet formulation (Drontal Plus) for broad-spectrum use in small animals.

Consistently excellent results against *Echinococcus* make praziquantel ideal for use in eradication programs to reduce the incidence of human hydatid disease. In the United States, Utah has an unusually high incidence of hydatidosis, and much of the investigation with this drug was conducted in that state (Andersen et al. 1978).

Praziquantel is also highly effective against cestodes of ruminants, poultry, and snakes and against certain flukes. All species of *Moniezia, Stilesia,* and *Avitellina* of sheep and/or goats are eliminated by a single dose of 10–15 mg/kg. The pancreatic fluke (*Eurytrema pancreaticum*) of sheep and the intestinal fluke (*Fasciolopsis buski*) of swine have been treated effectively in China with single oral doses of 50–70 and 30 mg/kg, respectively. The common tapeworms of chickens and snakes are expelled by doses of 10 and 3.5–7.0 mg/kg, respectively, without side effects. The skin fluke (*Gyrodactylus aculeatus*) of fish can be removed successfully by placing fish in small tanks for 3 hours in a concentration of 10 mg praziquantel/L water.

Human infections with *Taenia saginata, T. solium,* and *Diphyllobothrium pacificum* are eliminated by oral doses of 10 mg/kg. Removal of *D. latum* and *Schistosoma* spp. requires 25 mg/kg and 40 mg/kg, respectively. The efficacy of 25 mg/kg against *Hymenolepis nana* is incomplete if larval cestodes exceed 5 days of age. De Rezende (1983) and Goldsmith (1988) have reviewed the use of praziquantel against human parasites.

The efficacy of praziquantel against cestode larvae in the intermediate host has been evaluated extensively.

TABLE 48.1—Efficacy of praziquantel against various metacestode stages

Parasite, metacestode	Test host	Regimen		Daily minimum effective dosage	Parasite reduction
		Days	Route		
				(mg/kg)	(%)
Taenia saginata, cysticercus	Cattle	1	Oral	50	100
		10	Oral	10	100
T. taeniaeformis, strobilocercus	Mice	1	Oral	250	100
				100	0
		5	Oral	50	100
				25	63
		1	SC	250	100
				50	25
		5	SC	25	100
				10	40
T. pisiformis, cysticercus	Rabbit	1	SC	50	Sterilized
		5	SC	25	100
T. hydatigena, cysticercus	Sheep	1	Oral	50	100
		1	SC	50	100*
T. ovis, cysticercus	Sheep	1	SC	50	100
Echinococcus granulosus, hydatid	Sheep	1	SC	50	0
		42	Oral	10	100
	Mice	1	SC	500	**
		5	SC	500	**
Hymenolepis nana, cysticercoid	Mice	1	Oral	25	100

*100% efficacy when fewer than 100 cysts; incomplete when more than 100 cysts.

**Some degeneration of scolices and disruption of germinal epithelium, but no reduction in number or size of cysts.

Table 48.1 lists intermediate stages of tapeworms against which praziquantel has been tested. Of particular interest is its complete efficacy in cattle against the intermediate stage of the human beef tapeworm (*T. saginata*). The endemicity of this zoonotic agent validates the need for a drug that is effective against the metacestode stage (*Cysticercus bovis*).

Although praziquantel is highly effective against adult and juvenile *Echinococcus* organisms in the intestine of carnivores, its activity against the larval stage (hydatid cyst) is disappointing (Table 48.1). The persistent prevalence of human hydatid infections in many parts of the world fuels the search for a cestocidal drug that is totally effective against this stage in humans. Recently, albendazole has given encouraging results and is now undergoing extensive evaluation in the treatment of human hydatid disease.

SAFETY AND TOXICITY. Acute and chronic toxicity studies indicate a wide margin of safety for praziquantel (Muermann et al. 1976). The oral median lethal dose (LD_{50}) in mice and rats is between 2000 and 3000 mg/kg. The LD_{50} is even higher when the drug is given subcutaneously. An acute, oral LD_{50} has not been established in dogs because they vomit when dosages exceed 200 mg/kg. The single therapeutic dose is 3.8–12.5 mg/kg in dogs and 4.2–12.7 mg/kg in cats. Overdoses of up to fivefold are tolerated without adverse effect. Tenfold overdoses may cause transitory vomiting and depression in both dogs and cats. Twentyfold overdoses (200 mg/kg) may be fatal to cats. Dogs given daily dosages of 20, 60, or 180 mg/kg exhibit no changes in hematologic or clinicochemical parameters, except an occasional increase in alkaline phosphatase levels with the highest regimen. Dermal and eye tests in rabbits, guinea pigs, and/or humans indicate that praziquantel does not sensitize the skin or cause irritation.

Studies in pregnant rats and rabbits detected no embryotoxic or teratogenic effects of this drug when given orally at dosages of 30, 100, and 300 mg/kg from the 6th day to the 15th day (rat) or 18th day (rabbit) after copulation. Similar tests in dogs and cats support the use of praziquantel in breeding and pregnant animals without restrictions. Some changes in nuclear structures of treated animals suggest that at some levels praziquantel may have genotoxic effects possibly leading to development of neoplasia (Montero and Ostrosky 1997).

EPSIPRANTEL. *Epsiprantel*, INN (Cestex), is marketed solely as an anticestodal drug. It is chemically related to praziquantel and is a parazino benzazepine with the chemical name 2-(cyclohexylcarbonyl)-4-oxo-l,2,3,4,6,7,8,12b-octahydropyrazino-[2,1-a][2]benzazepine. It is an acid-stable white powder that is sparingly soluble in water. The structural formula of epsiprantel is shown in Fig. 48.2.

PHARMACOKINETICS. Following oral administration, only trace amounts of epsiprantel are absorbed from the gastrointestinal (GI) tract, and most is eliminated in the feces. Mean peak drug plasma levels of 0.13 µg/mL (range, <0.5–0.36 µg/mL) occur in dogs 1 hour after oral dosing with 5.5 mg/kg. After the same dosage, plasma levels are not detected in 83% of cats, and detectable drug concentrations reached only 0.21 µg/mL 30 minutes after dosing. Less than 0.1% of the

Mebendazole has demonstrated positive results against larval stages of *T. pisiformis* in rabbits, *T. hydatigena* in pigs, and *E. granulosus* and *E. multilocularis* in mice. A brief regimen of treatment (25 mg/kg/day for 5 days) was totally effective for *Taenia* cysticerci in rabbits and pigs. A much longer regimen (60–120 days, 500 ppm mebendazole in food) is necessary for 96% reduction of hydatid cysts of *Echinococcus* in mice. Similar or better results can be obtained against hydatid cysts in mice by giving IP doses of mebendazole (150 mg/kg/day for 3 days) or by oral treatment with fenbendazole (500 ppm in food for 16 weeks). Studies indicate that mebendazole readily crosses the cyst wall by simple diffusion. Protoscolices appear to be more sensitive to the drug than the germinal epithelium of the hydatid cyst. These results have encouraged use of mebendazole (Vermox, USSR) against hydatid disease in humans. Previously, surgical removal of cysts has been only 10% successful.

Mebendazole is also effective against the intermediate stage (tetrathyridium) of *Mesocestoides corti* in mice. Adults and tetrathyridia of *Mesocestoides* can infect dogs, and the latter stage may cause fatal, verminous peritonitis. Five of 6 infected dogs were successfully cleared of larval *Mesocestoides* infections by protracted regimens of fenbendazole at 100 mg/kg twice daily for 14–60 days (Crosbie et al. 1998).

Anticestodal Drugs for Horses. Historically, horses have not been treated routinely for cestode (*Anoplocephala perfoliata*) infections, but public interest in equine tapeworms is definitely increasing. Management of equine tapeworm infections has been hampered by the lack of sensitive diagnostic techniques and by a dearth of biological information about the tapeworm and its oribatid mite vectors. Little is known about the seasonal patterns of transmission, so strategic treatment recommendations to disrupt the annual cycle of reinfection are purely speculative at present.

No products are currently labeled in the United States specifically for treatment of equine cestode infections. Limited tests have shown that pyrantel pamoate (13.2 mg/kg), pyrantel tartrate (2.64 mg/kg daily for 30 days), niclosamide (88 mg/kg), dichlorophen (20 mg/kg), bithionol (7 mg/kg), mebendazole (20 mg/kg), and praziquantel (0.5–1.5 mg/kg) (Lyons et al. 1995; Lyons et al. 1998) are effective and safe cestocides for horses.

ANTITREMATODAL DRUGS. Fasciolosis (infection with *Fasciola hepatica*) is the most common and most economically important trematode disease of domestic animals worldwide. Most of the antitrematodal drugs discussed in this section are compounds used in treatment of fasciolosis. Brief attention also will be given to treatment of infections caused by rumen flukes (*Paramphistomum*) in cattle and sheep and by lung flukes (*Paragonimus*) in dogs and cats.

Fasciolosis. Liver-dwelling trematodes adversely affect the health of sheep and cattle in the United Kingdom, Australia, southern and western United States, and some tropical regions of the world. The United Kingdom has experienced three major outbreaks of acute and chronic fasciolosis in sheep since World War II. In the United States, liver fluke disease is typically more chronic and subclinical in nature.

Both immature and mature flukes damage the host liver. After metacercariae are ingested by grazing sheep or cattle, the immature fluke emerges from its cyst, penetrates the wall of the small intestine, traverses the peritoneal cavity, and penetrates the liver capsule within 4 days of infection. During the next several weeks, immature flukes tunnel through liver tissues, feeding and increasing rapidly in size. The extensive damage and resultant hemorrhaging of the liver often result in clinical signs of acute fasciolosis within 6–8 weeks after infection. This stage is often fatal. During the eighth week of infection, flukes begin to penetrate the main bile ducts, where they attain sexual maturity by ~10–12 weeks after infection. The flukes are most susceptible (or perhaps most accessible) to fasciolicidal drugs at this stage.

Adult flukes, often in pairs, lodge within a bile canal, causing biliary hyperplasia and progressive occlusion. Heavily infected areas may become walled off from the rest of the liver by connective tissue. Such areas become progressively less penetrable by therapeutic agents and consequently more difficult to treat.

The severity of *F. hepatica* infections in sheep may be enhanced by the fluke's potential role in disseminating enteric bacteria (*Clostridium novyi*) in the liver during migration. The resultant infectious, necrotic hepatitis (black disease) can be fatal. A vaccine against *C. novyi*, however, is helpful in controlling the disease.

DRUGS EFFECTIVE AGAINST ADULT FLUKES. Since the introduction of carbon tetrachloride for treatment of helminth infections of animals in the 1920s, numerous other compounds have been investigated for efficacy against *F. hepatica*.

On the basis of chemical structure, the fasciolicidal drugs can be separated into several groups: (1) the halogenated hydrocarbons (carbon tetrachloride, hexachloroethane, tetrachlorodifluoroethane, hexachloroparaxylene) were reviewed in the 6th edition of this text (Roberson 1988), (2) the bisphenolic compounds (hexachlorophene, bithionol sulfoxide, the bromsalans, oxyclozanide, clioxanide), (3) the nitrophenolic compounds (disophenol, niclofolan, nitroxynil), (4) the newer salicylanilides (closantel, brotianide), (5) sulfonamides (clorsulon), and (6) benzimidazoles (albendazole, triclabendazole). A common feature of the first three drug groups is the presence of halogen atoms. It is unknown whether the halogen atom presents a common mechanism for fasciolicidal activity of these drugs, but this is considered unlikely (Fowler 1971).

The flukicides discussed below are marketed in most livestock-producing areas, including Europe, Africa, and Australia. Richards et al. (1990) in Australia compared the efficacies of many antitrematodal drugs against immature and mature stages of *F. hepatica* in cattle. The drugs tested were triclabendazole, albendazole, clorsulon, nitroxynil, oxyclozanide, and rafoxanide. Earlier, Losson (1988) reviewed these drugs as well as closantel and diamphenethide. Among these compounds, however, only albendazole and clorsulon have Food and Drug Administration (FDA) approval for use against fluke infections in the United States.

Fasciolicidal drugs historically have targeted adult-stage flukes. Consequently, immature flukes in the liver parenchyma largely escaped therapeutic activity until the introduction of diamphenethide in 1971. This drug demonstrates greatest efficacy against young flukes, and its effectiveness diminishes as the flukes age.

HEXACHLOROPARAXYLENE. Hexachloroparaxylene is a chlorinated derivative of benzene. For a brief discussion of this compound, readers are referred to the 7th edition of this text (Roberson and Courtney 1995).

HEXACHLOROPHENE. Hexachlorophene is not approved for use in the United States. It has good efficacy against adult flukes but no effect against immature flukes less than 8 weeks of age. Hexachlorophene is discussed in the 7th edition of this text (Roberson and Courtney 1995).

BITHIONOL SULFOXIDE. Bithionol has activity against rumen flukes (*Paramphistomum* spp.) and liver flukes (*Fasciola* and *Fascioloides* spp.) of ruminants and also has some anticestodal properties. Roberson and Courtney (1995) offer further coverage of bithionol.

THE BROMSALANS. The bromsalans are available in some countries for the treatment of mature and immature *Fasciola* infections. These compounds are discussed by Roberson and Courtney (1995).

OXYCLOZANIDE. *Oxyclozanide,* INN (Zanil), was introduced over 30 years ago for use against adult fluke infections and in some countries is formulated together with levamisole to offer broad-spectrum helminth treatment. Oxyclozanide is discussed further by Roberson and Courtney (1995).

NICLOFOLAN. *Niclofolan,* INN (Bilevon, Distolon, Dertil, Menichlopholan), is a nitrosubstituted analog of hexachlorophene. Its chemical formula is 4,4′-dichloro-6,6′-dinitro-*o,o*-biphenol. In addition to the typical adulticidal spectrum, niclofolan has some efficacy against immature *Fasciola* organisms, but only at dosages that are clinically unsafe. Further discussion of niclofolan's properties is included in the 7th edition of this text (Roberson and Courtney 1995).

NITROXYNIL. *Nitroxynil,* INN (Dovenix, Trodax), has the chemical name 4-hydroxy-3-iodo-5-nitrobenzonitrile.

Nitroxynil was developed in the United Kingdom in the late 1960s as an injectable fasciolicide for sheep and cattle. It can be administered orally but is more effective when administered by the SC or IM route. SC or IM administration provides similar efficacy for liver flukes, but the SC route has become the method of choice in practice. It is injected in the side of the neck of cattle and at any convenient site in sheep. The ease of SC administration gives nitroxynil an advantage over fasciolicides that must be administered orally. This compound stains wool or hair yellow; thus, care must be exercised to avoid spilling. Local tolerance at the site of injection is satisfactory, although transitory inflammatory swellings are occasionally observed in cattle.

Nitroxynil is effective against mature *F. hepatica* and *F. gigantica,* but not paramphistomes in sheep and cattle. It also can be used to treat haemonchosis and *Parafilaria bovicola* infections in these hosts. Nitroxynil is more than 99% effective against ivermectin- and benzimidazole-resistant *Haemonchus contortus* of sheep.

Nitroxynil has high activity against mature liver flukes at 10 mg/kg, and its activity against immature flukes reduces mortality from acute fasciolosis in sheep. Efficacy drops off, however, against flukes that are younger than 6 weeks. Nitroxynil is well tolerated at the therapeutic dosage of 10 mg/kg, but higher dosages are not recommended because of potential adverse reactions.

RAFOXANIDE. *Rafoxanide,* INN (Flukanide, Ranide), is a halogenated salicylanilide. Its chemical formula is 3′-chloro-4′-(*p*-chlorophenoxy)-3,5-diiodosalicylanilide. It is an off-white crystalline powder and is commercially formulated for use as a bolus or drenching suspension.

Indications and Effectiveness. Rafoxanide was developed in 1969 and subsequently has been used extensively against fasciolosis and haemonchosis in sheep and cattle in the United Kingdom, Europe, Australia, Brazil, and South Africa. Its principal use is as an adulticide for *F. hepatica* and *F. gigantica,* but it also has respectable efficacy against immature flukes. A single therapeutic dose (7.5 mg/kg) in sheep provides the following efficacies for various ages of *F. hepatica:* nearly 100% for 12-week-old flukes, 86–99% for 6-week-old flukes, and 50–98% for 4-week-old flukes. The same dosages afford similar efficacies against *F. hepatica* in cattle. The reliable efficacy of this drug against 4- and 6-week-old flukes gives rafoxanide an advantage over strictly adulticidal drugs in the treatment of acute fasciolosis. Repeat treatment is advised at 3-week intervals to eliminate maturing flukes that may have escaped earlier treatment.

Rafoxanide is also indicated in the treatment of haemonchosis, bunostomosis, and sheep nasal bots. Greater than 96% efficacy is reported against adult *Haemonchus* and *Bunostomum* in cattle, and against adult and immature forms of these parasites in sheep. Rafoxanide also appears to be highly effective (98%) against all parasitic larval stages of the sheep nasal bot (*Oestrus ovis*).

Pharmacokinetics and Mode of Action. Following oral dosing, rafoxanide is absorbed (presumably from the small intestine) into the bloodstream. Peak plasma levels occur between 24 and 48 hours. The drug is not metabolized to any detectable degree by cattle or sheep. It is extensively bound (>99%) to plasma proteins and has a long (16.6-day) terminal half-life. Perhaps some of the efficacy of rafoxanide against immature flukes is due to its prolonged persistence in the plasma, with subsequent effects on maturing flukes as they reach the bile ducts. Following a single oral dose of 15 mg/kg in cattle, no residue of the compound is detectable in edible tissues at 28 days after treatment.

The mode of action of rafoxanide apparently is as a proton ionophore, transporting cations across cell membranes and ultimately uncoupling oxidative phosphorylation within parasitic mitochondria (Martin 1997).

BROMOPHENOPHOS. *Bromophenophos,* INN (Acedist), is an organophosphoric acid ester. Its chemical formula is 4,4′,6,6′-tetrabromo-2,2′ biphenyldiol mono (dihydrogen phosphate).

Bromophenophos is used to treat *F. hepatica* infections in cattle. Its efficacy for adult flukes is 85–100%, and it has reasonably good activity against immature flukes. Bromophenophos is administered orally to cattle at a dosage of 12 mg/kg.

CLORSULON. *Clorsulon* (Curatrem) is a benzenesulfonamide with the chemical formula 4-amino-6-trichloroethenyl-1,3-benzenedisulfonamide. Its structural formula is shown in Fig. 48.3. Clorsulon is formulated commercially as a drench for sheep and cattle and as a SC injection for cattle (in combination with ivermectin). In the United States, clorsulon and albendazole are the only drugs approved by the FDA for treatment of *F. hepatica* infections. Albendazole is approved for beef and nonlactating dairy cattle; clorsulon is approved for beef and dairy cattle, regardless of lactation status. Neither drug is approved for sheep in the United States.

Indications and Effectiveness. Oral administration of 3.75 mg/kg clorsulon provides 100% efficacy against adult *F. hepatica* (14 or 16 weeks old) in both sheep and cattle. Higher dosages are needed to attain similar levels of efficacy against younger flukes. A single dose of 15 mg/kg clorsulon was 92–99.5% effective against 6- and 8-week-old flukes; 30 mg/kg removed 99.7% of 3-week-old infections and 85.3% of 2-week-old infections. Based on these data, the label dosage of 7 mg/kg is predicted to be approximately 88% effective for immature flukes and 99% effective for mature forms of *F. hepatica* in sheep and cattle. In one endemic area of the United States (Florida) where snail vectors are present on pasture from December to June, it is suggested that treatment with clorsulon in late fall and again in early spring should prevent most transmission of *Fasciola* organisms (Courtney et al. 1985).

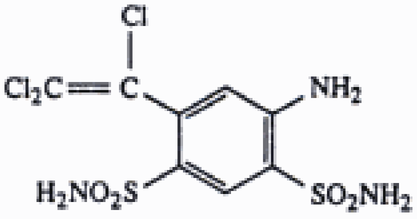

FIG. 48.3—Clorsulon.

The combination of clorsulon with ivermectin in a SC injectable formulation (Ivomec Plus) was designed for simultaneous treatment of *Fasciola* and nematode infections of cattle. The oral formulation of clorsulon (Curatrem) also can be used concurrently with other anthelmintics (e.g., ivermectin, fenbendazole) with no reduction in efficacy of the individual products (Malone et al. 1990).

The efficacy of clorsulon has been tested against infections with several other fluke species in ruminants. It is reasonably effective (>92%) against immature (8-week-old) *Fascioloides magna* in cattle and sheep at an elevated dosage of 21 mg/kg orally. It is not so effective (74%), however, against older (16-week-old) *F. magna* in these atypical hosts. Daily dosing at 7 mg/kg for 5 consecutive days has been 100% effective against adult and 92% effective against immature *Fasciola gigantica* in cattle. Clorsulon has poor efficacy against the rumen fluke, *Paramphistomum.*

Pharmacokinetics and Mode of Action. Schulman et al. (1979) used radiolabeling techniques to determine that clorsulon enters the blood rapidly after treatment and attains maximum concentration approximately 4 hours later, when 75% of the circulating drug is in the plasma and 25% is in erythrocytes. Drug concentration within flukes peaks at 8–12 hours after dosing.

Residue studies indicate a short half-life of clorsulon in tissues and milk. Milk taken from treated animals within 72 hours (six milkings) after treatment should not be used for human consumption, and beef animals should not be slaughtered within 8 days of treatment.

The mode of action of clorsulon has been studied by measuring its effect on glycolytic enzymes of *F. hepatica.* Inhibition of 3-phosphoglycerate kinase and phosphoglyceromutase occurred. This enzymatic inhibition effectively blocks the Embden-Myerhof glycolytic pathway and thereby deprives the fluke of its main source of metabolic energy.

Safety and Toxicity. Acute toxicity of clorsulon has been assessed in mice, rats, sheep, and cattle. The LD_{50} in mice is an IP dose of 761 mg/kg and more than

Treatment of Acute Fasciolosis. Diamphenethide is used for treatment of acute fasciolosis resulting from immature forms of *F. hepatica* migrating through the liver parenchyma of sheep. A dosage of 100 mg/kg diamphenethide is almost 100% effective against flukes from 1 to 63 days of age.

The activity of diamphenethide against 10-week-old (i.e., recently mature) flukes diminishes to 78%, and the efficacy for flukes 12 weeks of age or older is 70% or less. Accordingly, a single treatment normally eliminates all the young flukes but leaves at least 30% of the mature population to continue shedding eggs and contaminating pastures.

Prophylaxis. The fundamental prerequisites for successful prevention of fasciolosis include elimination of the existing fluke population in toto; halting contamination of pastures with fluke eggs; and prevention of acute, chronic, or subclinical fasciolosis. To accomplish all these prerequisites, an ideal fasciolicide must be highly efficacious against all parasitic stages of *F. hepatica.* Of the current drugs, only the combination of rafoxanide (with efficacy that spans 4-week-old to adult flukes) and diamphenethide (effective against 1-day-old to 10-week-old flukes) most closely approaches the ideal fasciolicide and therefore offers the best chance for successful chemoprophylaxis.

The value of rafoxanide for prophylaxis of fasciolosis has been demonstrated in Scotland (Armour and Corba 1972; Whitelaw and Fawcett 1981). Drenching of ewes twice (in the spring and early summer) at an interval of 6 weeks kept the test pastures virtually clear of fluke eggs over the vital periods of snail breeding and infection by miracidia. Two further treatments in the fall (6 weeks apart) reduced infection in ewes to negligible proportions in the winter. Armour and Corba (1972) and Rowlands et al. (1985) have proposed that treatments with diamphenethide at 6- to 8-week intervals (twice in the spring and twice in the fall) should provide excellent control of fasciolosis.

Toxicity. The usual oral dosage of 100 mg/kg in sheep apparently is safe. A single oral dose four times the therapeutic dosage (400 mg/kg) produces no toxic signs. At higher dosages, toxic effects include temporary impairment of vision and loss of wool. Pastured sheep are less susceptible to toxic effects than housed sheep. At a dosage of 1600 mg/kg, diamphenethide produces a low incidence of mortality. An acute LD_{50} value for sheep apparently has not been established.

Contraindications. There appear to be no significant contraindications for use of diamphenethide. Pregnant ewes dosed with 200 mg/kg once weekly on 2, 3, or 4 consecutive occasions during the 21-week gestation period exhibited no adverse effects on fertility or teratogenic effects in their offspring. Adverse effects on fertility have not been reported in ewes and rams dosed during the mating period.

Administration and Dosage. Diamphenethide is marketed as a suspension for oral administration to sheep in a single dose of 100 mg/kg. The same dosage is effective and safe for use in goats.

Paramphistomosis. Rumen fluke (*Paramphistomum* spp.) infections are common in cattle and sheep throughout the world. Adult flukes attach to the rumen wall and are of little consequence to the health of the animal. Large numbers of the immature stages, however, can be seriously pathogenic as they migrate within the gut lumen from the duodenum to the rumen. Symptoms are more pronounced in young, previously uninfected sheep or cattle and include severe anorexia, polydipsia, and watery, fetid diarrhea that ultimately results in reduced production or death.

Intestinal paramphistomosis generally responds well to treatment with drugs that are effective against liver fluke and/or cestode infections in ruminants. These include niclosamide, niclofolan, resorantel, and bithionol. Concurrent treatment of infected dairy cows with oxyclozanide and oxfendazole increased milk production by 0.4 liters/day (Spence et al. 1996). Roberson and Courtney (1995) discuss therapy of paramphistomosis at length.

Paragonimosis. Lung fluke (*Paragonimus* spp.) infection is diagnosed occasionally in dogs and cats in the Americas and in the Far East. Four drugs are apparently efficacious against *Paragonimus* organisms: bithionol, praziquantel, albendazole, and fenbendazole. The oral dose of bithionol for dogs and cats is 100 mg/kg every other day for a total of 10–15 treatments. The efficacy of bithionol is rather unpredictable (15–85% reduction in number of flukes), and the drug has undesirable side effects in small animals.

Praziquantel is effective against *Paragonimus* infection in dogs when given at 25 mg/kg on each of 3 consecutive days. The efficacy of praziquantel against *Paragonimus* infection in cats has not been evaluated.

Albendazole, at a dosage of 25 mg/kg twice daily for 14 days, is highly effective against *Paragonimus* infection in both cats and dogs. The twice-daily regimen is crucial; otherwise, single daily doses of 100 mg/kg for 14 days are required to effect a cure (Dubey et al. 1978).

Fenbendazole kills adult flukes in dogs and reduces lung lesions without side effects (Dubey et al. 1979). Effective doses include 50 mg/kg twice daily for 10 days and 25 mg/kg twice daily for 14 days. Shedding of fluke eggs in feces ceased 3 and 8 days after initiation of the respective regimens.

Isospora spp. Coccidiosis is extremely important in the poultry industry. It is estimated that 350 million dollars worldwide and about 80 million in the United States are spent on anticoccidial agents a year (Long 1993). Economic losses also occur in the cattle, sheep, goat, rabbit, and swine production industries, but the use of anticoccidial agents is less frequent in these industries. Coccidiosis can also occur in humans, other primates, dogs, and cats. Members of the genera *Eimeria* and *Isospora* generally are host specific and complete their entire life cycle in a single animal.

The coccidial life cycle is complex. It begins when sporulated oocysts containing sporozoites are ingested from the environment in contaminated food or water. The sporozoites undergo excystation in the intestine and are liberated from the oocysts. The sporozoites then actively penetrate host cells in the intestinal tract. The sporozoite transforms into a trophozoite, which undergoes multiple karyokinesis and eventually produces numerous merozoites. This sequence of developmental events occurs a predetermined number of times, and each cycle is called a generation. Eventually the merozoites produced by the terminal generation of merozoites transform into sexual stages. Macrogamonts are uninucleate and are the female gamete, while microgamonts become multinucleate and produce flagellated microgametes (sperm). The microgametes fertilize the macrogamonts, and the resulting zygote produces an oocyst. The oocyst is excreted in the feces, usually in the unsporulated condition. Sporulation occurs in the environment.

Members of the genus *Cryptosporidium* can be recognized as serious intestinal and respiratory pathogens of humans and domestic animals. Their life cycles are similar to the *Eimeria* and *Isospora* spp. A notable difference is that the parasite develops in the microvilli of host enterocytes.

Toxoplasma gondii, Neospora caninum, and *Sarcocystis* spp. are related parasites that cause abortion, death, and production losses in ruminants and other animals. These parasites have two hosts in their life cycles. Sexual stages are present in the definitive host, and asexual stages (tachyzoites, merozoites, tissue cysts) are present in the intermediate host. *Sarcocystis*-induced encephalitis is seen in several species of animals and is particularly important in horses, where the causative agent is *S. neurona. Neospora caninum* causes encephalitis and paralysis in dogs and abortions in ruminants. *Hepatozoon americanum* has emerged as the cause of often fatal disease in dogs in the southern United States (Macintire et al. 1997; Vincent-Johnson et al. 1997).

Timing and Mode of Action of Anticoccidial Agents. Anticoccidial drugs can act on extracellular stages (sporozoites, merozoites) to prevent penetration of cells or on the intracellular stages to stop or inhibit development. A few anticoccidials affect the sporulation of oocysts after they are excreted, and a few effect excystation (under experimental conditions). Anticoccidials can act at specific times during the life cycle or exert their effects at several phases. Anticoccidials are classified as coccidiostatic if they arrest the development of the parasite but do not kill the coccidial stages and as coccidiocidal if they kill most of the coccidial stages. The distinction between coccidiostatic versus coccidiocidal is often not clear. Factors such as length of time on medication, dosage, and species of coccidia can cause a compound to appear as coccidiostatic in some instances but coccidiocidal in others.

Anticoccidial Drug Resistance. Development of resistance to anticoccidial drugs is a major problem in the poultry industry. Anticoccidial drug resistance occurs when a coccidial parasite can multiply or survive in the presence of concentrations of an anticoccidial that normally destroy parasites of the same species or prevent their multiplication (Chapman 1997). The speed of development of drug resistance depends on the mode of action of the agent. Resistance to some anticoccidials has appeared in as early as weeks to months, while others require years before resistant strains appear. Cross-resistance to anticoccidials with the same mode of action from the same chemical class is common. The spectrum of activity of an anticoccidial agent must be taken into account when examining resistance.

Development of resistance to an agent does not mean that its use as an anticoccidial is completely abolished. Combination with other agents can improve activity. Also, once a product has been removed from routine use for several years, the drug-resistant coccidia will disappear due to lack of drug pressure.

Rotational and shuttle programs can be used to slow the development of drug resistance. Rotational programs change the agents between grow-out periods, and shuttle programs change anticoccidials during a single grow-out period.

New Anticoccidial Drug Targets. A vestigial, nonphotosynthetic plastid has recently been described in apicomplexan parasites (Köhler et al. 1997). It probably was acquired by secondary endosymbiosis of a green alga. The function of the plastid is not known but it is essential for parasite survival. In plants, the plastids are the site for many biochemical pathways, including the biosynthesis of folate, amino acids, ubiquinone, haem, nucleotides, lipid, and starch (Roberts et al. 1998). The shikimate pathway has been found in apicomplexan parasites (Roberts et al. 1998). The enzymes of the shikimate pathway are encoded in the nucleus, made in the cytoplasm, and targeted to the apicoplast (chloroplast). The seven enzymes involved in this pathway are attractive drug targets because vertebrate cells lack the shikimate pathway. Glyphosphate—*N*-(phosphonomethyl)glycine is a well-studied inhibitor of shikimate pathway enzyme 5-enolpyruvyl shikimate 3-phosphate synthase—inhibits development of apicomplexan parasites (Roberts et al. 1998), strengthening the hypothesis that this pathway and this organelle will prove to be good drug targets in the future. The apicoplast may also be important in fatty acid biosynthesis because several proteins involved in fatty acid biosynthesis accumulate in the apicoplast (Waller et al. 1998). Thiolactomycin, a fatty acid biosynthesis inhibitor, inhibits development of malarial parasites, indicating a vital role for the apicoplast and fatty acid biosynthesis. Clindamycin and ciprofloxacin—1-cyclopropyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-3-quinolinecarboxylic acid—have also been shown to act on the apicoplast and inhibit development of *Toxo. gondii* (Fichera and Roos 1997). Much research is presently being done on the apicoplast and its potential as a drug target.

The mannitol cycle has been identified in *Eimeria tenella* (Schmatz 1997) and all other *Eimeria* spp. that infect chickens (Liberator et al. 1998). It is an attractive drug target because it is not present in the chicken host. The mannitol pathway is important in the formation of oocysts, and mannitol functions as the endogenous energy source for sporulating oocysts. Nitrophenide—*bis*(3-nitrophenyl)disulphide—inhibits an enzyme needed in the biosynthesis of mannitol and will prevent the formation of oocysts. If nitrophenide is used at lower levels, the oocysts will not sporulate. Additional enzymes involved in the mannitol cycle are probably going to be attractive drug targets.

Anticoccidials used for Controlling Coccidiosis in Chickens. Because the vast majority of anticoccidial agents are intended for use in chickens, we will discuss them first in relation to these birds and then consider additional animal species separately.

HYDROXYQUINOLONES AND NAPHTHOQUINONES. Buquinolate, decoquinate (Deccox), and nequinate are quinolone (4-hydroxyquinolones) anticoccidials (Table 49.4). These compounds are coccidiostatic and allow penetration of sporozoites but not development. These inhibited sporozoites have the ability to resume development after the agents are removed. Little anticoccidial immunity develops in chickens on these medications. Recent evidence indicates that decoquinate can have an anticoccidial effect on first-generation schizonts of *E. tenella*, adversely affect sporulation, and permit the development of immunity if fed at levels that are lower than its coccidiostatic levels (Williams 1997). Buquinolate and nequinate are not presently used in the United States.

Decoquinate is a cream to pale buff, microcrystalline powder with a slight odor. It is practically insoluble in water and is stable for about 4 years if stored under appropriate conditions. Decoquinate is poorly absorbed from the intestinal tract, and what is absorbed is rapidly cleared from the blood and tissues. Decoquinate is fed at 0.003% for prevention of coccidiosis in broilers. It should be fed for at least 28 days when development of coccidiosis is likely. Do not feed to laying chickens. No withdrawal is required.

The quinolone anticoccidials inhibit coccidial respiration by interfering with cytochrome-mediated electron transport in the parasites' mitochondria. The site of action of quinolone anticoccidials is probably within the bc_1 complex, where the electrons are transferred from ubiquinone to cytochrome c.

Atovaquone (Mepron suspension) has broad-spectrum antiprotozoal activity and was developed for use in human beings. It is a yellow crystalline solid that is practically insoluble in water. Atovaquone is supplied as a bright yellow suspension of microfine particles at a concentration of 150 mg atovaquone/mL. It is highly lipophilic and administering it with food increases its absorption twofold. It was originally developed for the treatment of drug-resistant strains of malaria and *Pneumocystis carinii* pneumonia and is discussed here because it was also found to have excellent activity against *Toxo. gondii*. It also has activity against *Eimeria* spp. Atovaquone is also thought to affect the mitochondrial bc_1 complex because a mutant resistant to atovaquone is also resistant to decoquinate (Pfefferkorn et al. 1993).

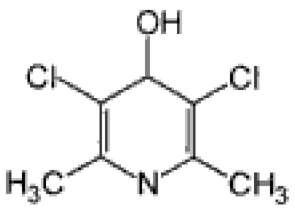
Parvaquone and buparvaquone are naphthoquinones that are used for the treatment of piroplasmosis and will be discussed below in that section.

CLOPIDOL. Clopidol (Coyden 25), 3,5-dichloro-2,6-dimethyl-4-pyridinol, is the only pyridinol to be used as an anticoccidial (Fig. 49.5). It is practically insoluble in water. It is active against the sporozoite stage, allowing host cell penetration but not parasite development. It also has activity against second-generation schizogony, gametogony, and sporulation. Sporozoites can resume development after the medication is removed. Little anticoccidial immunity develops in chickens receiving this agent.

Long (1993) suggested that the mode of action of clopidol was similar to that of the quinolone anticoccidials because of similar structure and biological activity of the agents. However, cross-resistance between clopidol and quinolone anticoccidials does not occur (Long 1993).

Clopidol is fed at 0.0125–0.0250% for prevention of coccidiosis. A 5-day withdrawal is required if the 0.0250% level is used. This level may be lowered to 0.0125% 5 days before withdrawal and fed. Clopidol is transmitted to the eggs of hens that are fed clopidol-containing diets (Long 1971).

ROBENIDINE. Robenidine (Cycostat, Robenz), 1,3-*bis* [(*p*-chlorobenzylidene)amino]-guanidine hydrochloride (Fig. 49.6), is a synthetic anticoccidial derivative of guanidine. It is active against the first-generation schizont of *E. tenella* by preventing formation of merozoites. Robenidine is fed at 33 ppm for the prevention of coccidiosis. Finish feeds must be fed within 50 days of manufacture. Do not feed with bentonite. Do not feed to layers. A 5-day withdrawal is required. If robenidine is not withdrawn 5 days before slaughter, the flesh of medicated birds will have an unpleasant taste. Robenidine is transmitted to the eggs of hens (Long et al. 1981), and these eggs may have an



Clopidol
($C_7H_7Cl_2NO$)
[192.06]

FIG. 49.5

Several formulations of amprolium are available. Amprolium is used for the prevention of coccidiosis in chickens and fed at 36.3–113.5 g/ton feed or given in the drinking water at 0.012%. No withdrawal is required.

NITROBENZAMIDES. Aklomide and dinitolamide (syn. zoalene) (Zoamix) are nitrobenzamide anticoccidial agents (Table 49.5). These agents act primarily on the first-generation schizonts, and dinitolmide inhibits sporulation of oocysts (Mathis and McDougald 1981). Dinitolmide is coccidiostatic if given for 6 days but is coccidiocidal if given for longer periods (Long 1993). The nitrobenzamides are often combined with other agents. Nitrobenzamide-resistant strains of coccidia are common. The anticoccidial mode of action of nitrobenzamides is not known.

Alkomide is not currently marketed as a single agent in the United States. It is still used in combination with other agents.

Dinitolmide is fed at 0.0125% to prevent coccidiosis in chickens. Do not feed to layers or birds over 14 weeks of age. No withdrawal is required.

NICARBAZIN. Nicarbazin (Nicarb, Cycarb) is an equimolecular complex of 4,4′-dinitrocarbanilide and 2-hydroxy-4,6dimethylpyrimidine (Fig. 49.8). Dry crystals are strongly electrostatic and present some dry-mixing problems. The agents are absorbed separately from the chicken digestive tract, and both are needed for anticoccidial activity. The precise mode of action of nicarbazin is not known. Nicarbazin is fed at 125 ppm for the prevention of coccidiosis. Do not feed to layers. Do not use for treatment of coccidiosis. A 4-day withdrawal is required. Nicarbazin causes reduced egg production, depressed egg weight, reduced eggshell thickness, and egg-yolk mottling when fed to white leghorn layers at 125 ppm (Jones et al. 1990). It also causes poor hatchability and depigmentation of brown-shelled eggs. Nicarbazin is usually restricted in use to the starting period because of potential growth-suppressing effects and to cooler months of the year because of its potential to enhance the effects of heat distress (McDougald 1993).

sporozoites and merozoites. Extracellular stages develop membrane blebs indicating alterations in membrane integrity and in internal osmolality. Because coccidia have no osmoregulatory organelles, this change in internal osmotic conditions would adversely affect the parasites.

Because of the unique mode of action of ionophores, development of anticoccidial resistance to ionophores was slow to occur in the field and difficult to produce under experimental conditions. In the mid- to late 1980s ionophore-resistant strains of chicken *Eimeria* spp. were documented in the United States, and ionophore resistance is now common. Cross-resistance between ionophores is common, although strain differences in response to specific ionophores have been demonstrated. In general, resistance to a monovalent polyether ionophore confers some cross-resistance to other monovalent polyether ionophores, but susceptibility to monovalent monoglycoside and divalent polyether ionophores may be retained.

Ionophores are potentially toxic for highly susceptible species, such as horses and other equines. Care should always be taken to prevent highly susceptible animals from gaining access to feeds containing these products.

MONENSIN. Monensin (Coban, Rumensin) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces cinnamonensis*. Monensin (Coban) is fed at 99–121 ppm for prevention of coccidiosis in broilers. Do not feed to layers or chickens over 16 weeks of age. No withdrawal is required. Tiamulin (Tiamutin), [(2-(diethylamino)ethyl) ethyl thio] acetic acid 6-ethenyldecahydro-5-hydroxy-4,6,9,10-tetramethyl-1-oxo-3a,9-propano-3a*H*-cyclopentacycloocten-8-yl ester, may interfere with the metabolism of monensin in chickens and cause weight suppression (Meingasser et al. 1979). Monesin is apparently not transmitted to eggs of hens fed monensin for 1 week, nor does it adversely affect egg production or quality. Mature turkeys and guinea fowl should not have access to monensin-containing diets. Monensin will cause deaths in horses that ingest feeds containing it.

LASALOCID. Lasalocid (Avatec, Bovatec) is a divalent polyether ionophore that is a fermentation product of *Streptomyces lasaliensis* and was the second ionophore marketed in the United States. Lasalocid is fed at 0.0075–0.0125% (75–125 ppm) for the prevention of coccidiosis. Lasalocid is well tolerated when fed with tiamulin (Meingasser et al. 1979). Lasalocid is transmitted to eggs of hens that have been fed lasalocid for 1 week. Lasalocid does not appear to accentuate heat distress, but its usage has been associated with wet litter at the higher dosage levels.

SALINOMYCIN. Salinomycin (Bio-Cox) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces albus* and was the third ionophore marketed in the United States. Salinomycin is active against sporozoites and early and late asexual stages of chicken coccidia (Conway et al. 1993). Salinomycin is fed at 66 ppm for prevention of coccidiosis in broilers. Do not feed to layers. It is not for use with pellet binders. No withdrawal is required. Salinomycin does not adversely affect egg production or egg quality. Tiamulin may interfere with the metabolism of salinomycin in chickens and cause weight suppression (Meingasser et al. 1979). Salinomycin will cause deaths in horses and adult turkeys that ingest feeds containing it.

NARASIN. Narasin (Monteban) is a monovalent polyether ionophore that is a fermentation product of *Streptomyces aureofaciens*. It is structurally similar to salinomycin, differing only in the presence of a methyl group in narasin that is not present in salinomycin. Narasin is fed at 70 ppm for the prevention of coccidiosis in broilers. It is for broilers only and should not be fed to other types of chickens. No withdrawal is required. It does not adversely affect egg production or egg quality. Narasin may cause fatalities in horses that ingest it, and it should not be fed to adult turkeys. Tiamulin may interfere with the metabolism of narasin in chickens and cause weight suppression (Meingasser et al. 1979).

A combination of narasin and nicarbazin (Maxiban) is fed at 40 ppm for prevention of coccidiosis in broilers. It is for broilers only and should not be fed to other types of chickens. A 4-day withdrawal period is required. The use of this combination has been associated with increased mortality of broilers in times of heat distress. Feed containing this combination may cause fatalities in horses that ingest it, and it should not be fed to adult turkeys.

MADURAMICIN. Maduramicin (Cygro) is a monovalent monoglycoside polyether ionophore that is a fermentation product of *Actinomadura yumaense*. It is no longer available in the United States. It is used for the prevention of coccidiosis in broilers and fed at 5 ppm. It is for broilers only and should not be fed to other types of chickens. A 5-day withdrawal period is required. Maduramicin does not adversely affect egg production or egg quality (Jones et al. 1990). Maduramicin is well tolerated when fed with tiamulin (Meingasser et al. 1979). If maduramicin is fed at 6 ppm, an adverse effect on growth and feathering may occur.

SEMDURAMICIN. Semduramicin (Aviax) is a monovalent monoglycoside polyether ionophore that is a fermentation product of a mutant of *Actinomadura roseorufa* (Ricketts et al. 1992). The parent produced a diglycoside form of semduramicin that had to be semisynthetically modified. Both forms of the monoglycoside agent have identical activity. It is fed at 25 ppm for prevention of coccidiosis in broiler chickens. No withdrawal time is required. It is well tolerated when coadministered with tiamulin (Ricketts et al. 1992).

TABLE 49.7—Sulfonamides

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Sulfadiazine	4-amino-*N*-2-pyrimidinylbenzenesulfonamide ($C_{10}H_{10}N_4O_2S$) [250.28]	Sulfadimethoxine	4-amino-*N*-(2,6-dimethoxy-4-pyrimidinyl)-benzenesulfonamide ($C_{12}H_{14}N_4O_4S$) [310.33]	Sulfadoxine	4-amino-*N*-(5,6-dimethoxy-4-pyrimidinyl)-benzenesulfonamide ($C_{12}H_{14}N_4O_4S$) [310.34]	Sulfaguanidine	4-amino-*N*-(aminoiminomethyl)-benzenesulfonamide ($C_7H_{10}N_4O_2S$) [214.24]	Sulfamethazine	4-amino-*N*-(4,6-dimethyl-2-pyrimidinyl)-benzenesulfonamide ($C_{12}H_{14}N_4O_2S$) [278.32]	Sulfamethoxazole	4-amino-*N*-(5-methyl-3-isoxazolyl)-benzenesulfonamide ($C_{10}H_{11}N_3O_3S$) [253.31]	Sulfaquinoxaline	4-amino-*N*-2-quinoxalinyl-benzenesulfonamide ($C_{14}H_{12}N_4O_2S$) [300.33]	Sulfanitran	4′-[(*p*-nitrophenyl)sulfamoyl]acetanilide ($C_{14}H_{13}N_3O_5S$) [335.34]	
the bile. The remainder is excreted as metabolites by the kidneys. Use of trimethoprim and other DHFR/TS inhibitors is associated with adverse effects on bone marrow. Administration of folinic acid usually will counteract these adverse effects (see toxoplasmosis, EPM below).

Pyrimethamine is available in 25 mg tablets (Daraprim). Pyrimethamine is well absorbed after oral administration and is slowly but extensively metabolized. Less than 3% is excreted in the urine in the first 24 hours, and the half-life is 4–6 days in human beings (Van Reken and Pearson 1990). It accumulates in the kidneys, lungs, liver, and spleen. It is excreted in urine as metabolites, but some pyrimethamine can be found in the milk. Very high doses of pyrimethamine are teratogenic in laboratory animals.

Combinations of Sulfonamides and DHFR/TS Inhibitors. Ormetoprim combined with sulfadimethoxine (Rofenaid 40) is the only combination

Toltrazuril, although not available in the United States, has been shown to reduce the signs of coccidiosis in naturally infected nursing pigs when a single oral 20–30 mg/kg BW dose is given to 3- to 6-day-old pigs (Driesen et al. 1995). Clinical signs were reduced from 71 to 22% of nursing pigs, and diarrhea and oocyst excretion were also decreased by the single oral treatment.

DOG COCCIDIOSIS. Oocysts of four *Isospora* spp. (*I. canis, I. ohioensis, I. neorivolta,* and *I. burrowsi*) can be found in the feces of dogs (Lindsay et al. 1997a). Additionally, oocysts of *Cryptosporidium, Hammondia,* and *Neospora* spp. and sporocysts of *Sarcocystis* spp. are found in the feces of dogs. These usually are not associated with disease.

Clinical signs of canine coccidiosis caused by *Isospora* spp. are bloody or mucoid diarrhea, abdominal pain, dehydration, anemia, anorexia, weight loss, and emesis, as well as neurologic and respiratory signs. Animals that are nursing, recently weaned, or immunocompromised are most likely to develop clinical signs of disease. Coccidiosis can cause severe problems in some kennels, and the stress of shipping may cause outbreaks of coccidiosis in young dogs.

Several agents have been used for the treatment of intestinal coccidiosis in dogs (Lindsay et al. 1997a), but only sulfadimethoxine is approved by the FDA for this usage. Sulfadimethoxine is used for treatment of coccidiosis at 50 mg/kg BW for 10 days or at 55 mg/kg BW for 1 day, then at 27.5 mg/kg BW until clinical signs disappear. Sulfadimethoxine is combined with ormetoprim (Primor) and used as a treatment for coccidiosis at 11 mg/kg BW ormetoprim plus 55 mg/kg BW sulfadimethoxine for up to 23 days.

Sulfadiazine is combined with trimethoprim (Tribrissen, Di-Trim) and used as a treatment for coccidiosis at 5–10 mg/kg BW trimethoprim combined with 25–50 mg/kg BW of sulfadiazine and given for 6 days to dogs over 4 kg BW; dogs under 4 kg BW are given half this dosage for 6 days.

Amprolium is used in the treatment of coccidiosis at 300–400 mg/kg BW for 55 days or at 110–220 mg/kg BW for 7–12 days. Amprolium is also used in the drinking water (sole source) at 1.5 tbsp/gal for up to 10 days. Amprolium can be combined with sulfadimethoxine and used for the treatment of coccidiosis at 150 mg/kg BW amprolium and 25 mg/kg BW sulfadimethoxine for 14 days.

CAT COCCIDIOSIS. Oocysts of two *Isospora* spp. are found in cats (Lindsay et al. 1997a). Additionally, oocysts of *Toxo. gondii, Hammondia hammondi, Besnoitia* spp., *Cryptosporidium parvum,* and *Sarcocystis* spp. (sporocysts) are found in the feces of cats. Clinical signs are usually not associated with the presence of these oocysts.

Clinical coccidiosis in cats is similar to that seen in dogs. No agents are approved by the FDA for the treatment of coccidiosis in cats. Agents and dosages used for the treatment of canine coccidiosis are also used for the treatment of feline coccidiosis.

RABBIT COCCIDIOSIS. Intestinal and hepatic coccidiosis in rabbits is one of the most economically important diseases of commercially reared rabbits. *Eimeria stiedai* is the cause of hepatic coccidiosis, and important intestinal species include *E. flavescens* and *E. intestinalis.* Traditionally, the sulfonamides have been used extensively in prophylaxis and treatment. However, resistant strains have developed, limiting the effectiveness of these agents in some facilities. Sulfaquinoxaline is used at 0.03% in the drinking water for 10 days for treatment of coccidiosis. A 10-day withdrawal is required. Lasalocid is approved for use in the prevention of hepatic coccidiosis in rabbits and is fed at 0.0125% until the rabbits are 6.5 weeks old. No withdrawal is required.

Cryptosporidiosis. The life cycle of this coccidian is direct. It is unusual in that it develops in the microvillous borders of a variety of epithelial tissues and produces fully sporulated oocysts. *Cryptosporidium parvum* causes intestinal disease in immunocompetent human beings and other mammals (Fayer et al. 1997). Respiratory and biliary tract infections and disease occur in immunocompromised humans and nonhuman primates. *Cryptosporidium baileyi* causes respiratory disease in chickens and other avian species, and *C. meleagridis* causes intestinal and respiratory disease in turkeys (Fayer et al. 1997).

Cryptosporidial infections are remarkably resistant to treatment with most anticoccidials and other antimicrobial agents. Blagburn and Soave (1997) reported that over 100 therapeutic agents have been examined against cryptosporidiosis in humans and animals with little success. The most promising agent identified to date is paromomycin. A naturally infected cat with cryptosporidial diarrhea was successfully treated with oral paromomycin given at 165 mg/kg BW every 12 hours for 5 days (Barr et al. 1994). Treatment of calves with oral paromomycin at 50, 25, or 12.5 mg/kg BW twice daily was effective in preventing oocyst production (50 mg/kg dose) or in delaying the onset of oocyst production and in greatly reducing the numbers of oocysts excreted (12.5–25 mg/kg BW doses) when started 1 day before inoculation and continued for 10 days (Fayer and Ellis 1993). Treatment of 2- to 4-day-old goat kids with oral paromomycin at 50 mg/kg BW twice daily for 10 days was effective in preventing cryptosporidiosis (Mancassola et al. 1995).

The anticryptosporidial activity of paromomycin apparently does not involve trafficking through the host cell cytoplasm but involves movement of the agent through altered apical membranes that surround the developing parasites (Griffiths et al. 1998). Paromomycin does not exert its effects on extracellular stages of *C. parvum* (Griffiths et al. 1998).

Experimental studies demonstrate that *C. baileyi* of chickens is refractory to treatment with approved

Most of the chemotherapeutic agents used to treat malaria in human beings were first evaluated against malaria in birds. Chloroquine, 7-chloro-4-(4-diethylamino-1-methylbutylamino)quinoline, has been used in the treatment of avian malaria. *Plasmodium relictum* causes clinical malaria in penguins that are kept in zoos or aquaria. It is treated with an oral loading dose of 10 mg/kg BW chloroquine, followed by oral doses of 5 mg/kg BW given 6, 18, and 24 hours later (Clubb 1986).

Leucocytozoon spp. occur only in birds and most are nonpathogenic. *Leucocytozoon smithi* of turkeys, *Leu. simondi* of ducks and geese, and *Leu. caulleryi* of chickens are the most important and pathogenic species. Anemia and enlargement of the liver and spleen are the clinical signs associated with these pathogenic species. *Leucocytozoon simondi* occurs in North America, Europe, and parts of Asia, and *Leu. smithi* occurs in the United States. *Leucocytozoon caulleryi* occurs mainly in southern and eastern Asia. Pyrimethamine (1 ppm) combined with sulfadimethoxine (10 ppm) will prevent but not cure *Leu. caulleryi* infections. Clopidol is approved for the prevention of *Leu. smithi* infections when fed at its anticoccidial levels (0.0125–0.0250%).

Haemoproteus spp. are usually nonpathogenic. Treatment of *Haemoproteus* infections in most birds is not justified because of the minor impact on health.

Canine Hepatozoonosis. *Hepatozoon canis* is a normally nonpathogenic species found in dogs in many regions of the world, including Asia, Africa, southern Europe, the Middle East, Japan, Malaysia, and the Philippines. Diagnosis is made by demonstrating stages in infected leukocytes. Its primary vector is *Rhipicephalus sanquineous,* the brown dog tick. Dogs eat the tick and become infected.

Hepatozoon americum causes canine hepatozoonosis in the Americas (Vincent-Johnson et al. 1997). In the southern United States, *H. americanum* infections are being identified more frequently (Macintire et al. 1997). It is transmitted by *Amblyoma maculatum,* the Gulf Coast tick (Mathew et al. 1998). Clinical signs include fever, stiffness, gait abnormalities, marked lethargy, weight loss, and mucopurulent ocular discharge. A marked leukocytosis is present but no or few gamont stages are present in the blood. Asexual stages are present in muscle tissues, and a pyogranulomatous myositis develops. Periostial bone growth can often be documented on radiographs. Diagnosis is made by demonstrating stages in muscle biopsy or occasionally demonstrating gamonts in blood smears. Relapse is common and most untreated cases are fatal. Toltrazuril given orally at 5 mg/kg BW every 12 hours for 5 days and toltrazuril given orally at 10 mg/kg BW every 12 hours for 10 days caused remission of clinical signs in naturally infected dogs in 2–3 days (Macintire et al. 2000). Unfortunately, most treated dogs relapsed and eventually died from hepatozoonosis. The response of *H. americanum*–infected dogs to treatment with a combination of trimethoprim plus sulfadiazine (orally 15 mg/kg BW every 12 hours) plus clindamycin (orally 10 mg/kg BW every 8 hours) plus pyrimethamine (orally 0.25 mg/kg BW daily) (TCP therapy) for 14 days demonstrated that remission of clinical signs in naturally infected dogs occurred in 2–3 days, but most treated dogs relapsed and eventually died from hepatozoonosis (Macintire et al. 2000). The best results have been seen in dogs that have undergone TCP therapy and then been placed on a daily oral treatment program with 10–20 mg/kg BW decoquinate. The decoquinate treatment must be continued because once it is stopped, relapse and clinical disease occur (Macintire et al. 2000). Dogs have tolerated this treatment and survived for over 18 months.

SUBCLASS PIROPLASMASINA: THE PIROPLASMS. Piroplasms are tick-transmitted protozoans that include the genera *Babesia, Theileria,* and *Cytauxzoon.* Asexual multiplication occurs in the vertebrate host's blood cells (*Babesia*) and host's lymphoid cells and blood cells (*Theileria* and *Cytauxzoon*). Sexual stages and sporulation occur in the tick host. Animals become infected when the tick feeds and injects sporozoites. Tick control programs and vaccination are used in conjunction with chemotherapy to prevent and treat animal infections.

Babesiosis. Clinical signs associated with babesiosis are hemolytic anemia, anorexia, jaundice, fever, central nervous system signs, and hemoglobinuria. Death may result from infection with some of the highly pathogenic species. Babesiosis has the greatest economic impact on cattle and is one of the most important diseases of tropical and subtropical regions, where approximately 600 million cattle are at risk of infection. *Babesia bigemina, Bab. bovis,* and *Bab. divergens* are the causative agents of bovine babesiosis. Bovine babesiosis has been eradicated from the United States.

Equine babesiosis is caused by *Bab. equi* and *Bab. caballi* and is widely distributed throughout the Tropics and, less frequently, the Subtropics. The movements of infected horses are restricted; carrier horses must be cleared of infection before being imported into areas free of the disease.

Canine babesiosis is caused primarily by *Bab. canis* and is transmitted by *Rhipicephalus sanguineous* in the United States. *Babesia gibsoni* has recently been documented in dogs in the United States and is much harder to treat.

Babesia felis and *Bab. herpailuri* cause babesiosis in cats in South Africa.

Babesia infection in wild ruminants is common but its significance is unknown.

Several drugs are used to treat *Babesia* infections and most are potentially toxic for the host. Treatment of species having large piroplasms is generally more successful than treatment of species that have small piroplasms. Treated animals may become carriers. Agent

Imidocarb given at 1–2 mg/kg BW will eliminate *Bab. caballi* from horses if given twice during a 24-hour period (Kuttler 1988). A single 7.5 mg/kg BW SC imidocarb treatment will completely clear *Bab. canis* infections in dogs (Penzhorn et al. 1995). Feline babesiosis is refractory to treatment with imidocarb.

A single dose of 3.5 mg/kg BW SC diminazene, followed the next day by a single dose of 7.5 mg/kg BW SC imidocarb, will completely clear *Bab. canis* infections in dogs (Penzhorn et al. 1995).

TETRACYCLINES. A long-acting formulation of oxytetracycline (LA/200) is useful in prophylaxis of bovine *Bab. divergens* infection if 20 mg/kg BW is given IM every 4 days for 3 weeks after exposure; 15–10 mg/kg BW given IM every 4 days causes moderation in the clinical signs (Kuttler 1988). Chlortetracycline may be effective against *Bab. equi* infection in horses if 0.5–2.6 mg/kg BW is given IV daily for 6 days early in the infection (Kuttler 1988). Doxycycline is effective at preventing clinical *Bab. canis* infections in dogs if given at 10 mg/kg BW twice daily for 11 days (Vercammen et al. 1996).

Theileriosis. Theileriosis is a severe disease of cattle in Africa and is caused by *Theileria parva*. Several *Theileria* spp. infect wild ruminants in the United States, but none of these causes serious illness.

Parvaquone (Clexon) (Table 49.4) is given IM at 20 mg/kg BW for a single treatment and is curative for *Theileria* infections in cattle. It acts on the macroschizonts and intraerythrocytic piroplasms.

Buparvaquone (Butalex) (Table 49.4) is given IM at 2.5 mg/kg BW for 1–2 treatments and is curative for *Theileria* infections in cattle. It acts on the macroschizonts and intraerythrocytic piroplasms.

Halofuginone is given orally at 1–2 mg/kg BW for a single treatment and is curative for *Theileria* infections in cattle. At 2 mg/kg BW transient diarrhea may occur.

Tetracyclines can also be used to treat *Theileria* infections in cattle but are less effective and must be given in large doses early in the infection and used for longer periods of treatment.

Cytauxzoonosis. *Cytauxzoon felis* infections in cats are treated with parvaquone IM or SC at 10–30 mg/kg BW daily for 2–3 days (Kier 1990). However, only 2 of 18 treated cats survived, indicating that *C. felis* is less sensitive to this agent than are the cattle *Theileria* spp.

Buparvaquone is not effective against *C. felis* in cats when given IM or SC at 10 mg/kg BW daily for 2–3 days (Kier 1990).

PHYLUM CILIOPHORA: THE CILIATES

CILIATES OF MAMMALS. Ciliates move by means of cilia. Ciliates of mammals are generally commensal and cause little harm. They reproduce asexually by transverse binary fission, and most form cyst stages. *Balantidium coli* rarely causes GI disease in human beings, nonhuman primates, pigs, and dogs. Metronidazole and tetracycline are active against *Bal. coli*. *Balantidium coli* infections in human beings are treated orally with 500 mg tetracycline 4 times a day for 10 days.

CILIATES OF FISH. Ciliates are the most important parasites of farm-raised fish and include the well-known *Ichthyopthirius multifiliis*, the causative agent of "Ich" or "white spot" disease. Other important ciliates include *Ambiphrya* spp., *Chilodonella* spp., *Trichodina* spp., and *Trichophyra* spp. These protozoans infect the gills and skin and cause respiratory problems. The agents used to treat fish protozoans are limited because of the lack of approval. Formalin (Formalin-F, Paracide-F) is approved for use in commercially reared food-fish. Water conditions and chemistry as well as host species are important considerations. Copper sulfate can be toxic in acidic water.

Formalin, dyes (malachite green, methylene blue), and salts are used in the treatment of *Ichthyopthirius* infections, and many of these treatments are designed to kill stages in the environment (tomites) and do not directly kill intradermal or intralamellar stages (trophozoites). The external mucus layer of the fish makes penetration of these agents difficult. Treatment regimes that are effective for *Ichthyopthirius* are also effective for other ciliates and many flagellates ectoparasitic on fish. Formalin is used at 200 mg/L in a bath for 1 hour or at 20 mg/L for 5 days. Malachite green is used at 1.5 mg/L in a bath for 6–24 hours. Methylene blue is used at 1–3 mg/L in a bath for 3 days. Potassium permanganate is used at 4 mg/L in a bath for 30–60 minutes. Sodium chloride is used at 30,000 mg/L in a bath for 1 hour for 7 days.

PHYLUM MICROSPORA

The phylum Microspora is made up of a group of obligatorily intracellular spore-producing parasites that have a direct life cycle. They are important pathogens of insects and cultured fish but are of little importance in veterinary medicine. *Encephalitozoon cuniculi* occasionally causes central nervous system and renal lesions in laboratory rabbits. It can cause central nervous system disease in young dogs. Several new species of this phylum have been recognized as causes of ocular, pulmonary, biliary, intestinal, and muscular disease in human beings that have AIDS. Albendazole given at 400 mg twice daily for 3 weeks has been shown to clear *Enceph. intestinalis* infections in human AIDS patients (Molina et al. 1998).

Arthropods include a large and diverse group of parasites of domestic animals. Parasitic arthropods of veterinary importance include insects (fleas, lice, flies) and acarines (mites and ticks). Insects not normally considered parasites, such as blister beetles or assassin bugs, also may cause irritation either by inflicting painful bites or by producing toxic substances that irritate the skin or mucosal surfaces of animals exposed to them. Mechanisms of ectoparasite-induced diseases or means by which parasitic arthropods affect animal health include (1) loss of blood, resulting in anemia, (2) physical damage and irritation to skin and hides, (3) allergic reactions to venoms and toxins, (4) decreased resistance to other diseases, (5) reductions in weight gains, milk and egg production, and feed conversion efficiencies in food-producing animals, (6) reduction in reproduction efficiency, and (7) transmission of other disease agents (Loomis 1986).

Impacts of ectoparasitism are also of economic concern to veterinarians, livestock producers, and pet owners. For example, one estimate of annual losses imposed by arthropod pests on livestock, excluding horses, exceeded $3 billion (Drummond et al. 1988). This estimate did not include the costs of control of arthropod pests. Another estimate predicted that losses from arthropod parasites in the beef and dairy cattle production industry, combined with the costs of control, would reach $2 billion (Loomis 1986). In the companion animal arena, control of flea infestations on pet animals and in premises is estimated to cost pet owners in excess of $750 million per year. Given the increases in costs of animal production and veterinary care, today's estimates of ectoparasite impacts and cost to producers and pet owners would certainly exceed those estimates of more than a decade ago.

Chemicals commonly used to control external parasites are known as ectoparasiticides. Chemically, they are a heterogeneous group of agents that act through various mechanisms. Ectoparasiticidal agents are classified on the basis of either their chemistry or their mechanisms of action. The major groups of ectoparasiticides are the plant-derived agents (botanicals), the synthetic pyrethroids, the chlorinated hydrocarbons, the organophosphates, the carbamates, the formamidines, and the miscellaneous compounds comprising the inorganics, the growth regulators and development inhibitors, and macrocyclic lactones (avermectins and milbemycins). Several of the new miscellaneous agents are currently entering the marketplace.

Information presented in this chapter will deal primarily with the chemistry, pharmacology, and toxicology of ectoparasiticides of domestic animals, excluding poultry. It is not the intention of the authors to review the biology of ectoparasites. For those who require a review of common and important arthropod parasites of domestic animals, there are several excellent treatises to which we refer you: Soulsby 1982; Urquhart et al. 1996; Bowman 1999.

TABLE 50.2—Synthetic pyrethroid compounds

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Allethrin	2,2-dimethyl-3-(2-methyl-1-propenyl)cyclo-propanecarboxylic acid 2-methyl-4-oxo-3-(2-propenyl)-2-cyclopentenl-1-yl ester ($C_{19}H_{26}O_3$) [302.40]	Cyfluthrin	3-(2,2-dichloroethenyl)-2,2-dimethylcyclopropane-carboxylic acid cyanol(4-fluoro-3-phenoxyphenyl)-methyl ester ($C_{22}H_{18}Cl_2FNO_3$) [434.29]	Cyhalothrin	3-(2-chloro-3,3,3-trifluoro-l-propenyl)-2,2-dimethyl-cyclopropanecarboxylic acid cyano(3-phenoxy-phenyl)methyl ester ($C_{23}H_{19}ClF_3NO_3$) [449.86]	Cypermethrin	3-(2,2-dichloroethenyl)-2,2-dimethylcyclopropane-carboxylic acid cyano(3-phenoxyphenyl)-methyl ester ($C_{22}H_{19}Cl_2NO_3$) [416.30]	Fenvalerate	4-chloro-α-(l-methylethyl)benzeneacetic acid cyano(3-phenoxyphenyl)methyl ester ($C_{25}H_{22}ClNO_3$) [419.92]	Permethrin	3-(2,2-dichloroethenyl)-2,2-dimethyl-cyclopropane-carboxylic acid (3-phenoxyphenyl)methyl ester ($C_{21}H_{20}Cl_2O_3$) [391.29]	Resmethrin	[5-(phenylmethyl)-3-furanyl]methyl 2,2-dimethyl-3-(2-methyl-l-propenyl)cyclopropanecarboxylate ($C_{22}H_{26}O_3$) [338.40]	
Pyrethroids are classified on the basis of symptoms and neurophysiological effects on target organisms (Gammon et al. 1981). Pyrethroids whose actions result in rapid onset of hyperactivity and repetitive action potentials are type I compounds (e.g., permethrin, resmethrin). Those whose lethal effects are observed at very low doses and with few behavior changes are classified as type II compounds (e.g., fenvalerate, cypermethrin; Hart 1986).

TOXICITY. Pyrethrins and pyrethroids are among the safest of the ectoparasiticides. The selectivity ratio of the pyrethrins and pyrethroids, which compares their toxicity in mammals to their toxicity in insects, generally exceeds 1000 (Table 50.14). In contrast, agents such as the organochlorines, organophosphates, and carbamates have selectivity ratios of 100 or less.

Mechanisms of toxicity of pyrethrins and pyrethroids in mammals are similar to those described for insects. As a result, clinical signs of pyrethrin and pyrethroid toxicity are exemplary of nerve and muscle disorders (Table 50.15; Valentine 1990). Clinical signs in mildly affected dogs and cats include hypersalivation, vomiting, diarrhea, mild tremors, hyperexcitability, or depression. In severely affected animals, signs include hyperthermia, hypothermia, disorientation, and seizures. The period of onset of clinical signs varies from several to many hours, depending on the agent and route of exposure.

ALLETHRIN. Allethrin is one of several first-generation pyrethroids; another is resmethrin. Allethrin, a mixture of several isomers, is a clear, amber-colored, viscous liquid that is insoluble in water but freely soluble in alcohol. The acute oral LD_{50} value for allethrin in the rat is greater than 900 mg/kg BW. The esters of the natural, dextrorotatory (1*R*)-*trans*-chrysanthemic acid are known as bioallethrins. In shampoos for control of fleas and ticks on dogs, *d-trans* allethrin is the active ingredient.

PERMETHRIN. Permethrin, a third-generation pyrethroid, occurs either as a colorless crystalline powder or as a pale yellow, viscous liquid. It is a mixture of *trans* (60%) and *cis* (40%) isomers. The acute oral LD_{50} value of permethrin in the rat is 3800 mg/kg BW. Permethrin is a widely used pyrethroid. It is an active ingredient in collars, sprays, shampoos, dips, and topical concentrates for control of fleas and ticks on dogs and cats; in sprays, dusts, roll-ons, pour-ons, and ear tags for control of flies, lice, ticks, and mites on cattle; in sprays and pour-ons for control of flies, lice, ticks, and keds on sheep and goats; in sprays, paints, dips, and dusts for control of flies, lice, mites, and ticks in swine; and in sprays, wipes, and dusts for control of flies and ticks on horses. The superior stability of permethrin results in residual activity of up to 28 days for some formulations (MacDonald and Miller 1986).

FENVALERATE. Fenvalerate, a type II pyrethroid, occurs as a clear, yellow, viscous liquid, with an acute oral LD_{50} value of 451 mg/kg BW in the rat. Fenvalerate is the active ingredient in ear tags for control of flies on cattle; in sprays and pour-ons for control of lice and keds on sheep and goats; in sprays and pour-ons for control of lice and mites on swine; and in sprays for control of flies, lice, and ticks on horses.

CYPERMETHRIN. Commercial cypermethrin, a viscous semisolid material, is a mixture of eight different isomers. The acute oral LD_{50} value of cypermethrin in the rat is 250–4123 mg/kg BW. Cypermethrin is combined with chorpyrifos as the active ingredients in ear tags for control of flies and ticks on cattle.

ZETAMETHRIN. Zetamethrin is beta-cypermethrin. Zetamethrin is very similar in structure to cypermethrin. However, its oral LD_{50} (106 mg/kg) is less than that of cypermethrin. Beta-cypermethrin is the active ingredient in ear tags for the control of horn flies, face flies, ticks, and lice on cattle.

RESMETHRIN. Resmethrin is a waxy, white to tan, solid material, with a chrysanthemum-like odor. It is insoluble in water but moderately soluble in kerosene. The safety of resmethrin is evident in its very low mammalian toxicity. The acute oral LD_{50} of resmethrin in the rat is in excess of 4000 mg/kg BW. The activity of resmethrin is not enhanced by synergists. It is the only active ingredient in sprays and shampoos for control of fleas and ticks on dogs and cats.

Λ CYHALOTHRIN. Λ Cyhalothrin is a white, odorless, crystalline solid that is virtually insoluble in water. Its acute oral LD_{50} value in the rat is 50.8–75.3 mg/kg BW. Λ Cyhalothrin is the active ingredient in ear tags for control of flies on cattle.

CYFLUTHRIN. Cyfluthrin is a fluorinated pyrethroid that occurs as a yellow-brown oil. Its acute oral LD_{50} value in the rat is 500–800 mg/kg BW. Cyfluthrin is the active ingredient in ear tags for control of flies and ticks on cattle.

Rotenone. Rotenone is an extract of certain plants of the genus *Derris*, principally *Derris elliptica*. It is also known as derris root, tuba-root, and aker-tuba. The extract is a white, odorless, crystalline material that is insoluble in water but is soluble in many organic solvents. The acute oral LD_{50} value for rotenone in the rat is 132–150 mg/kg BW. It exerts its effects by inhibiting the target ectoparasites' respiratory systems, specifically nicotinamide adenine dinucleotide (NADH) oxidation and subsequent generation of adenosine triphosphate (ATP) (Fukami 1976). Rotenone is more toxic to mammals than either the pyrethrins or the pyrethroids but is still considered safe for use in dogs and cats (MacDonald and Miller 1986). It is prohibitively toxic to swine, fish, and snakes and should not be used on these hosts. Rotenone is an active ingredient in ear drops and dips for control of fleas, ticks, lice, and mites on dogs and cats (Table 50.9). It is sometimes formulated with pyrethrins or synergists to potentiate its ectoparasiticidal activity.

***d*-Limonene and Linalool.** Limonene and linalool are natural insecticidal products found in the volatile oil expressed from the peel of oranges and other citrus fruits. A monoterpene, *d*-limonene is a fast-acting agent, immobilizing insects within minutes of exposure. The vapors of *d*-limonene are toxic to target insects; hence, direct contact with the insect is unnecessary for the agent to exert its effect. *d*-Limonene evaporates completely from treated animals, leaving no residual insecticide on their hair coats. It is a safe insecticide, although toxicoses have been reported in cats following its use (Hooser 1990; Table 50.15). The acute oral LD_{50} value in the rat is greater than 5000 mg/kg BW. *d*-Limonene and linalool are active ingredients in sprays, shampoos, and dips for control of fleas on dogs (Table 50.9).

CHLORINATED HYDROCARBONS (ORGANOCHLORINES). The term "chlorinated hydrocarbon insecticide" connotes to many a sole agent with a history of controversy. That agent of course is dichlorodiphenyltrichloroethane, or DDT. Few can forget Rachel Carson's 1962 book *Silent Spring*, which initiated widespread discussion on the environmental problems associated with its use. In reality, widespread resistance to DDT probably contributed as much to its decline as did its persistence in the environment. At the height of its production, 400,000 tons of DDT were used annually in worldwide pest control programs.

The chlorinated hydrocarbons are divided into four chemical groups: the DDT group, the diene-organochlorine group, the hexachlorocyclohexane

Table 50.4—Organophosphate compounds

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Chlorfenvinphos	phosphoric acid 2-chloro-1-(2,4-dichlorophenyl)-ethenyl diethyl ester ($C_{12}H_{14}Cl_3O_4P$) [359.56]	Chlorpyrifos	phosphorothioic acid O,O-diethyl O-(3,5,6-trichloro-2-pyridinyl) ester ($C_9H_{11}Cl_3NO_3PS$) [350.57]	Coumaphos	phosphorothioic acid O-(3-chloro-4-methyl-2-oxo-2*H*-1-benopyran-7-yl) O,O-diethyl ester ($C_{14}H_{16}ClO_5PS$) [362.78]	Diazinon	phosphorothioic acid O,O-diethyl O-[6-methyl-2-(1-methylethyl) -4-pyrimidinyl] ester ($C_{12}H_{21}N_2O_3PS$) [304.36]	Dichlorvos	phosphoric acid 2,2-dichloroethenyl dimethyl ester ($C_4H_7Cl_2O_4P$) [220.98]	Ethion	O,O,O,O-tetraethyl S,*S*-methylene bisphosphorodithioate ($C_9H_{22}O_4P_2S_4$) [384.48]	Famphur	phosphorothioic acid O-[4-[(dimethyl-amino)-sulfonyl] phenyl] O,O-dimethyl ester ($C_{10}H_{16}NO_5PS_2$) [325.36]	Fenthion	phosphorothioic acid O,O-dimethyl O-[3-methyl-4-(methylthio)phenyl] ester ($C_{10}H_{15}O_3PS_2$) [278.34]	Malathion	[(dimethoxy phosphinothioyl)thio] butanedioic acid diethyl ester ($C_{10}H_{19}O_6PS_2$) [330.36]	
(continued)

CARBAMATES

Chemistry. Early carbamate insecticides were derivatives of dithiocarbamic acid. Continued development led to the synthesis of the substituted-phenyl monomethylcarbamates, several of which possessed excellent insecticidal potential. A major milestone in insecticide chemistry was achieved when the methylcarbamates were successfully synthesized (Kuhr and Dorough 1976). Thousands of methylcarbamate insecticides have been synthesized, although only about a dozen have been developed successfully as commercial agents (Ivie and Rowe 1986).

Mechanism of Action. Carbamates inhibit the action of the enzyme AChE in a manner somewhat different from that of the organophosphates. Carbamates compete for enzyme-active sites utilizing a process known as carbamylation, a reaction that blocks the action of the enzyme without changing it structurally. When the bond joining the carbamate insecticide and AChE is hydrolyzed, the fully active enzyme is released. Carbamate agents are considered slowly reversible inhibitors of AChE (Fikes 1990). This terminology, as discussed above with the organophosphates, is somewhat misleading in that the carbamate agent undergoes hydrolysis during the reaction. True reversible inhibitors are not destroyed during their reactions with target molecules. Regardless of the mechanism of inhibition of AChE, the effects on target organisms and signs of toxicosis in nontarget mammalian hosts are the same.

Toxicity. The nature and severity of carbamate-induced toxicosis are quite variable. Characteristics and severity depend upon the carbamate agent involved, its route of exposure, its affinity for AChE, and its pharmacokinetics in the host. In general, signs of toxicosis and interventional strategies are similar to those discussed for the organophosphates (Table 50.15).

Carbaryl. Carbaryl occurs as a white, crystalline solid material with an extremely low solubility in water (Table 50.5). However, carbaryl is readily solubilized in nonpolar organic solvents. Its acute oral LD_{50} value in the rat is 850 mg/kg BW. It is widely used in products for control of ectoparasites of companion animals. It is the active ingredient in shampoos, sprays, dusts, and ear drops for control of fleas, ticks, mites, and lice on dogs and cats. Carbaryl-containing products also often contain organophosphates, pyrethrins, synergists, or repellents to enhance their activity and effects (Table 50.9).

Propoxur. Propoxur is a white to tan, crystalline solid material (Table 50.5). It is virtually insoluble in water but is readily soluble in polar organic solvents. The acute oral LD_{50} value of propoxur in the rat is 100 mg/kg BW. Propoxur is the active ingredient in flea and tick collars for use on dogs (Table 50.9).

FORMAMIDINES. The formamidines are a novel group of acaricides that exert their effects in part by inhibiting the enzyme monoamine oxidase. Monoamine oxidase is responsible for metabolism of neurotransmitter amines present in the nervous system of susceptible ticks and mites (Atkinson et al. 1974). Treatment with formamidines leads to detachment of blood-feeding arthropods (Stone and Knowles 1974). Amitraz in the only formamidine ectoparasiticide currently used in veterinary medicine. Amitraz (Table 50.6) is a straw-colored, crystalline material, slightly soluble in water but freely soluble in most organic solvents. The acute oral LD_{50} value for amitraz in the rat is 800 mg/kg BW. Amitraz is the active ingredient in dips and collars for control of mites and ticks on dogs (Table 50.9). Toxicosis in dogs following overexposure to liquids (dips) or after consumption of collars has been reported (Table 50.15). Lethargy and transient sedation are the signs most commonly associated with intoxication. Amitraz is also the active ingredient in sprays for control of lice, ticks, and mites on cattle, and in liquids for the control of lice and mites on swine (Tables 50.10, 50.12).

TABLE 50.5—Carbamate compounds

Name	Chemical name (Empirical formula) [Molecular weight]	Chemical structure
Carbaryl	1-naphthalenol methylcarbamate ($C_{12}H_{11}NO_2$) [201.22]	Propoxur	2-(1-methylethoxy)phenol methylcarbamate ($C_{11}H_{15}NO_3$) [209.24]	
Milbemycin Oxime. The milbemycins are 16-membered macrocyclic lactones that are structurally similar to the avermectins. They differ in the absence of the disaccharide substituent at carbon 13 (Table 50.7). The potent ectoparasiticidal properties of the milbemycins were actually discovered before those of the avermectins (Fisher and Mrozik 1989). It was the later discovery of the avermectins' anthelmintic properties that led to their development as parasiticides. The oxime derivative of milbemycin is currently approved and marketed for prevention of heartworm infection and control of major intestinal nematode infections in dogs (see Chap. 47). Little published information is available regarding its efficacies against ectoparasitic arthropods. One therapeutic arena in which milbemycin oxime is receiving considerable attention is in the treatment of recalcitrant generalized demodicosis (Miller and Scott 1991; Kwochka 1993). Data suggest that in cases of amitraz-resistant generalized demodicosis in dogs, daily oral milbemycin oxime therapy can be effective in ameliorating clinical signs and in eradicating mites. Miller and Scott (1991) administered milbemycin oxime daily at 0.5–1.0 mg/kg BW for a minimum of 30 days or until mites could not be demonstrated on repeated skin scrapings. Treatment was then continued for an additional 30 days. In a similar study (Reedy and Garfield 1991), successful treatment was apparently achieved in over 60% of the treatment subjects. On the basis of results obtained thus far, it is likely that 50–60% of animals with amitraz-resistant demodicosis will respond positively to treatment with milbemycin oxime (Kwochka 1993). As stated above, ivermectin is also effective against demodicosis and also should be considered in cases in which amitraz is ineffective.

Doramectin. Doramectin (Table 50.7) is also a member of the avermectin class of compounds. It is more accurately described as a mutational biosynthetic agent, presumably because it is a fermentation product obtained from a mutant strain of *Streptomyces avermitilis*. Nonetheless, much of what was stated for ivermectin will also apply to doramectin. One distinct difference between ivermectin and doramectin is their different elimination times. Doramectin has an elimination half-life that is approximately twice that of ivermectin. Doramectin is the active ingredient in both injectable and pour-on formulations for control of grubs, mites, and biting and sucking lice on cattle (Table 50.10). Doramectin is also the active ingredient in an injectable formulation for use in the control of lice and mites on swine (Table 50.12).

Eprinomectin. Eprinomectin (Table 50.7) is another representative of the avermectin class of molecules. It is a mixture of semisynthetic avermectins and is composed of greater than 90% of component B1a and less than 10% of component B1b. Its mechanism of action is similar to that described for ivermectin. Eprinomectin is a crystalline solid with an oral LD_{50} in mice of 24 mg/kg. Eprinomectin is the active ingredient in a pour-on for control of horn flies, grubs, mites, and biting and sucking lice of cattle. Eprinomectin has a very broad spectrum of activity and is unique among this class of compounds in that it has a zero time withdrawal for meat and milk.

Moxidectin. Moxidectin (Table 50.7) is the methyloxime analog of nemadectin. It is structurally more similar to the milbemycins than to the avermectins, although its spectrum of activity is similar to other endectocides such as ivermectin, eprinomectin, and doramectin. Moxidectin is a product of *Streptomyces noncynogenus*. The marketed product represents a chemically altered version of the natural product. Moxidectin is the active ingredient in a pour-on for use in cattle for control of horn flies, grubs, mites, and biting and sucking lice, and in an oral gel for control of stomach bots in horses (Tables 50.10, 50.13).

Selamectin. Selamectin is a new semisynthetic avermectin compound derived by modification of a precursor molecule produced by fermentation of a new strain of *Streptomyces avermitilis* (Table 50.7). As mentioned for other avermectins, selamectin induces muscular paralysis in target parasites by modulating movement of chloride ions through membrane ion channels. It remains unresolved as to whether modulation of chloride ion channel function is a GABA- or a glutamate-mediated event. Pharmacokinetics data indicate that selamectin enters the vascular compartment following topical administration. The estimated terminal-phase half-life following topical administration was approximately 11 days in dogs and 8 days in cats. Since this was substantially longer than the observed half-life following intravenous administration, it appears as though selamectin is continuously absorbed from the skin and subcutaneous tissues. Selamectin is the active ingredient in a 6% or 12% liquid (spot-on) for control of flea, tick, and mite infestations on dogs and cats (Table 50.9).

SYNERGISTS AND REPELLENTS

Synergists. Synergists (Table 50.8) enhance the activity of ectoparasiticides by inhibiting oxidative and hydrolytic enzymes responsible for their degradation. In so doing, synergists potentiate the activity of the active ingredients and extend their periods of knockdown. Synergists not only improve the performance of active agents but also permit their incorporation into formulations at lower rates than would be required without synergism. In addition, they are generally less toxic than active ingredients, thereby improving the safety of formulated products. Synergists are commonly employed in products containing pyrethrins, synthetic pyrethroids, organophosphates, chlorinated hydrocarbons, and carbamates.

TABLE 50.9—Ectoparasiticides for use on dogs and cats

Compound(s)	Marketed formulation(s)	Target animal(s)	Target parasite(s)
d-trans Allethrin (some formulations contain PBO[a], MGK 264[b] or sumethrin)	Shampoo	Dog, cat	Fleas, ticks
Amitraz	Dip	Dog	Mites
	Collar	Dog	Ticks
Benzyl benzoate	Lotion	Dog	Mites
Carbaryl (some formulations contain methoxychlor, PBO, BPG[c], MGK 326[d], and/or pyrethrins)	Shampoo	Dog, cat	Fleas, ticks, mites (some products claim efficacy against lice; see specific product labels)
	Spray	Dog, cat	
	Dust	Dog and/or cat	
	Ear drops	Dog, cat	
Chlorpyrifos (some formulations contain methoprene PBO, pyrethrins, or MGK 264)	Spray	Dog	Fleas, ticks
	Dip	Dog	Fleas, ticks, mites
	Collar		Fleas, ticks, mites
	Shampoo	Dog or cat	Fleas, ticks, mites
	Streaker (for back and chest streak treatment)	Dog	Fleas
Diazinon	Collar	Dog or cat	Fleas, ticks
Dichlorvos	Collar	Dog or cat	Fleas, ticks
Fipronil	Liquid (spot-on)	Dog, cat	Fleas, ticks
	Spray	Dog, cat	Fleas, ticks
Imidacloprid	Liquid (spot-on)	Dog, cat	Fleas
d-Limonene (some formulations contain linalool)	Spray	Dog, cat	Fleas
	Shampoo	Dog, cat	Fleas
	Dip (also may be added to shampoo)	Dog, cat	Fleas
Linalool (some formulations contain *d*-limonene)	Spray	Dog, cat	Fleas
Lindane	Dip, spray, bath	Dog	Fleas, ticks, lice, mites
Lufenuron (also combined with milbemycin oxime for dogs)	Tablet	Dog, cat	Fleas
	Six-month injectable	Cat	Fleas
Malathion	Liquid	Dog, cat	Fleas, ticks, lice
Methoprene (some formulations contain permethrin, chlorpyrifos or tetrachlorvinphos	Collar	Dog or cat	Fleas, ticks
	Liquid (spot-on)	Dog	Fleas, ticks
Methoxychlor (some formulations contain carbaryl)	Powder	Dog, cat	Fleas, ticks
	Collar	Dog	Fleas, ticks
Permethrin (some formulations contain PBO, MGK 264, MGK 326[b], pyrethrins, pyriproxyfen or BPG)	Collar, spray, shampoo, dip, cream rinse or topical concentrate (spot-on)	Dog and/or cat (see specific product labels)	Fleas, ticks (see specific product labels)
Phosmet	Dip	Dog	Fleas, ticks, mites
Propoxur	Collar	Dog	Fleas, ticks
Pyrethrins (some formulations contain PBO, MGK 264, MGK 326, BPG, permethrin, carbaryl, or rotenone)	Spray, foam, dust, shampoo, dip, or ear drops	Dog and/or cat (see specific product labels)	Fleas, ticks, or mites (some products claim efficacy against lice; see specific product labels)
Pyriproxyfen (combined with permethrin in certain formulations)	Spray, collar, liquid (spot-on), strip-on	Dog or cat	Fleas (combinations may control additional ectoparasites)
Resmethrin	Shampoo	Dog, cat	Fleas, ticks
Rotenone (some formulations contain pyrethrins)	Ear drops	Dog, cat	Mites
	Dip	Dog	Fleas, ticks, lice
Selamectin	Liquid (spot-on)	Dog	Fleas, ticks, mites
		Cat	Fleas, mites

[a] PBO = piperonyl butoxide (synergist).
[b] MGK 264 = *N*-octyl bicycloheptene dicarboximide (synergist).
[c] BPG = butoxypolypropylene glycol (repellent).
[d] MGK 326 = di-*n*-propyl isocinchomeronate (repellent).

TABLE 50.10—Extoparasiticides for use on cattle

Compound(s)	Marketed formulation(s)	Method of application	Target parasite(s)
Amitraz	Liquid	Spray	Lice, ticks, mites
Chlorpyrifos	Liquid	Spray	Screwworm, ear ticks
Chlorpyrifos, diazinon	Ear tag	One tag in each ear	Horn flies, face flies, stable flies, house flies, lice, ticks
Coumaphos	Wettable powder	Spray or dip	Horn flies, lice, ticks, grubs, screwworms, mites
	Liquid	Spray or dip	Horn flies, lice, mites, ticks, grubs
	Dust	Dust bag or shaker can	Horn flies, face flies, ticks
Cyfluthrin	Ear tag	One tag in each ear	Horn flies, face flies, Gulf Coast ticks, ear ticks
Λ Cyhalothrin	Ear tag	One tag in each ear	Horn flies, face flies
	Pour-on	Backline treatment	Horn flies, lice
Cypermethrin, chlorpyrifos	Ear tag	One tag in each ear	Horn flies, face flies, Gulf Coast ticks, ear ticks
Beta-cypermethrin (zetamethrin)	Ear tag	One tag in each ear	Horn flies, face flies, ticks, lice
Diazinon, chlorpyrifos	Ear tag	One tag in each ear	Horn flies, face flies, stable flies, houseflies, lice, ticks
Dichlorvos (some formulations contain pyrethrins)	Liquid	Spray	Stable flies, horn flies, houseflies, mosquitoes, gnats
Diflubenzuron	Bolus	1 bolus per 1,100 lb	Horn flies, face flies, houseflies, stable flies
Doramectin	Injectable solution	Inject subcutaneously	Grubs, mites, biting and sucking lice
	Pour-on	Backline treatment	
Eprinomectin	Pour-on	Backline treatment	Grubs, mites, biting and sucking lice, horn flies
Ethion	Ear tag	One tag in each ear	Horn flies, face flies, stable flies, lice, ticks
Famphur	Pour-on	Backline treatment	Grubs, lice
	Liquid	Spray, spot-on, backrubber	Horn flies, lice, mites, ticks (spectrum depends on formulation)
Fenthion	Pour-on	Backline treatment	Lice, horn flies
	Ear tag	One tag in each ear	Horn flies, face flies
	Low-volume pour-on	Spot treatment on the backline	Grubs, lice
	Pour-on	Backline treatment	Grubs, lice
Fenvalerate	Ear tag	One tag in each ear	Horn flies, face flies, stable flies, houseflies, ticks, lice
Invermectin	Injectable solution	Inject subcutaneously	Grubs, mites, sucking lice
	Pour-on	Backline treatment	Grubs, mites, biting and sucking lice, horn flies
	Sustained-release bolus	Oral	Grubs, sucking lice, mites, ticks
Lindane	Spray	Direct application to infested site	Ear ticks, screwworms
Malathion	Liquid	Spray, backrubber	Horn flies, lice, ticks
Moxidectin	Pour-on	Backline treatment	Grubs, mites, biting and sucking lice, horn flies
Permethrin	Liquid	Spray	Horn flies, face flies, mites, ticks, lice, various other flies
	Liquid	Spray	Horn flies, face flies, stable flies, horseflies, lice, ticks, mites
	Wettable powder	Spray	Horn flies, face flies, stable flies, horse flies, lice, ticks, mites
	Dust	Direct application	Horn flies, face flies, lice
	Ear tag	One or two tags	Horn flies, face flies (generally two tags), Gulf Coast ticks, ear ticks (some tags do not claim horn flies)
	Roll-on paste	Roll on to different body areas	Horn flies, face flies, stable flies, black flies, houseflies, botflies

TABLE 50.10—(continued)

Compound(s)	Marketed formulation(s)	Method of application	Target parasite(s)
Permethrin, chlorpyrifos	Ear tag	One or two tags	Horn flies, face flies (generally two tags), Gulf Coast ticks, ear ticks
Permethrin	Pour-on	Backline treatment	Horn flies, face flies, lice
Pirimiphos	Ear tag	One tag in each ear	Horn flies, face flies
Tetrachlorvinphos	Premix	Mix in feed	Horn flies, face flies, houseflies, stable flies
	Wettable powder	Spray	Horn flies, lice, ticks
	Dust	Dust bag, shaker can	Horn flies, lice, face flies
Trichlorfon	Dust	Dust bag	Horn flies, face flies, ticks
	Wettable powder	Spray	Horn flies, lice, ticks

Note: Some products also may contain synergists and/or repellents.

Refer to label directions for compounds approved for lactating dairy cattle and for compound withdrawal period prior to slaughter.

TABLE 50.11—Ectoparasiticides for use on sheep and goats

Compound(s)	Marketed formulation(s)	Method of application	Target parasite(s)
Fenvalerate	Liquid	Spray, pour-on	Lice, keds
Ivermectin	Drench (sheep only)	Oral drench	Nasal bots
Lindane	Spray	Direct application	Ear ticks, screwworms
Malathion	Emulsifiable concentrate	Spray	Lice, keds, ticks
Permethrin	Liquid	Spray	Lice, ticks (some formulations also claim activity against keds or various flies)
	Pour-on	Pour-on	Lice, keds
	Emulsifiable concentrate	Spray	Lice, ticks, blowflies

Note: Refer to label directions for compounds approved for lactating goats and for compound withdrawal period prior to slaughter.

TABLE 50.12—Ectoparasiticides for use on swine

Compound(s)	Marketed formulation(s)	Method of application	Target parasite(s)
Amitraz	Liquid	Ears and backline treatment	Lice, mites
Coumaphos	Dust	Shaker can	Lice
	Liquid	Spray	Lice
Doramectin	1% injectable solution	Inject subcutaneously	Lice, mites
Fenthion	Pour-on	Pour-on	Lice
Fenvalerate	Liquid	Spray, pour-on	Lice, mites (pour-on only for lice)
Ivermectin	1% injectable solution	Inject subcutaneously	Lice, mites
	0.27% injectable solution	Inject subcutaneously	Lice, mites
	Pre-mix	Mix with feed	Lice, mites
Lindane	Spray	Direct application	Ear ticks, screwworms
Malathion	Liquid	Spray	Lice, mites
Permethrin	Liquid	Spray, paint, dip	Lice, mites (some formulations also claim horn flies, and ticks
	Dust	Direct application	Lice (some formulations also claim horn flies, ticks, and mites)
	Wettable powder	Spray, paint, dip	Horn flies, lice, ticks, mites
Tetrachlorvinphos	Wettable powder	Spray	Lice
	Dust	Direct application	Lice

Note: Refer to label directions for compound withdrawal period prior to slaughter.

TABLE 50.15—Clinical signs and treatment of ectoparasiticide toxicosis

Ectoparasiticide group	Clinical signs of toxicosis	Treatment
Carbamates	Abdominal cramping, vomiting, diarrhea, miosis, dyspnea, cyanosis, muscle twitching seizures; rarely tetany followed by weakness and paralysis	Atropine sulfate: 0.2–0.5 mg/kg to effect (mydriasis and reduced salivation) usually 1/4 dose IV and 3/4 SC; may need to repeat at 3–6 hr for 1–2 days depending on response; 2–PAM (pralidoxime) is contraindicated
Chlorinated hydrocarbons	Onset can be minutes to days after exposure, usually several hours; signs include apprehension, exaggerated response to stimuli, vomiting, muscle twitching of face and head that progresses posteriorly to severe fasciculations and tremors; clonic and tonic seizures; elevated body temperature; chlorinated hydrocarbons are stored in fat; therefore, course may be protracted	Emesis (may induce seizures), gastric lavage; no specific antidote; seizures may be controlled with diazepam at 2.5–20 mg IV as needed; barbituate to effect; do *not* use phenothiazines, because they lower seizure threshold; calcium gluconate 10% at 2–10 mL given slowly IV and vitamin B complex IM to protect liver function; critical period, 24–36 hr
d-limonene, linalool, crude citrus oil extracts	(Cats) Hypersalivation, ataxia, and muscle tremors; hypothermia in some animals	Supportive therapy; wash agent from hair coat with nondetergent-, nonalcohol-containing shampoo; external warming for hypothermia
Formamidines	Lethargy, hypotension, hyperglycemia, mydriasis, hypothermia, bradycardia; ataxia, vomiting, and diarrhea have also been reported	Emesis, activated charcoal after oral ingestion (collar); wash agent from hair coat with nondetergent-, nonalcohol-containing shampoo (dip); yohimbine 0.1 mg/kg IV
Organophosphates	*Muscarinic:* salivation, lacrimation, diarrhea, abdominal cramping, miosis, pallor, cyanosis, dyspnea, emesis	Atropine as for carbamates
	Nicotinic: twitching of facial and tongue muscles progressing to generalized twitching followed by paralysis	2-PAM (pralidoxime): 20 mg/kg IV twice per day; give over 5-min duration; if poisoned for less than 24 hr, treatment is necessary for 1–2 days; if longer, therapy may be required for several days
	Central nervous system: depression, tonic/clonic seizures, death is due to hypoxia from respiratory muscle paralysis, bronchoconstriction, excessive pulmonary secretions, pulmonary edema, and bradycardia	Diphenhydramine hydrochloride: animal becomes depressed, decrease 4 mg/kg IV (dogs) or IM (dogs or cats) every 8 hr until asymptomatic; if animal becomes depressed, decrease dose to 1–mg/kg
Pyrethrins, synthetic pyrethroids	Only at very high doses; hypersalivation, vomiting, diarrhea, ataxia, CNS excitation and seizures, hyperthermia, hypothermia	Supportive as for chlorinated hydrocarbons; wash agent from hair coat with nondetergent-, nonalcohol-containing shampoo, monitor and control body temperature
Rotenone	Vomiting, nausea, diarrhea, respiratory stimulation, convulsions, followed by respiratory depression, coma, respiratory failure and death; in humans, causes irritant dermatitis	Emesis, gastric lavage before convulsive state; warmth, quiet; assist respiration; diazepam, calcium gluconate and B complex vitamins as for chlorinated hydrocarbons

Source: Modified from Kwochka 1987.

USEPA also requires a product chemistry package for pesticides that includes specific pesticide composition and characteristics. Also in the case of pesticides, resistance studies may be necessary to determine how easy it will be for the target parasite to develop resistance to the drug. Studies must also be conducted for many drugs and for all pesticides to determine their potential impact on the environment. Efficacy of the candidate drug must be evaluated in detailed laboratory studies and in realistic use situations. This is achieved by conducting numerous laboratory studies and clinical field trials in different geographic regions of the country, although according to the new Food and Drug Administration Modernization Act, field trials are not always required by the USFDA. If required, clinical field trials generally are conducted by either veterinarians or scientists in collaboration with animal owners or producers to obtain detailed information on the performance of the product under realistic use conditions. If new label claims or formulation changes are sought for a drug which is currently approved for use, many of the safety and efficacy studies can be waived if the new formulation is shown by properly conducted studies to be pharmacologically equivalent to the existing formulation.

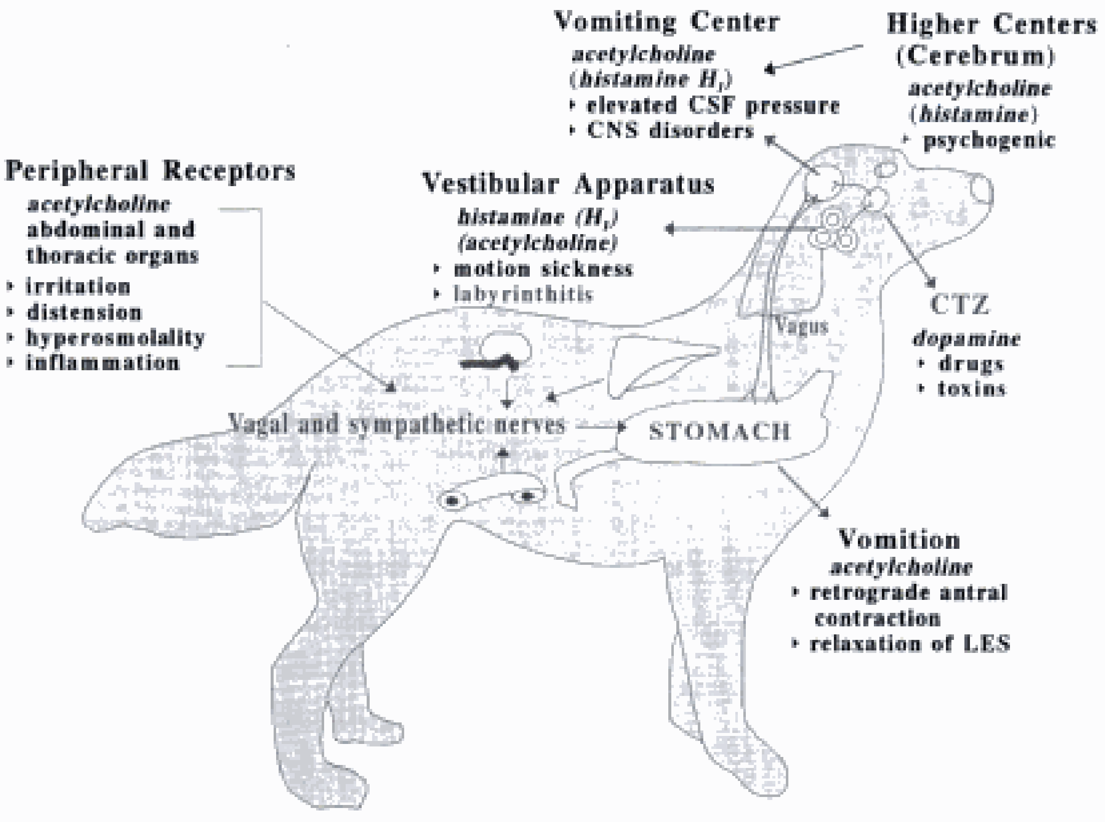

FIG. 51.1—Sites that mediate the emetic reflex. The major neurotransmitter responsible for mediating the reflex at each site is noted in italics; secondary neurotransmitters at each site are in parentheses. Stimuli that mediate emesis at each site are listed below the neurotransmitter.

fluid (CSF)-borne chemical compounds because free nerve endings directly contact the CSF. Free nerve endings reach the CSF either via ependymal pores or in the sheath surrounding fenestrated capillaries. Emesis caused by blood-borne mediators (e.g., uremia, pyometra, liver disease, endotoxemia, and those associated with radiation sickness disease) and drugs (e.g., digitalis glycosides, apomorphine, narcotic analgesics, and estrogens) is mediated by the CTZ. Stimulation of the CTZ is initiated by dopaminergic receptors that respond to agonists such as dopamine and apomorphine (Merrifield and Chaffee 1989). Alpha$_2$ receptors associated with the area postrema also induce emesis in dogs (Hikasa et al. 1992) and cats (Hikasa et al. 1989). Serotonin may also be important in this area (Kohler and Goldspiel 1991). Histamine via H_1 receptors acts as a secondary neurotransmitter at the CTZ. As with dopaminergic receptors, H_1 receptors may also be competitively and noncompetitively inhibited by antagonists.

Impulses originating from the semicircular canals of the vestibular apparatus are transmitted by the 8th cranial nerve to the vestibular nuclei and then via the CTZ and uvula and nodulus of the cerebellum to the emetic center. This pathway, mediated by histaminergic (subtype H_1) receptors, is responsible for eliciting the emesis that accompanies motion sickness and labyrinthitis (Peroutka and Snyder 1982).

Peripheral impulses causing vomition which arise from stimulation of the pharynx and fauces are transmitted by afferent nerves in the 9th cranial nerve to the emetic center. Other peripheral afferent pathways include those arising from stimulation (i.e., irritation or distension) of various visceral organs and tissues. Impulses may be carried by sympathetic or vagal afferents from the heart, stomach, duodenum, small intestine, liver, gallbladder, peritoneum, kidneys, ureter, urinary bladder, and uterus. ACh is the primary neurotransmitter mediating the afferent limb of the emesis reflex from peripheral causes. Muscarinic receptors initiate the impulse which travels to the emetic center via the vagus nerve. Efferent signals which stimulate the emetic reflex travel back to the stomach by the 10th cranial (vagus) nerve. ACh also acts as the primary efferent neurotransmitter in the vagus and in the smooth muscle of the stomach.

Clinically, emesis is pharmacologically induced in order to empty the anterior portion of the digestive tract. Indications include induction of general anesthesia if there is any possibility of food being in the stomach, or ingestion of noncorrosive poisons.

Peripherally Acting, or Reflex, Emetics. Distension of the pharynx, esophagus, stomach, or duodenum (hollow organs) with warm water, hydrogen peroxide, or saline can induce the emetic response. In addition, in the case of toxin ingestion, administration of warm water by stomach tube may help dilute poisons. Although their efficacy and safety vary, a number of substances induce emesis by irritating the epithelium of the GI tract. Emesis can be induced in dogs by oral administration of a solution of warm saturated (strong) sodium chloride or by pharyngeal placement of a small amount of plain table salt or neutral salt crystals, such as Sodium Carbonate, NF. Orally administered hydrogen peroxide (3%) often induces emesis rapidly in cats and dogs, although fatal aspiration of hydrogen peroxide foam is possible. Ipecac syrup is an over-the-counter emetic commonly recommended to induce emesis in human pediatric patients. It contains the alkaloid emetine, which increases lachrymation, salivation, and bronchial secretions. Emesis usually, but not consistently, occurs as a result of both peripheral and central stimulation. However, if repeated use fails to induce emesis, gastric lavage may be indicated to remove potentially toxic doses of the drug. Although ipecac syrup or powder has been used as an emetic for many years in cats, it has been known to induce toxic effects, including death.

Centrally Acting Emetics. Although a number of drugs are capable of stimulating the CTZ centrally, certain opiates, particularly apomorphine, are the most commonly used. Apomorphine Hydrochloride, USP, is a synthetic derivative of morphine with only marginal depressant activity. Its emetic activity predominates over other morphine-like actions and reflects stimulation of dopaminergic receptors in the CTZ. Apomorphine can be administered by almost any route, although oral doses are greater in order to compensate for reduced oral bioavailability. Emesis generally occurs in 2-10 minutes following subcutaneous or conjunctival administration. Although apomorphine stimulates vomiting at the CTZ, it also directly depresses the emetic center, and subsequent doses are less likely to induce emesis even if emesis does not occur following the first dose. Excessive doses of apomorphine can depress the central nervous system (CNS), particularly the respiratory center, and are contraindicated in the presence of existing central depression.

Xylazine (Rompun) is an α_2 agonist used most commonly for its sedative analgesic properties. However, emesis mediated by α_2 stimulation consistently occurs in cats when xylazine is administered at recommended doses (Hikasa et al. 1989). Emesis can also be induced at low doses (0.05 mg/kg) not associated with sedation. Emesis also occurs in dogs, but not as consistently as in cats. The incidence of emesis induced by xylazine is also somewhat lower following IV than IM administration and may be reduced further by fasting prior to use.

ANTIEMETICS. Antiemetics control emesis by either a central or a peripheral action. Both actions depend on and can be correlated to blockade of neurotransmission at receptor sites (Peroutka and Snyder 1982; Costall and Naylor 1992).

Centrally Acting Antiemetics. Antiemetic agents possess either a limited or a broad effect depending on which centers are depressed. Centrally acting antiemetics block impulses at higher centers and at the emetic center and include muscarinic anticholinergics; antidopaminergics which block dopaminergic receptors at the CTZ; and antihistaminergics which block H_1 receptors at the vestibular apparatus and secondarily at the CTZ and the emetic center.

VESTIBULAR APPARATUS. Vomition caused by motion sickness or inner ear disease is mediated by the vestibular apparatus. Motion sickness in dogs and cats can be controlled for several hours (8-12) by administering antihistaminics such as cyclizine hydrochloride, meclizine hydrochloride, or diphenhydramine hydrochloride. Although efficacy depends on a direct effect on neural pathways arising in the vestibular apparatus, it appears to be independent of antihistaminic or sedative potencies. Emesis produced by other stimuli is not controlled by these drugs. Drowsiness and xerostomia are typical side effects encountered with use of this group of drugs.

ANTIMUSCARINICS. Selected antimuscarinic agents are used to control motion sickness in dogs. The belladonna alkaloids, especially hyoscine (scopolamine), and synthetic compounds such as dicyclomine hydrochloride and isopropamide iodide are effective antiemetics. Their duration of action is short (up to 6 hr), and xerostomia, drowsiness, and other side effects should be anticipated. These drugs are not generally used in cats, because of potential adverse reactions.

DRUGS ACTIVE AT THE CTZ

PHENOTHIAZINES. These broad-spectrum antiemetics control emesis induced by most central causes other than labyrinthine stimulation. Phenothiazines block emesis mediated by the CTZ at low doses because of their antidopaminergic and antihistaminergic effects. At higher (perhaps nonpharmacologic) doses, their anticholinergic effects may also act at other central sites, including the emetic center. A variety of phenothiazine derivatives, e.g., chlorpromazine, prochlorperazine, triflupromazine, perphenazine, trifluoperazine, and mepazine, are used in small animals as antiemetics. The primary adverse effects associated with their use as antiemetics are sedation and hypotension due to peripheral α blockade. Selection of a particular phenothiazine may be based on avoidance of adverse reactions. Fluid replacement therapy should be instituted if necessary prior to use of a phenothiazine.

BUTYROPHENONE DERIVATIVES. Haloperidol (Haldol) and droperidol (Inapsine), which are also used as major tranquilizers, are potent antiemetics because of their antidopaminergic activity. Possible side effects are similar to those encountered with the phenothiazine group.

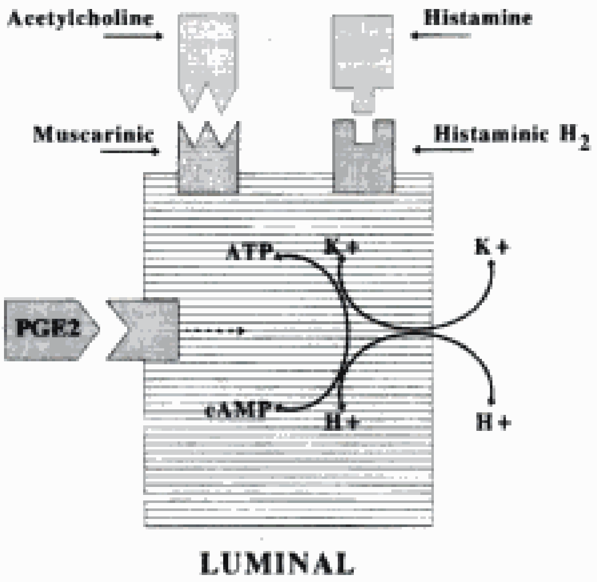

FIG. 51.2—Receptor interactions that mediate gastric acid secretion by the parietal cell include acetylcholine with muscarinic receptors and histamine with H_2 receptors. Gastrin may interact with either receptor. Receptor stimulation activates the K^+,H^+-ATPase pump and exchange of potassium for hydrogen into the lumen. Prostaglandin E_2 modulates gastric acid secretion by inhibiting cAMP.

Intracellular messengers mediating gastric acid secretion vary with the receptor stimulated. Histamine increases cAMP production, which subsequently activates cAMP-dependent protein kinases. Gastrin and muscarinic stimulation by cholinergic drugs increases cytosolic calcium, probably by increased influx through selective receptor-activated calcium channels in the cell membrane. Prostaglandins of the E series (PGEs) modulate these effects, inhibiting gastric acid secretion by blocking cAMP production (Wolfe and Soll 1988).

Mucosal Defenses. Defenses of the GI mucosa which act to prevent or repair GI ulceration include (1) secretion of bicarbonate into the lumen and neutralization of hydrochloric acid in the lumen; (2) secretion of a thick, alkaline mucus which traps and neutralizes inward-moving hydrogen ions; (3) a gastric epithelial barrier comprising active phospholipids, a lipoprotein cell membrane, and tight junctional complexes, all of which prevent hydrogen ion back-diffusion; (4) mucosal blood flow, which, first, provides nutrients and oxygen to mucosal cells and, second, removes hydrogen ions that have penetrated the gastric barrier; (5) rapid replication of mucosal epithelial cells; and (6) production of cytoprotective agents (Fig. 51.3) (Baker 1966; Toutain et al. 1983; Shorrock and Rees 1988). Local secretion of PGE_2 is an important defense mechanism because it modulates hydrochloric acid secretion, increases bicarbonate and mucus production, and enhances mucosal blood flow and epithelialization (Miller 1983; Charlet et al. 1985). Sulfhydryls also produced locally may act as scavengers of oxygen and other tissue-damaging radicals (Szelenyi and Brune 1986).

Gastroduodenal Ulceration. The events leading to gastroduodenal ulceration are complex and reflect interactions between acid-secreting and defense mechanisms of the GI mucosa (Robert and Kauffman 1989; Moreland 1988). Regardless of the cause of GI erosion or ulceration, the basic pathologic mechanism is similar. Gastric acid secretion is a prerequisite for damage to the GI mucosa (Kleiman et al. 1988; Moreland 1988), although damage does not usually occur if luminal pH is greater than 7.0. Pepsin and bile acids can contribute to mucosal damage. Damage is exacerbated when the mucosa loses its ability to sufficiently protect itself through secretion of bicarbonate and mucus and epithelialization. Deceased mucosal blood flow can profoundly affect the injured mucosa's ability to heal itself. Drugs used to control or treat GI erosion and/or ulceration include drugs used to inhibit gastric acid secretion and cytoprotective drugs.

Gastric Antisecretory Drugs. Drugs used to prevent or modulate gastric acid secretion include anticholinergics, H_2 receptor antagonists, proton pump inhibitors, and PGE_2 (Whittle and Garner 1988; Wolfe and Soll 1988; Miller 1983; Muir 1990). Drugs which modify gastric acid (e.g., antacids) are discussed in the section on cytoprotective drugs. All drugs that modify gastric pH can cause complications of achlorhydria when used chronically. Although both gastric acid and pepsin are required for hydrolysis of proteins and other foods, achlorhydria is rarely accompanied by malabsorption unless bacterial overgrowth occurs. Achlorhydria can lead to malabsorption of certain nutrients (e.g., vitamin B_{12} and iron).

ANTICHOLINERGICS. Despite the role of muscarinic receptors in gastric acid secretion, anticholinergics have not proven effective for the control of GI ulceration in animals. In humans, these drugs reduce food-induced gastric acid secretion by 30% and potentiate the inhibitory effect of H_2 receptor antagonists (see below). Side effects, as previously described, further limit their usefulness. Side effects are reduced, however, when selective drugs for muscarinic receptors of the M_1 subtype are used. Pirenzepine, an M_1 antagonist, inhibits food-induced secretion by 50-60%, with fewer antimuscarinic side effects (Wolfe and Soll 1988).

H_2 RECEPTOR ANTAGONISTS. H_2 receptor antagonists are reversible, competitive antagonists that reduce gastric secretion of both hydrochloric acid (HCl) and pepsin (Krishna and Ulrich 1988) induced by a variety of secretogogues (Hirschowitz and Gibson 1987). Cimetidine and ranitidine and, to a lesser degree, famotidine have been used to control gastric acid secretion in animals. Nizatidine is the newest of the H_2 receptor antagonists. Each drug varies in potency, duration of

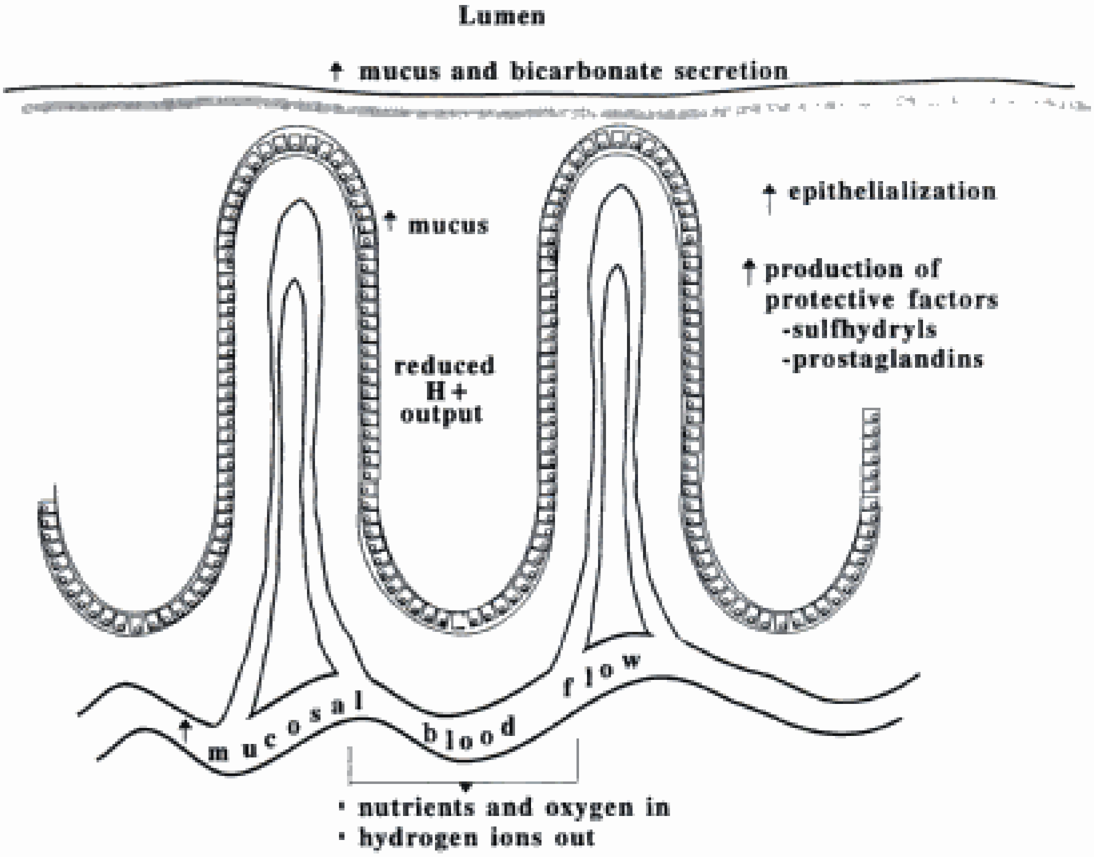

FIG. 51.3—Protective mechanisms against gastroduodenal ulceration provide targets for drug therapy. Bicarbonate secretion neutralizes gastric acid; mucus protects against hydrochloric and bile acids. The rapid turnover of epithelial cells is paramount for rapid healing if damage occurs. Mucosal blood flow not only provides critical oxygen and nutrients necessary for epithelialization but also removes H⁺ ions that have penetrated the protective barrier. Other protective factors include mechanisms to control gastric hydrochloric acid secretion and to scavenge mediators capable of cell damage.

action, disposition, and drug interactions (Bemis et al. 1989). Ranitidine is 5-12 times more potent as an inhibitor of gastric acid secretion than cimetidine, while famotidine is 9 times more potent than ranitidine and 32 times more potent than cimetidine. Famotidine has the longest duration of action (Howard et al. 1985). In animal models including dogs, nizatidine is more potent than cimetidine (Price and Brogden 1988).

DISPOSITION. Cimetidine, the oldest of the clinically used H_2 receptor antagonists, is rapidly absorbed from the GI tract, although food will delay the process. The drug undergoes hepatic metabolism and is about 70% bioavailable following oral administration. It is excreted in the urine, primarily in an unchanged form. The plasma half-life is about 1 hour but may be prolonged in the presence of liver or kidney disease.

Ranitidine is less bioavailable (50%) than cimetidine following oral administration. Its elimination half-life is approximately 2.5 hours. Absorption is not impaired by food as it is with cimetidine. Ranitidine is minimally protein bound (15%). Hepatic elimination is responsible for 30% of an IV dose and 73% of an oral dose (Brogden et al. 1982).

Famotidine is only 37% bioavailable after oral administration, due to poor oral absorption. In contrast, nizatidine is rapidly and completely absorbed (Krishna and Ulrich 1988). Both drugs are eliminated unchanged in urine (Krishna and Ulrich 1988). Nizatidine is almost exclusively eliminated by renal excretion, which suggests it might be the preferred H_2 receptor antagonist in patients with hepatic disease. Its efficacy apparently has not been studied clinically in animals, although its safety has been established in healthy dogs (Bemis et al. 1989).

Ranitidine has been studied in dogs and horses. In Beagle dogs receiving 5 mg/kg, ranitidine was characterized by an elimination half-life of 4 hours. Bioavailability after oral administration was 73%, yielding peak concentrations of 2000 ng/mL. Elimination appears to reflect both hepatic metabolism and, for 40% of each dose, renal elimination (Eddershaw et al. 1996). In adult horses, following IV administration of 2.2 mg/kg, ranitidine reached a concentration of 5175 ng/mL and was characterized by a mean residence time of 113 minutes. Following oral administration, mean absorption time was 59 minutes and bioavailability was 27% (Holland et al. 1997).

myenteric plexus. The net effect is stimulation of peristalsis to stimulate ACh release, whereas α_2 receptor stimulation inhibits ACh release (Demol et al. 1989). Both H_1 and H_2 receptors have been identified in the GI tract. They are located both prejunctionally, where they control ACh release, and postjunctionally. Stimulation of H_1 receptors induces smooth muscle contraction, whereas H_2 receptor stimulation induces relaxation (Demol et al. 1989). Serotoninergic receptor stimulation results in complex neural and myogenic responses in the GI tract. Presynaptically, these receptors inhibit ACh release, activation of cholinergic neurons in the myenteric plexus, and activation of the noncholinergic, nonadrenergic inhibitory neurons responsible for bowel relaxation (Demol et al. 1989). Prostanoids, and specifically PGE receptors, have been identified in the gastric fundus and ileum. PGE receptors are thought to be important in the modulation of GI motility from the esophagus to the colon (Demol et al. 1989). Generally, PGE inhibits mechanical activity of circular smooth muscle, while PGs of the D and F series are stimulatory. At high doses, PGEs stimulate peristaltic activity, although this may represent mechanical response to excess watery fluid in the intestinal lumen (Demol et al. 1989). Several agents promote the functional activity of the stomach by increasing secretions and motility.

Prokinetics. Prokinetics enhance the transit of intraluminal contents (Reynolds 1989). The mechanisms of action of these drugs are varied and are not completely understood. Their effect on intestinal functions generally reflects either promotion of an agonist, such as ACh by muscarinic drugs, or inhibition of an inhibitory transmitter, such as dopamine (Reynolds 1989). Organ- and species-specific differences complicate our comprehension of these drugs (Reynolds 1989). Clinically, the use of these drugs is limited by their tendency to cause systemic effects.

CHOLINERGICS. Bethanechol is a cholinergic agonist. As an ester derivative of choline, it acts almost exclusively at muscarinic (M_2) receptors (Demol et al. 1989). Bethanechol will enhance the amplitude of contractions throughout the GI tract, including the lower esophageal sphincter (Demol et al. 1989; Reynolds 1989). However, its effects on the coordination of small-intestinal contraction may be minimal, and thus it is often not considered to be a prokinetic agent (Reynolds 1989). Adverse effects reflect direct enhanced parasympathomimetic stimulation and include abdominal cramps, diarrhea, salivation, and bradycardia (Reynolds 1989).

METOCLOPRAMIDE. Metoclopramide is a lipid-soluble derivative of para-aminobenzoic acid. It is structurally related to procainamide, a cardiac antiarrhythmic (Reynolds 1989). In addition to its central antidopaminergic (antiemetic) effects, metoclopramide acts peripherally both as an antidopaminergic and as a direct and indirect stimulator of cholinergic receptors (Reynolds 1989; Burrows 1983). Although clinically its effects appear to be limited to the upper intestinal tract (Hunt and Gerring 1986; Wingate et al. 1980; Burrows 1983; Albibi and McCallum 1983; Hunt and Gerring 1986), in vitro studies suggest that the most dramatic effects of metoclopramide are on the colon. The peripheral effects of metoclopramide apparently reflect enhanced release of ACh from intrinsic cholinergic neurons. These effects are completely inhibited by pretreatment with atropine (Reynolds 1989; Albibi and McCallum 1983; Sojka et al. 1988). Peripheral effects may also be mediated by effects on other local neurotransmitters such as dopamine and serotonin (Reynolds 1989). Dopamine has an inhibitor effect on smooth muscle of the stomach, duodenum, and colon and has been implicated as a mediator of receptive relaxation in dogs (Reynolds 1989). Dopamine may exert its inhibitor effect through inhibition of ACh, thus explaining the complex mechanism of metoclopramide (Reynolds 1989). Peripheral antidopaminergic effects of metoclopramide appear to reflect interaction with D_2 receptors (Reynolds 1989). Metoclopramide physiologically antagonizes emesis by increasing the tone in the lower esophageal sphincter, increasing the force and frequency of gastric antral contractions (gastrokinetic effect), relaxing the pyloric sphincter, and promoting peristalsis in the duodenum and jejunum, resulting in accelerated gastric emptying and upper intestinal transit (Burrows 1983).

Metoclopramide is well absorbed orally but undergoes significant first-pass metabolism, with a bioavailability in the 50-70% range. Tissue distribution is rapid, and excretion is both renal and hepatic. The plasma half-life in the dog is only 90 minutes, and metoclopramide has a short duration of action (Burrows 1983). Dose-dependent CNS side effects range from nervousness and restlessness to listlessness, depression, and disorientation (Reynolds 1989; Clark and Becht 1987; Burrows 1983). Extrapyramidal antidopaminergic effects include tremors and motor restlessness. Gynecomastia due to enhanced release of prolactin has been reported in humans (Reynolds 1989). GI disorders may also be observed, with constipation being common with long-term use. As an antiemetic, the main indications of metoclopramide include severe and intractable emesis caused by chemotherapy or other blood-borne toxins, nausea and vomition associated with delayed gastric emptying, gastroesophageal reflux, reflux gastritis, and peptic ulceration. As a prokinetic, metoclopramide is indicated for treatment of a variety of gastric motility disorders, including gastric dilatation, volvulus, postoperative ileus, gastric ulceration, and idiopathic gastroparesis (Albibi and McCallum 1983). Metoclopramide is contraindicated in GI obstruction or perforation, in epilepsy, and in patients receiving neuroleptics. Because of their anticholinergic effects, atropine and the opioid analgesics will antagonize the action of metoclopramide.

Metoclopamide appears to competitively antagonize dopamine-induced renal arterial relaxation. The effect

activated charcoal suspension may be used for gas lavage in simple-stomached animals.

Cholestyramine is a basic anion exchange resin that binds to acidic side chains such as those occurring in bile acids. In order to increase the number of basic binding sites, cholestyramine is attached to a polystyrene matrix which can act as a nonspecific adsorbent. As bile salts are bound in the GI tract, lipoprotein, cholesterol, and neutral fat absorption are also decreased. Although specifically indicated for pruritus associated with increased bile acids, cholestyramine has also been used to symptomatically treat diarrhea. Nausea, constipation, steatorrhea, and decreased fat-soluble vitamin absorption are reported undesirable effects. The product should be administered in food or water (Wilcke and Turner 1987).

LAXATIVES AND CATHARTICS. Laxatives and cathartics promote defecation by increasing frequency of defection or fecal volume or consistency (Clark and Becht 1987; Dimski 1989; Horn 1987; Burrows 1984). Laxatives (or aperients) promote elimination of a soft-formed stool, whereas cathartics (or purgatives) tend to produce a more fluid evacuation. The difference between these two effects may be just a matter of dose, but in some instances laxatives are only capable of increasing the hydration or softness of the fecal mass without ever inducing catharsis. The enhanced intestinal transit times that occur with use of some of these cathartics are usually due to intrinsic local myenteric reflexes within the visceral smooth muscle or to stimulation of the cholinergic receptors of the extrinsic parasympathetic nervous system. Although a traditional classification of the group will be presented here, it should be noted that many cathartics alter intestinal electrolyte transport to increase fecal water excretion, so the grouping of these compounds should perhaps more logically follow their effects on intestinal electrolyte movement (Thompson 1980).

Emollient Laxatives. The emollient laxatives (lubricant laxatives, mechanical laxatives, fecal softeners) act unchanged. They are not absorbed to any appreciable extent and simply soften and lubricate the fecal mass, which in turn facilitates expulsion. Though not always reliable, particularly in the ruminant, they are used in all species.

Mineral oil (liquid paraffin) is very commonly employed as a lubricant laxative. Mineral oil is bland and generally safe to use, but a few untoward effects may be encountered. Chronic administration may impair absorption of fat-soluble vitamins, other nutrients, and coadministered therapeutic agents. Decreased irritability of the intestinal mucosa becomes evident with protracted use and, paradoxically, chronic constipation may ensue. Lipid pneumonitis, following maladministration into the trachea and bronchial tree, is a serious complication. Following prolonged use, limited absorption of mineral oil, principally into the intestinal lymphatics but also into the intestinal wall and even the liver, does take place. The subsequent tissue reaction leads to development of granulomatous lesions. Anal leakage of mineral oil may be a nuisance in a house pet and will interfere with healing of wounds in the anorectal area. Administration of mineral oil to confirm or treat intestinal obstruction has a shortcoming: the oil may easily bypass a partial obstruction, and its presence in the anal area may lead to a false conclusion. White or yellow soft paraffins are also used as lubricant laxatives (e.g., cats with hair balls).

Several anionic surfactants are employed as fecal softeners. Examples include docusate sodium (previously named dioctyl sodium sulfosuccinate) and dioctyl calcium sulfosuccinate.

Simple Bulk Laxatives. The simple bulk laxatives are hydrophilic in nature and are not digested within the GI tract. They absorb water and swell, and an emollient gel forms. The increased volume or bulk leads to distension, with resultant reflex contraction producing peristaltic activity. The feces remain soft and hydrated. Methylcellulose, carboxymethylcellulose sodium, and plantago seed (psyllium seed) are examples of simple bulk purgatives. Wheat bran, prunes, and other fruits also belong in this group. Besides the bulk action of these laxatives, it should be noted that the celluloses and hemicelluloses present are fermented in the hind gut by bacteria to produce volatile fatty acids and other products that in turn exert an osmotic effect and thus enhance laxative action. Meteorism and a very fluid stool often result from the use of simple bulk laxatives.

Osmotic Cathartics. The osmotic cathartics (saline purgatives) consist of salts or compounds that either are not absorbed at all or are only slowly and incompletely absorbed from the GI tract. They retain or attract water into the intestinal lumen mainly by osmotic forces, although enhanced mucosal secretion of fluid may contribute to their effect. It is imperative that drinking water be made freely available to an animal that has been dosed with an osmotic cathartic; use of this group of purgatives is contraindicated in dehydrated animals. In monogastric animals an effect may generally be anticipated in 3-12 hours, and in ruminants within about 18 hours of dosing.

Magnesium salts are frequently used as saline purgatives. Magnesium ions also bring about release of CCK, which will increase peristaltic activity. Magnesium sulfate (Epsom salts), isotonic in a 6% solution, magnesium hydroxide, magnesium oxide (milk of magnesia), and magnesium citrate are the magnesium salts most commonly employed. The solutions need not be hypertonic to produce an effect. About 20% of the magnesium ions are absorbed when magnesium sulfate is dosed orally, and if purgation does not occur, additional amounts of magnesium may be absorbed with subsequent depression of the excitable tissues in the body. This is even more likely to occur if renal function is impaired. Magnesium sulfate is not often used in horses.

Salts such as sodium sulfate (Glauber's salt), sodium phosphate, potassium sodium tartrate (Rochelle salt), and even large quantities of sodium chloride are effective saline purgatives.

The sugar alcohols mannitol and sorbitol will also induce an osmotic catharsis as will the synthetic disaccharide lactulose, which is not digested in the small intestine because no specific enteric enzyme is present. It passes to the large intestine, where saccharolytic microflora ferment lactulose to produce acetic, lactic, and other organic acids, which in turn lower the pH of the colonic content and exert an osmotic effect. Water is attracted, the fecal mass softens, and colonic peristalsis ensues. Lactulose is used for chronic constipation and treatment of hepatic encephalopathy. Acidification of the content of the large intestine favors greater formation of the nonabsorbable ammonium ion than the readily absorbable ammonia molecule, which requires detoxification in the liver by the urea cycle. Hyperammo-nemia is thus prevented to some degree. Absorption of other toxic amines from the hind gut is also reduced by acidification of the contents. Some meteorism may be evident following administration of lactulose.

Irritant Cathartics. Contact or irritant purgatives were thought to stimulate the mucosal lining of the GI tract and thereby initiate local myenteric reflexes that would enhance intestinal transit. However, it now seems that members of this group also provoke fluid accumulation in the lumen by activating secretory mechanisms. Irritant cathartics are regarded as direct acting or indirect acting depending on whether a metabolic alteration is first required to form an active product.

Several bland vegetable oils act as irritant purgatives. Their action is based on hydrolysis by pancreatic lipase in the small intestine and subsequent formation of sodium and potassium salts of the released fatty acids. These are then irritant soaps, which differ in potency depending on the oil used. Castor oil produces highly irritant ricinoleates; raw linseed oil leads to formation of less irritant linoleates; and olive oil leads to rather mild oliveates. The response to castor oil is prompt, and evacuation of the whole intestinal tract occurs, leading to an almost complete emptying. Moist bulky feeds are needed following purgation with castor oil. It is used mainly in nonruminants and is often employed in calves and foals. The effect occurs in 4-8 hours in small animals and 12-18 hours in large animals.

Another group belonging in this class includes the diphenylmethane cathartics, which appear to have a greater effect on the large intestine. Their precise mechanism of action is unclear. An effect is usually seen within 6-8 hours, and excessive catharsis may occur with overdosage. Phenolphthalein, the well-known indicator, is a potent purgative but only in primates and swine. Bisacodyl also is a diphenylmethane cathartic that inhibits glucose absorption and Na^+,K^+-ATPase activity as well as altering motor activity of the visceral smooth muscle. Only about 5% of any dose of bisacodyl is absorbed. This agent is used both orally and by enema.

Anthraquinone cathartics, also known as the emodin purgatives, exert an indirect secondary purgative action. They are mainly of plant origin, but a synthetic compound, to which all the anthraquinone derivatives are related, is the prototype of the group. This substance is 1,8-dihydroxyanthraquinone, or danthron. The other anthraquinones are precursor glycosides, which may be absorbed from the intestinal tract to some extent, but the portion remaining in the gut is hydrolyzed by bacterial enzymes in the large intestine to release the active aglycones known as emodins. These cathartics are not effective if transit through the small intestine is delayed. Their action is principally on the large intestine, where the myenteric plexuses are stimulated. With prolonged use of these agents, these myenteric plexuses actually degenerate, with a resultant loss in intestinal motility. The effect of danthron may be manifested within 6-14 hours in small animals and within 12-36 hours in large animals. Repeated dosing should be avoided in large animals because of the long latent period. A too hasty second administration may lead to severe superpurgation, especially in the horse. Sufficient anthraquinone can distribute into milk to affect nursing young. Urine color may show changes following administration of members of this group. The naturally occurring anthraquinone glycosides include senna and other sennosides from *Cassia* spp., cascara sagrada from *Rhamnus* spp., and aloins from *Aloe* spp.

Some purgatives are so highly irritant that they may cause severe colic and superpurgation.

Neuromuscular Purgatives. Cholinergic agents with muscarinic actions will initiate hypermotility of the GI tract and promote defecation and urination. Peristaltic activity increases within 10-30 minutes following parenteral administration and within 2-4 hours following oral administration. Neostigmine, physostigmine, bethanecol, and carbachol have been used for this purpose. Neostigmine has fewer side effects than the others. Colic may be precipitated, so care should always be taken when using these agents when a mechanical obstruction is present or viability of the bowel is doubtful. Several other substances will also stimulate visceral smooth muscle to contract, either directly or indirectly. Vasopressin, oxytocin, $PGF_{2\alpha}$, and other PG analogs are capable of promoting evacuation of the rectum. Oxytocin and neostigmine have been shown to stimulate release of VIP from the intestine, so the mechanism of action of this group may be more complex than at first believed.

A number of deleterious effects may occur with excessive or constant use of cathartics. Severe, continuous diarrhea and abdominal colic, leading to dehydration and even shock, may follow overdosage. Other potentially harmful effects include decreased sensitivity of the intestinal mucosa, megacolon, flatulence, loss of electrolytes (especially sodium, potassium, chloride,

Administration of chemotherapy for treatment of pets with cancer has become an integral skill in many small-animal hospitals. Proper use of these drugs requires a working understanding of their unique pharmacology and range of expected toxicities, as well as current recommendations regarding safe drug handling. Treatment of many cancers remains a challenging task because, despite increased experience with the use of chemotherapeutic agents, therapy is often not curative. Expense of the drugs with appropriate monitoring and the supportive care required in the event of toxicity may discourage some owners from pursuing treatment of their pet with chemotherapy. However, with careful patient selection and monitoring and client discussions designed to be informative and outline realistic goals, chemotherapy can be a rational means of improving the patient's quality and/or quantity of life.

TREATMENT PERSPECTIVES. Cancer is defined as *cured* when all cancer cells that have the capacity for tumor regeneration have been eradicated. While cancer cure is the ideal goal, producing remission and/or palliation is often more readily achievable. A cancer is said to be in *remission* when all clinical evidence of cancer has disappeared but microscopic foci of cancer cells may remain. *Palliative treatment* refers to the treatment of cancer (when cure is unlikely) to reduce pain, improve the sense of well being, or correct some physiological malfunction. The therapeutic regimen selected must be consistent with the goal for the patient (i.e., cure, remission, or palliation).

For most solid tumors, the lower limit of clinical or radiologic detection is about 1 gram of tissue, or approximately 10^9 cells (Tannock and Goldenberg 1998). Recognizing the need to continue aggressive treatment in the face of apparent complete remission ($<10^9$ cells) was one of the factors leading to success in the treatment of many acute childhood leukemias and lymphomas. Unfortunately, for most solid tumors, a drug-resistant subpopulation emerges and eventually leads to relapse. *Adjuvant chemotherapy* is given to patients with no overt evidence of residual cancer after local treatment with surgery or radiation. This strategy derives from past experience with similar patients who have shown a high rate of relapse from local microscopic or distant micrometastatic disease and from the failure of chemotherapy or combined-modality treatment to ultimately cure these patients after recurrence of disease (Kaufman and Chabner 1996). In addition, there is experimental evidence to support the hypothesis that neoplasms are most sensitive to chemotherapy at their earliest stages of growth, probably due to their higher growth fraction and shorter cell cycle times. *Neoadjuvant therapy* refers to adjuvant therapy that is started in patients before treatment of the primary tumor with surgery or radiation. A complete response (CR) is defined as the disappearance of all clinical evidence of tumor (Morrison 1998a). A partial response (PR) is defined as at least a 50% regression of all measurable lesions. Stable disease (SD) is defined as a less than 50% increase in measurable tumor volume with no new tumor lesions, and progressive disease (PD) is defined as a greater than 50% increase in measurable tumor volume or the appearance of new tumor lesions.

Chemotherapy may be broadly defined as the application of drugs to kill or inhibit the growth of viruses or foreign cells, such as bacteria, in the body. Cancer cells can be considered "foreign" in this sense. Cancer chemotherapy was first successfully practiced when nitrogen mustards used as war gases were found to inhibit tumor growth. Unfortunately, they were also extremely toxic for the patient. Effective chemotherapy with more specific agents was not widely used prior to

the 1960s. Use of chemotherapy in cancer patients grew markedly in the 1970s, providing a means of curing some cancers and lengthening life expectancy with others. In contrast to radiation and surgery, where the limitations are damage to local vital structures and access to metastatic lesions, chemotherapy is principally limited by the presence of a population of resistant cells. The probability that resistant cells will be present within a tumor is correlated to the number of cells present and tumor volume. Thus, it has been found in human medicine that it is difficult to completely cure many solid tumors consisting of more than 1 million cells (approximately 1 mg of tissue) with chemotherapy alone.

The decision to use one or several of the treatment modalities for a patient with cancer rests on factors such as those listed in Table 52.1. Detailed recommendation of specific treatment protocols is beyond the scope of this chapter. Protocols for timing and dosage of drug combinations have been published (Morrison 1998d; Ogilvie and Moore 1995). Veterinary practitioners may also seek the advice of an experienced medical oncologist before instituting therapy with the drugs to be discussed. Cancer chemotherapy should be approached in a judicious manner because the disease process is often intractable and the drugs are frequently toxic. However, carefully planned and monitored therapy can prolong an animal's life while improving quality of life and can be a positive and rewarding experience for both the pet owner and the veterinarian.

CANCER BIOLOGY. A brief review of certain aspects of cancer biology will aid in understanding the rationale behind treatment protocols and the limitations of chemotherapy. Discovery of qualitative differences between normal and cancerous cells would facilitate development of more selective drugs, i.e., drugs that have relatively lower toxicity for normal tissues. Selectivity is currently based primarily on quantitative differences. That is, both normal and cancer cells have essentially the same ongoing biochemical processes, but the rates and timing may be very different. For most tumors, the success of chemotherapy depends on having drugs that are taken up more avidly by tumor cells, that bind more tightly to some tumor cell constituent, or that affect processes that occur more rapidly in tumor cells, thus enhancing their effect on cancer cells relative to normal cells.

Cell Cycle. The *cell cycle* is the progression of a dividing cell through phases from one mitosis to the next. G1, a presynthetic phase, immediately follows mitosis and is extremely variable in duration, depending on the cell type and the presence or absence of nutrients, growth factors, and metabolic by-products. During this phase, normal cellular events, including protein and ribonucleic acid (RNA) synthesis, occur, in preparation for deoxyribonucleic acid (DNA) synthesis during the S phase. Control of initiation of the S phase, as well as other events in the cell cycle, has been intensively investigated for clues to unique reactions that could be targets of anticancer drugs. The S phase may require between 8 and 20 hours for completion. Constituents required for mitosis are synthesized during the next phase, G2, which may last 3 hours. Mitosis (M phase) typically requires 1 hour for completion to end the cell cycle.

For a variety of reasons, as tumors mature, certain cells may stop traversing the cell cycle. Others may traverse it so slowly that for purposes related to cancer therapy, they are not in the population of actively dividing cells. Operationally, these cells may be grouped and referred to as being in the G0 phase. Such cells are not part of the "growth fraction" of the tumor. However, under proper growth conditions, those that were merely traversing the cycle extremely slowly may be "recruited" back into the pool of actively dividing cells. Cells that have stopped dividing because of differentiation to more mature cell types are less likely to be recruited into the population of dividing cells. One line of anticancer research is investigating means of inducing such terminal differentiation.

Tumor Growth Rate. The apparent growth rate of a tumor does not necessarily reflect the rate at which cells traverse the cell cycle. If it did, and the tumor consisted of only one immortal cell type, tumor growth could be described by a simple geometric progression; i.e., the number of cells would double after an interval equal to the cell cycle time. If this were the case, and if 10^9 cells were required for diagnosis of a tumor, approximately 32 cell cycle times would be required for a single cancer cell to result in a clinically apparent tumor.

In an experimental tumor system it was observed that the time required for the number of cells to double

perspective on the relationship. The following values for the dog list the weight in kilograms followed by the surface area in square meters: 1, 0.1; 10, 0.46; 20, 0.74; 30, 0.96; 40, 1.17; and 50, 1.36. Obviously, failure to convert the patient's weight from pounds to kilograms prior to using the conversion table will result in an approximately doubled dosage being administered to the patient. For many drugs, this calculation error could be fatal.

For several drugs, it has been shown that using body surface area for dose calculation rather than weight may lead to inappropriate drug levels and toxicities, particularly in smaller patients (Arrington et al. 1994; Page et al. 1988). For further discussion of the use of body surface area–based dose calculations, see Price and Frazier 1998 and Frazier and Price 1998.

As one might predict, drug dosage, interval between doses, and duration of therapy are crucial factors in determining the success of cancer therapy. It is important to realize that drugs must be used at the maximum dose possible to achieve optimal therapeutic effects. If the dose of a drug is decreased to the point that it does not produce clinical toxicity, the regimen will likely fail.

Resistance. Despite increasing success in treating cancer, particularly in producing initial responses, too often the long-term result remains failure. Although drug resistance can be viewed from the perspective of the whole tumor, ultimately drug effectiveness will depend on the response of each individual cell to the drug. Resistance to drugs by individual cells can be temporary or permanent and can be present when therapy is begun or arise during its course. Resistance mechanisms can be divided into three broad categories: low concentration of drug in the tumor (pharmacokinetic resistance); small fraction of cells in a susceptible state (kinetic resistance); and biochemical resistance of the tumor cells to the drug even in normally susceptible phases (genetic resistance).

Pharmacokinetic resistance can occur in response to changes in absorption, distribution, biotransformation, and elimination of drugs. Distribution to tumor cells is one of the most important of these. Blood flow to tumors is not as well regulated as it is to normal tissues. In fact, tumors may outgrow their blood supply, leading to extremely slow growth in affected portions of the tumor due to lack of nutrients, including oxygen, and a buildup of metabolic by-products. Under these conditions, drug delivery to many parts of the tumor may be impaired, and further, drug that does reach these sites may find fewer responsive cells because under unfavorable conditions, cells may leave the growth fraction.

As mentioned earlier in this chapter, most cytotoxic drugs are more effective against cells that are rapidly moving through the cell cycle, as would occur in tumors with a large growth fraction. Since the growth fraction is generally inversely proportional to the tumor volume, it is not surprising that cytotoxic drug therapy is less effective on large tumors due, in part, to the decreased growth fraction. This type of resistance has been termed *kinetic resistance* and is considered to be reversible. In this type of resistance, large numbers of cells may become resistant at once.

As important as pharmacokinetic and kinetic resistances may be, they are ultimately less responsible for drug failure than *genetic resistance,* where the trait for the particular resistance is passed to daughter cells and is irreversible. This type of resistance arises from a single mutant cell and may be present before therapy is begun or may appear during therapy. By the time they are diagnosed, most tumors have at least a few cells that are resistant to a particular chemotherapeutic regimen. Regardless of how or when resistant cells appear, as sensitive cells are killed, the resistant cells constitute an increasing proportion of the total number of tumor cells. After they become the predominant cell type, what was originally a "clinically sensitive" tumor becomes a "clinically resistant" tumor.

The *Goldie-Coldman model* assumes that genetic resistance is a permanent all-or-none phenomenon and predicts that once a single cell within a tumor becomes resistant to the current course of therapy, that therapy is ultimately doomed to failure. This assumption has been challenged, however, by the finding that in at least one in vitro tumor model, resistance is associated with shifts in the dose-response curve to the right, i.e., to requiring higher doses of drug (Kuczek and Chan 1992). Nevertheless, the Goldie-Coldman model is valuable because it highlights the importance of early, aggressive therapy to minimize the time available for resistant cells to appear. Biochemical mechanisms of genetic drug resistance in tumor cells are similar to those of bacteria. The following mechanisms have been listed: decreased intracellular accumulation of drug, defective transport, defective drug activation, altered DNA repair, gene amplification, altered target protein, increased drug detoxification, and defective apoptosis (Kaufman and Chabner 1996).

Decreased intracellular accumulation of drug is the ultimate result of a well-known phenomenon called *multidrug resistance* (MDR), which leads to resistance to structurally different drugs, e.g., anthracyclines, epipodophyllotoxins, and vinca alkaloids. Other mechanisms of MDR continue to be investigated, including alteration of DNA topoisomerase activity, alteration of glutathione metabolism, increased lung-resistance protein, increase in DNA-repair associated protein, inhibition of apoptosis, and multiresistance protein-associated MDR (Goldie and Coldman 1998; Kaufman and Chabner 1996; Tannock and Goldenberg 1998). The following discussion will focus on the best-studied example, membrane-bound p-glycoprotein (Gp170) activity.

Decreased accumulation of drug in MDR cells is associated with overexpression of p-glycoprotein (Gp170), which acts as a membrane transporter for a variety of molecular structures from the interior of the cell. This membrane glycoprotein pumps drugs out of cells by a mechanism that requires ATP. Substrates for

other drugs, but requires multistep activation in the liver. The first step in the activation of cyclophosphamide is accomplished by a hepatic cytochrome P-450 mixed-function oxidase. One of the metabolites, aldophosphamide, may be converted to phosphoramide mustard and acrolein in target cells. Phosphoramide mustard alkylates and cross-links DNA strands. Increased aldehyde dehydrogenase concentrations have been documented in some tumors resistant to cyclophosphamide.

When used clinically, the dose-limiting side effect of cyclophosphamide is bone marrow suppression, leading to leukopenia and thrombocytopenia. The nadir occurs 7–10 days following oral or IV administration. Sterile necrotizing hemorrhagic cystitis, probably caused by the metabolite acrolein, has been associated with administration of cyclophosphamide in both cats and dogs (Crow et al. 1977) and is a cause for stopping therapy with the drug. To decrease the incidence of this toxicity, which is manifested by bloody urine, dysuria, and frequent secondary bacterial infections, the oral drug should be administered in the morning (if the pet can be let out during the day) so that the animal can be allowed to urinate frequently. Water intake may be encouraged by lightly salting the food and, in some instances, by the concurrent administration of corticosteroids. Sterile hemorrhagic cystitis has developed after a single IV dose of cyclophosphamide (Peterson et al. 1992). In addition, cyclophosphamide has been associated with the development of transitional cell carcinoma of the urinary bladder (Macy et al. 1983).

Ifosfamide is a structural analog of cyclophosphamide that has been proven to have some efficacy against canine lymphoma (Frimberger et al. 1995). It is also similar to cyclophosphamide in that it must be converted to cytotoxic metabolites in the liver. One of these metabolites, phosphoramide mustard, can alkylate and cross-link DNA chains. Currently, ifosfamide is not a first-line drug. Its propensity to cause dysuria, frequent urination, and other signs of bladder irritation is even greater than that of cyclophosphamide. Bladder irrigation with thiol compounds may help, and systemically administered *N*-acetylcysteine may also be of value. It is highly recommended that mesna be concurrently administered (Elias et al. 1990; Frimberger et al. 1995). Mesna (sodium 2-mercaptoethanesulfonate, Mesnex) is an injectable used prophylactically and specifically to reduce the incidence of cystitis. The physically inert mesna disulfide (administered form) is reduced by renal tubules to mesna. Mesna binds to and detoxifies urotoxic metabolites of cyclophosphamide and ifosfamide (Elias et al. 1990) Myelosuppression (neutropenia and milder thrombocytopenia) remains a dose-limiting toxicity.

Melphalan, USP (L-Phenylalanine mustard, Alkeran), has been used primarily for treatment of multiple myeloma. It may produce anorexia, nausea, and vomiting but tends to be well tolerated. Leukopenia, thrombocytopenia, and anemia are the dose-limiting toxicities.

Chlorambucil, USP (Leukeran), is used in cases of chronic lymphocytic leukemia and small cell lymphoma, as well as inflammatory disorders characterized by lymphocyte infiltration in dogs and cats. It is also used as a substitute for cyclophosphamide, particularly when hemorrhagic cystitis has developed. It can be used orally and is the slowest acting of the mustards. Its toxic effects are bone marrow suppression, including leukopenia and delayed thrombocytopenia, but it is typically well tolerated by dogs and cats. High doses may cause cerebellar necrosis and atrophy. Nausea, vomiting, diarrhea, and skin pigmentation are rare.

ALKYLSULFONATES. *Busulfan*, USP (Myleran), is the only significant member of the alkylsulfonates. It is used to treat chronic granulocytic leukemia and polycythemia vera in people. Therapeutic doses produce myelosuppression; in humans, the leukocyte count begins to fall after approximately 10 days of therapy and continues to fall for 2 weeks after discontinuation of the drug. Thrombocytopenia and anemia may also be evident. It may produce so-called busulfan lung, in which pulmonary fibrosis is the end result. Skin hyperpigmentation occasionally occurs.

NITROSOUREAS. The nitrosoureas include carmustine and lomustine. Streptozotocin, another nitrosourea, is rarely used in treatment of animal cancers due to nephrotoxicity but has been used to treat insulinomas in dogs (Meyer 1976, 1977). The nitrosoureas are primarily bifunctional alkylating agents but also act by carbamoylation of lysine residues of proteins. Because they are highly lipid soluble, they have proven useful against tumors of the canine CNS, as well as relapsed canine lymphoma (Dimski and Cook 1990; Fulton and Steinberg 1990; Hamilton et al. 1991b; Moore et al. 1995a). There are reports of its use for unresectable mast cell tumors in dogs.

Limiting toxicities of this group are severe: cumulative myelosuppression and thrombocytopenia. Delayed and cumulative bone marrow suppression is a noteworthy characteristic of the nitrosoureas. In humans the nadir is reached in 4–6 weeks. There is no cross-resistance with other alkylating agents, and the drugs are not cell-cycle-specific. The nitrosoureas have extremely short plasma half-lives; in humans the α and β half-lives are 6 and 68 minutes, respectively. In humans, the drugs are primarily metabolized in the liver.

Carmustine, *N,N-bis*(2-chloroethyl)-*N*-nitrosourea (BiCNU, BCNU), is used in humans with meningeal leukemia and other brain tumors. The treatment interval, dosage, or both are altered if myelosuppression is severe or persistent. The infusion rate must be slow (dose given over 1–2 hr) to prevent local pain. Nausea and vomiting are major problems and occur about 2 hours after drug administration. Hepatotoxicity is manifested by increased serum glutamic pyruvic transaminase (SGPT), alkaline phosphatase, and bilirubin. In addition to the already mentioned bone marrow suppression, there may be renal toxicity. Lomustine

PYRIMIDINE ANALOGS. *Cytarabine,* USP (β-cytosine arabinoside, arabinosyl cytosine, Ara-C, Cytosar), is a pyrimidine analog that is well established in the treatment of acute leukemia in humans, as the sole agent and in combinations. It has also been used for lymphoreticular and myeloproliferative disorders in dogs and cats, particularly when the CNS is involved. It has been reported to cause remission in a cat with megakaryocytic leukemia (Hamilton et al. 1991c).

Cytarabine enters cells via a membrane transporter. It inhibits DNA synthesis and is, therefore, active in the S phase of the cell cycle. It must be activated to Ara-cytidine triphosphate (Ara-CTP) to inhibit DNA synthesis. The first step in the activation of Ara-C is phosphorylation catalyzed by deoxycytidine kinase to form Ara-cytidine monophosphate (Ara-CMP), the 5′-monophosphate nucleotide. Ara-CMP is then converted to Ara-CTP, which serves as a substrate for DNA synthesis. DNA polymerase is inhibited by Ara-CTP, but the dominant cytotoxic effect stems from incorporation of Ara-CTP into the DNA chain, where it terminates chain growth.

Acquired or de novo resistance may be related to increased intracellular concentration of cytidine deaminase, which converts cytarabine to a less toxic form, Ara-U. Resistant mutants that lack deoxycytidine kinase, the activating enzyme, have been identified. Some resistant mutants have been shown to have high intracellular concentrations of deoxycytidine triphosphate (dCTP), causing decreased activation (phosphorylation) of cytarabine.

Bone marrow suppression is the dose-limiting toxicity. It is manifest by leukopenia, thrombocytopenia, anemia, and megaloblastosis. The leukocyte count may drop within 2 days and continue to fall for up to a week after treatment is stopped. Rapid IV injection is especially likely to induce anorexia, nausea, and vomiting. In contrast to fluorouracil, stomatitis is uncommon. Mild, reversible hepatic dysfunction may occur. The drug should be given by IV infusion for best results but has been administered subcutaneously in animals.

Cytarabine is included in many protocols for treatment of CNS leukemia and lymphoma in dogs and cats. A pharmacokinetic study revealed that cytarabine did cross the blood-brain barrier and that therapeutic doses could produce effective concentrations in the cerebrospinal fluid (CSF) of dogs (Scott-Moncrieff et al. 1991). The plasma elimination half-life in dogs was approximately 64–69 minutes, whereas the half-life of cytarabine in CSF was 165 minutes. The peak concentration of cytarabine in CSF was 29 μM.

Fluorouracil, USP, 5-fluoro-2,4(1*H*,3*H*)-pyrimidinedione (5-FU, Efudex, Adrucil), is a pyrimidine analog used in people for carcinomas of the mammary gland, GI tract (colorectal carcinomas), and ultraviolet light–induced tumors of the skin. Some exploratory work has been done in dogs with GI tract tumors. The topical preparation of 5-flourouracil has been used on cutaneous squamous cell carcinomas in dogs and horses (Madewell and Theilen 1987; Fortier and Harg 1994).

Both DNA synthesis and RNA synthesis and function are altered by 5-FU metabolites. The pro-drug, 5-FU, is metabolized intracellularly to 5′-fluorouridine monophosphate (FUMP) and then to 5′-fluorodeoxyuridine monophosphate (FdUMP). FdUMP, a potent inhibitor of thymidylate synthase, decreases the synthesis of DNA precursors. Fluorouracil is also incorporated into RNA. It is highly cell-cycle-specific, but no clear association with a particular phase has been demonstrated. The relative importance of inhibition of DNA synthesis versus effects on RNA synthesis appears to be tumor dependent.

Fluorouracil is most toxic to bone marrow and oral and GI mucosa. Thus, bone marrow suppression manifested by neutropenia, thrombocytopenia, and anemia can be severe and is the major dose-limiting factor. Anorexia, nausea, and vomiting are frequently seen. Diarrhea and stomatitis are indications for the interruption of therapy. CNS toxicity is regarded as unusual in humans but may be more common in animals (Morrison 1998b). The signs include dementia, excitement, tremors, and ataxia, sometimes followed by opisthotonos, tonic-clonic convulsions, dyspnea, shock, and death. Unexpected neurotoxicity was reported when 5-FU was used in combination with dactinomycin and cyclophosphamide (Hammer et al. 1994a). The drug is contraindicated in cats due to neurotoxicity (Morrison 1998b). Other manifestations of toxicity include skin rash, alopecia, hyperpigmentation, photosensitization, and mild tissue irritation. A cream formulation has been shown to be very toxic if accidentally eaten. A report on 5-FU toxicity in dogs has been published (Dorman et al. 1990).

Fluorouracil is unpredictably absorbed from the GI tract and is usually given by IV injection. The drug is highly metabolized and readily enters the CSF. Fluorouracil is supplied in ampules containing 500 mg of drug for IV injection and as a 5% cream (Efudex). The cream is intended for actinic keratoses and superficial basal or squamous cell carcinoma.

PURINE ANALOGS. *Mercaptopurine,* USP (6-mercaptopurine, 6-MP, Purinethol), is a purine analog used mainly to treat lymphoreticular tumors in humans and has been rarely used to treat leukemias in dogs. Its close relative, *Azathioprine,* USP (Imuran), is used as an immunosuppressive agent.

6-Mercaptopurine must be activated in vivo. It is a substrate for hypoxanthine-guanine phosphoribosyltransferase (HGPRT) and is converted to the corresponding ribonucleotides. The product of the HGPRT reaction with 6-MP, 6-thioinosine-5′-phosphate, inhibits conversion of IMP to AMP and GMP, possibly the cytotoxic effect. Acquired resistance is not shared with other neoplastic agents and may be most often caused by a deficiency of the enzyme HGPRT. Other mechanisms, including decreased uptake by target cells, have been reported. Leukopenia, anemia, and a less severe thrombocytopenia may occur. GI toxicity includes frequent nausea, vomiting, and anorexia.

Stomatitis and diarrhea are rare. Reversible cholestatic jaundice is fairly frequent. Mercaptopurine is variably absorbed after oral administration.

Natural Products

VINCA ALKALOIDS. The vinca alkaloids are large, complex substances derived from the periwinkle plant (*Vinca rosea* L.). Although similar in structure, *Vincristine Sulfate*, USP (Oncovin), and *Vinblastine Sulfate*, USP (Velban, Velsar), differ considerably in antitumor efficacy as well as in the doses that produce toxic effects. These drugs, especially vincristine, are widely used in veterinary medicine in combination with others. Vincristine is the drug of choice for treating transmissible venereal tumor and is commonly used against lymphoreticular neoplasms in a variety of combination protocols. In addition, it may be used in combination with doxorubicin and cyclophosphamide to treat soft-tissue sarcomas. While vincristine has not proven particularly effective, vinblastine has been used with some success to treat unresectable canine mast cell tumors (McCaw et al. 1997; Thamm et al. 1999). Vinca alkaloids are specific to the M phase.

Vinca alkaloids are taken into cells by an energy-dependent carrier-mediated transport system. Both produce a colchicine-like arrest in metaphase. They bind to tubulin, a key protein in microtubules, and cause their dissolution. Microtubules are important for maintaining structural integrity of cells, as conduits for transport of solutes and neurotransmitters, and for secretion of some hormones, such as insulin and thyroid hormones. They are also important for mitotic spindle formation. Inability to segregate chromosomes may be the cytotoxic effect, but the alteration of transport processes may underlie some of the adverse effects. Both colchicine and podophyllotoxin bind to tubulin, but apparently at sites different from the vinca alkaloids. Taxol, an exploratory anticancer drug, also binds to tubulin, but the effect is to increase stability of microtubules rather than to cause their dissolution. It is remarkable that although structurally similar, there is no cross-resistance between vincristine and vinblastine. The vinca alkaloids are, however, susceptible to the MDR phenomenon related to the presence of p-glycoprotein in affected cell membranes (Georges et al. 1990).

Vinblastine may produce a dose-limiting leukopenia, the nadir of which occurs at 5–10 days. Hematologic effects of vincristine are mild, but neutropenia is occasionally seen (Hahn et al. 1996). Thrombocytopenia and anemia are rare with both drugs. Indeed, vincristine induces thrombocytosis and is used to treat severe cases of immune-mediated thrombocytopenia. Both are severe tissue irritants.

Vincristine is much more likely than vinblastine to produce neurotoxicity, although entry of either drug into the brain and CSF is minimal. This difference is paradoxic because vinblastine is more lipid soluble. One hypothetical explanation is that the slower elimination of vincristine relative to vinblastine may lead to prolonged exposure of nerve tissue to high concentrations of vincristine. Mild sensory neuropathy presenting with sensory impairment and paraesthesia is common in humans and is not dose-limiting. Peripheral neuropathy manifested as paresis, voice change, or muscle wasting may be noted in animals (Hamilton et al. 1991a; Morrison 1998b).

In dogs, vinca alkaloids are eliminated by biliary excretion into the feces (Golden and Langston 1988). Both drugs are bound rapidly after injection by platelets, leukocytes, and other tissues rich in tubulin, which probably contributes to their rapid clearance from plasma. Because of the vesicant action of the vinca alkaloids, they should be carefully administered through a butterfly or indwelling catheter.

TAXOL. Taxol (paclitaxel) is the subject of intense interest because it has shown antitumor activity in drug-refractory ovarian and breast carcinomas in people (Horwitz 1992). Its source, the bark of the slowly growing yew, *Taxus brevifolia,* found only in old-growth forests of the Pacific Northwest, made its use problematic. Many trees had to be destroyed to obtain sufficient bark for a limited number of doses. However, supplies of the drug are now more plentiful due to successful efforts to synthetically produce the drug. Veterinary applications have not yet been extensively developed.

The mechanism of taxol promises new approaches to therapy. It is most effective as an inhibitor of cell replication in late G2 and M phases of the cell cycle. Taxol binds specifically and reversibly to tubulin subunits, preferentially to the β subunit. In the presence of microtubule-associated proteins, it can polymerize tubulin into stable microtubules. Ordinarily, microtubules are formed at 37° with expenditure of GTP. Calcium ions and reduced temperature (4°) depolymerize microtubules, but taxol converts the polymer into a stable form that will not depolymerize. Because polymers must continually be formed and broken down to meet changing needs of cells, taxol-induced stability of microtubules is obviously toxic.

Resistance to taxol stems from alterations in α and β subunits of tubulin and from the p-glycoprotein transport system associated with MDR. An interesting observation is that some cells with altered α and β subunits are actually dependent on taxol. This is reminiscent of bacteria that may be sensitive, resistant, or dependent on streptomycin depending on which one of three specific amino acids has been incorporated at a specific location in a ribosomal subunit.

In preclinical normal dog studies, sensitivity to the vehicle used to keep the drug in solution, cremophor EL plus alcohol, was manifested as pruritus, anaphylaxis, hypotension, and edema (Ogilvie et al. 1993a; Ogilvie 1994). Myelosuppression may be the dose-limiting toxicity and occurs on days 3–7. Although slowing the IV infusion rate may also lessen acute side effects, hypersensitivity reactions can be minimized by pretreating the patient with corticosteroids, cimetidine, and diphenhydramine 1 hour before administering paclitaxel (Morrison 1998b). Cats receiving the drug may develop anorexia that can last several days.

EPIPODOPHYLLOTOXINS. Podophyllotoxin is an extract of the mandrake plant that has led to the development of two synthetic derivatives: teniposide (VM-26) and etoposide (VP-16, VP-16-213, VePesid). Etoposide has become an important agent in the treatment of some human tumors. The mechanism of action of these drugs is apparently quite different from that of their parent, which is a spindle poison and produces metaphase arrest. Protein-linked single-strand breaks in DNA have been observed after exposure to etoposide. It inhibits nucleoside transport into cells as well as RNA and DNA synthesis. Etoposide binding to topoisomerase II may be responsible for the cytotoxic effect. Topoisomerase II catalyzes topological alterations in chromosomes that allow replication, transcription, and repair of DNA. Etoposide acts primarily in the G2 phase but may also act in late S or M phases. Increased expression of the p-glycoprotein associated with MDR has been observed in some tumors resistant to this drug. In a study of 13 dogs with lymphoma, only 2 had a response after treatment with etoposide (Hohenhaus and Matus 1990).

In people, the predominant dose-limiting adverse effect is hematologic, particularly neutropenia. The nadir occurs during the second week and recovery occurs during the third week. Nausea and vomiting are usually mild, and hair loss is common. Peripheral neuropathy has been observed and may be additive with that caused by other anticancer drugs. Parenterally administered etoposide should be given by infusion to avoid hypotension. Dogs receiving etoposide become hypotensive and exhibit a cutaneous reaction characterized by moderate to severe pruritus, urticaria, and swelling of the head and extremities attributed to the drug vehicle, polysorbate 80 (Ogilvie et al. 1988; Hohenhaus and Matus 1990).

Etoposide is highly lipophilic but still produces a low concentration in CSF. Approximately half of the dose is eliminated in the urine, of which 30% is inactive as metabolites. The remainder is eliminated by hepatic biotransformation and biliary secretion. Severe hepatic dysfunction is an indication for dose reduction. Half-lives after a single IV dose are 2.8 and 15.1 hours in humans (Slevin 1991). Etoposide may be given orally or IV. Oral bioavailability is approximately 50% but is not linear with dose.

ANTIBIOTICS. Clinically useful antineoplastic antibiotics were obtained by screening the broth of *Streptomyces* organisms for antitumor activity. All of the drugs in this series interact with DNA and/or RNA but may act on other cellular substituents as well. Currently, it is believed that most of the toxicity and antitumor activity is the result of free-radical formation or inhibition of topoisomerase II, which causes DNA fragmentation (Morrison 1998a). In addition, alteration of the DNA helical structure that occurs with DNA intercalation may trigger enhanced topoisomerase II activity and provide a more vulnerable target for anthracycline activity. Dosage does not appear to be as schedule dependent as with the antimetabolites, so the antibiotics may be less cell-cycle-phase-dependent, but their major activity is still evident during the S phase. It is difficult to generalize about the toxicity of this group. All except bleomycin must be given IV because they produce tissue necrosis.

The three *anthracycline* derivatives used in clinical oncology are doxorubicin, daunorubicin, and mitoxantrone. Mitoxantrone differs from the other two in that it is semisynthetic and lacks a sugar moiety.

Doxorubicin Hydrochloride, USP (Adriamycin), is one of the most important chemotherapy agents in veterinary medicine and has antitumor activity against a wide variety of tumors, including solid tumors (Ogilvie et al. 1989a). It is included in many sequential combination drug protocols and is also used as a solitary agent.

The anthracyclines are tetracycline ring structures substituted with the sugar daunosamine. Doxorubicin intercalates between base pairs of DNA. Because of the lack of correlation between intercalation in DNA and cytotoxicity, it has been argued that drugs said to act by "intercalating" actually interfere with the topoisomerase II reaction. As a result, it has been suggested that these drugs should be referred to as "DNA topoisomerase II poisons" (Schneider et al. 1990).

Inhibition of DNA-dependent RNA synthesis as a result of interactions described above is only one of the reputed mechanisms of action of doxorubicin. It is also well established that generation of free radicals by the electron-accepting and electron-donating quinone and hydroquinone moieties of doxorubicin cause membrane damage and DNA strand breaks.

Doxorubicin enters cells by a passive transport process. It is now well established that one cause of resistance to anthracyclines is excess activity of the p-glycoprotein transport system. The p-glycoprotein pumps anthracyclines and other drugs out of cells, leading to decreased intracellular concentration. Other causes of resistance to doxorubicin include changes in the cell membrane, changes in intracellular generation of free radicals, gene amplification, and decreased affinity of topoisomerase II for the drug. Calcium antagonists have been noted to reverse resistance in some model tumors. Other approaches to modulating MDR include encapsulation of drug in liposomes, which may alter its intracellular distribution (Thierry et al. 1993).

Toxicoses caused by doxorubicin have been reviewed and classified as acute, short-term, or chronic (Ogilvie et al. 1989b). Acute toxicosis manifests as head shaking, localized urticaria along the course of the vein used for administration of the drug, and signs associated with histamine release, including generalized blushing of the skin and acute collapse. Short-term

A large number of cases seen in the everyday practice of small- and large-animal veterinary medicine involve lesions of the skin or its appendages. This chapter reviews the salient features of the general anatomy, histology, and biochemistry of skin relevant to the treatment of dermatologic disease, acquaints the practitioner with the features of percutaneous drug absorption relevant to the treatment of skin disease, and discusses the categories of pharmacologic preparations available on the veterinary market to treat skin diseases in domestic animals.

Only in the last few decades have scientists begun to understand how the skin functions in normal and diseased states, to understand the skin's barrier function in terms of water loss and drug delivery, and to attempt to improve the delivery of pharmaceutical agents through the skin by temporarily adjusting that barrier to deliver the drug. In order to successfully minimize the skin's ability to block the absorption of drugs in the treatment of dermatologic disease in domestic animals, it is imperative to understand the normal functional anatomy and biochemistry of the skin. In veterinary medicine, transdermal delivery is widely employed, as when pesticides are applied monthly to a single area of skin for the control of fleas and ticks over the entire body. Transdermal fentanyl patches are widely used for postsurgical analgesia. This topical port of drug delivery will see increased use for other therapeutic indications. However, most drugs applied to the skin are not intended to be absorbed systemically but are used to elicit a local therapeutic effect in the treated skin.

The characteristic which separates dermatologic therapy from other components of veterinary pharmacology is this use of topical dosage formulations to target the underlying skin. A full understanding of the biological factors that modulate absorption and of the pharmaceutical composition of dermatologic formulations (e.g., vehicles) is essential to a proper understanding of dermatopharmacology. The drugs incorporated into these formulations are the same as those used to treat diseases of other systems and will not be extensively dealt with in this chapter.

ANATOMY AND HISTOLOGY. The skin is the largest organ of the body, with the integument of the dog accounting for 24% of the overall body weight in the puppy and 12% in the adult dog (Pavletic 1991). The skin has the responsibility of protecting the internal organs of the body from extremes in temperature fluctuations, allergens, pollutants, toxic chemicals, and organisms such as bacteria, fungi, parasites, and viruses found ubiquitously in the environment.

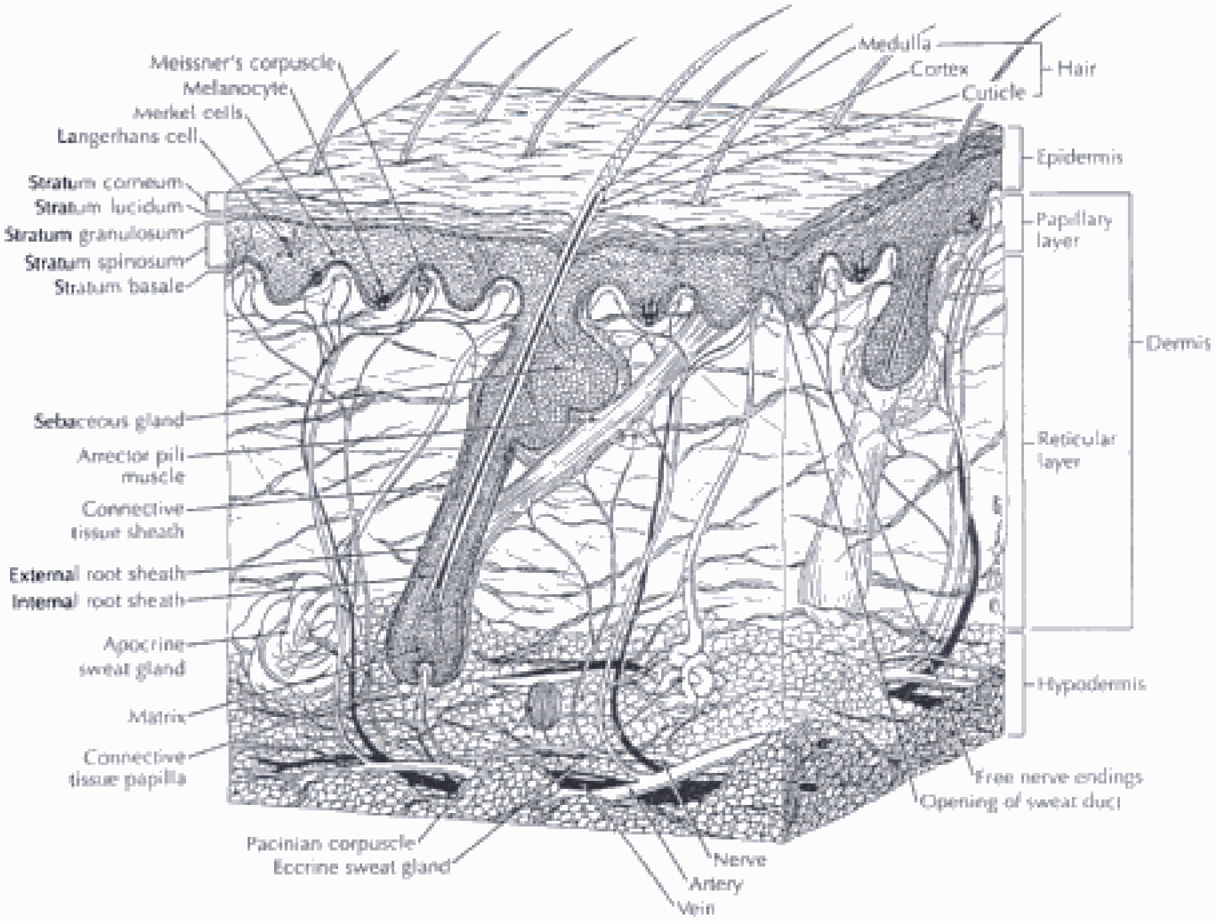

FIG. 53.1—A schematic view of the epidermis and dermis of the skin. (Monteiro-Riviere 1991)

The skin of domestic animals is quite similar in gross and histologic morphology across species lines and is usually thickest over the head, dorsum of the neck, back, and sacrum and on the plantar and palmar surfaces of the feet (Pavletic 1991), thinner on the ventral abdomen, the medial surfaces of the limbs, and the inner pinnae, and thinnest over the scrotum of male animals and the earlobe of the human. Perforating the skin are several types of appendages (depending on the species), such as hair follicles, sebaceous and sweat glands, spines, quills, scales, spurs, horns, claws, nails, and hooves (Montagna 1967). The specific anatomy of skin and hair has been reviewed extensively elsewhere (Monteiro-Riviere et al. 1993b; Blackburn 1965; Lloyd et al. 1979a; Lloyd et al. 1979b; Sar and Calhoun 1966; Kozlowski and Calhoun 1969; Strickland and Calhoun 1963; Talukdar et al. 1972; Pavletic 1991; Montagna 1967; Amakiri 1973).

The Epidermis. On the histological level, the skin can be divided into two distinct units: the epidermis and the dermis. The epidermis consists of stratified squamous keratinized epithelium that undergoes a programmed proliferation and differentiation that will eventually result in the formation of the major barrier to drug penetration: the stratum corneum. Two primary cell types exist in the epidermis: those of keratinocyte origin and those of nonkeratinocyte origin.

Five distinct layers of keratinocytes can be present in the epidermis, as shown in Fig. 53.1. Listed from the deepest layer of the epidermis to the most superficial, they are (1) stratum basale (basal layer), (2) stratum spinosum (prickle layer), (3) stratum granulosum (granular layer), (4) stratum lucidum (clear layer), and (5) stratum corneum (horny layer). Each cell layer has its point of origin at the stratum basale. The stratum basale is a single layer of cuboidal or columnar cells that rest on the basal lamina. These cells are attached to the basal lamina by hemidesmasomes, and to each other and to the cells of the stratum spinosum by desmasomes. The stratum basale cells continuously divide, with some remaining as basal cells and others beginning to move more superficially and mature by changing their intracellular content through the process called keratinization. The next more superficial layer next to the stratum basale, the stratum spinosum, is composed of irregularly shaped polyhedral cells that make up much of the bulk thickness of the epidermis. The next layer composes the stratum granulosum, which consists of several layers of cells that begin to flatten horizontally. Of primary interest are the lamellated granules within these cells, which contain polar phospholipids, such as glycosphingolipids and free steroids, and numerous hydrolytic enzymes, including acid phosphatase, proteases, lipases, and glycosidases. As these intracellular products accumulate, these cells will exocytose their intracellular products and fill in the intercellular spaces, eventually forming the extracellular lipid matrix of the stratum corneum. As these epidermal cells continue their migration, they form the stratum lucidum, a translucent line of cells found only in areas having very thick skin, such as plantar and palmar surfaces (foot pads) and the planum nasale. These cells are translucent because both nuclei and cytoplasmic organelles are missing (Monteiro-Riviere 1991; Monteiro-Riviere et al. 1993b; Idsen 1975; Montagna 1967).

The stratum corneum is the final and most superficial layer of the epidermis and is the most important layer when considering the feasibility of topical drug therapy since it is the primary barrier to percutaneous absorption. In addition to the barrier function for xenobiotics trying to enter the body from the environment, the stratum corneum also provides a barrier to insensible water loss, an evolutionary adaptation that allows terrestrial animals to exist in a nonaquatic environment. In fact, most veterinary dermatologic vehicles are targeted at this action. The stratum corneum consists of several dead layers of cells, organized into vertical columns in a tetrakaidecahedral (14-sided) configuration, the thickness of which varies depending on location (Monteiro-Riviere 1991). This particular cell shape provides a minimal surface-to-volume ratio and also minimizes systemic water loss through the skin (transepidermal water loss). Each cell is ingrained in the lipid matrix produced by the lamellated granules when the cells were still in the stratum granulosum layer. These dead cells are also surrounded by a thick plasma membrane with a submembranous layer of involucrin, also produced earlier in development. With intracellular and intercellular barriers firmly in place, the stratum corneum has the ability to constrain the passage of unwanted chemicals and toxins from the environment. Unfortunately, the stratum corneum does not discriminate between these unwanted substances and the pharmaceuticals the veterinarian may wish to penetrate the skin for topical drug therapy for the treatment of dermatologic disease.

Melanocytes are cells located in the basal layer of the epidermis and contain dark cytoplasmic granules called melanosomes. These cells impart color to the skin, the color and intensity determined by the number, size, distribution, and degree of melanization of the melanosomes. Merkel cells are also located in the basal region of the epidermis and are thought to function as slow-adapting mechanoreceptors for touch. Langerhans cells are located in the stratum spinosum but can also be present in dermal lymph vessels, lymph nodes, and dermis. The Langerhans cells' primary function is to present antigen to lymphocytes; they may also be the initial receptors for cutaneous immune responses.

The Dermis. The dermis is composed of connective tissue consisting of collagen, elastin, and reticular fibers dispersed in an amorphous ground substance and can be divided into two rather poorly demarcated areas. The papillary layer consists of loose connective tissue and connects the epidermis (stratum basale/basal lamina) to the deeper reticular layer of the dermis. The reticular layer consists of dense connective tissue connected to the hypodermis, which is composed mostly of fat.

Dispersed throughout both layers of the dermis is a network of arterial and venous blood vessels needed to nourish the cells of the epidermis and dermis as well as to take part in the last stages of the percutaneous absorption of compounds. Lymph vessels, nerves, apocrine and eccrine sweat glands, sebaceous glands, Pacinian (pressoreceptor), Meissner's (touch receptor), and Ruffini (mechanical receptor) corpuscles, hair follicles, and smooth muscles (arrector pili) are the other major structures found in the dermis. Two types of arteries, musculocutaneous and direct cutaneous, supply the needed nutrients to the epidermis. Direct cutaneous arteries run parallel to the skin, directly supplying the skin with blood, while musculocutaneous arteries supply both the skin and underlying musculature and run perpendicular to the skin. Cutaneous blood supply by each type of artery varies with species and location. Cutaneous blood flow rates may be one of the factors affecting the passive percutaneous absorption of chemicals. Table 53.1 clearly demonstrates this by comparing laser Doppler cutaneous blood flow parameters in nine species of domestic animals (Monteiro-Riviere et al. 1990).

Species Differences. As a general rule, skin structure and function are similar across species lines. However, some minor differences are apparent.

Avian integument possesses the most-profound differences in skin morphology from other domestic species. The four layers of the epidermis are, from the deepest to the most superficial, the stratum basale, the stratum intermedium (stratum spinosum), the stratum transitivum (stratum granulosum), and the stratum corneum (stratum germinativum). Unlike mammals, avians possess no skin glands (Monteiro-Riviere et al. 1993b).

The skin of aquatic mammals has a very thick stratum corneum resembling parakeratosis and there is no stratum granulosum (Montagna 1967).

Pig skin is similar histologically to human skin (Monteiro-Riviere and Stromberg 1985) and has been used experimentally to reliably predict the percutaneous absorption of chemicals in humans. With respect to cutaneous circulation, musculocutaneous arteries are the primary vascular supply to the skin of humans, apes, and swine. Loose-skinned animals (canines and felines) lack musculocutaneous arteries; all vessels involved in cutaneous circulation travel parallel to the skin (Pavletic 1991). Recent studies of piroxicam (a nonsteroidal anti-inflammatory drug) in pigs suggest

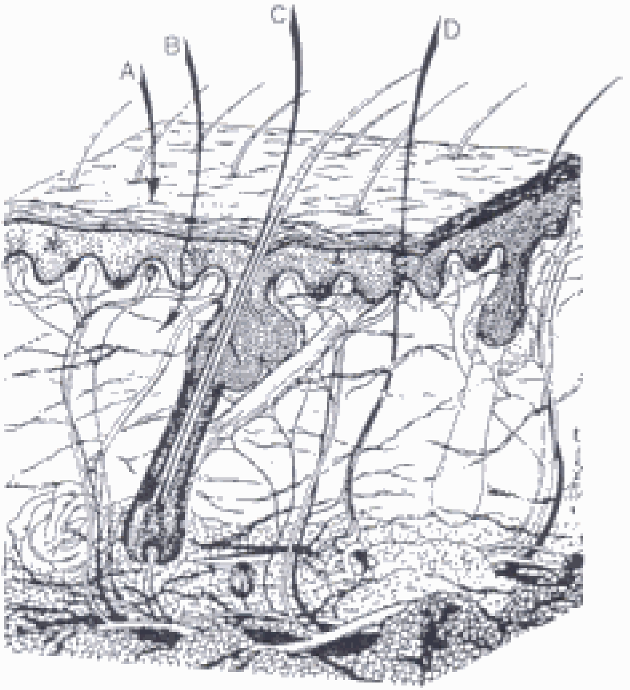

FIG. 53.2—A schematic view of the skin and the four routes of drug penetration. Drugs can penetrate through the stratum corneocytes (A), between the stratum corneocytes (B), transfollicularly via any hair follicle (C), or via an eccrine sweat gland or sebaceous gland (D).

better understand how substances diffuse through the stratum corneum, it is convenient to think of the stratum corneum as a wall in a "brick and mortar" configuration (Elias 1983), with the bricks representing the stratum corneocytes and the mortar representing the lipid matrix around them, as shown in Fig. 53.3. Permeation through the stratum corneum might occur via two routes. The first involves the drug traversing through the stratum corneocytes ("bricks") and extracellular lipid matrix ("mortar"), through the cells of the deeper epidermal cells, and then into the systemic circulation. The second route involves the chemical maneuvering its way through the stratum corneum via the intercellular lipid matrix only. It is generally accepted that the primary route of penetration is via the intercellular pathway. Because of the structure of the stratum corneum and the metabolic capabilities of the lower epidermal cells, the veterinarian must be aware that only a small percentage of the drug that is topically applied is going to actually penetrate the stratum corneum. This small fraction of the total dose will need to be able to affect the disease process occurring in the underlying layers of the epidermis.

The molecular structure of the intercellular lipid matrix throughout the epidermis is in a liquid crystalline configuration, consisting of fatty acids, ceramides, triglycerides, sterols, sterol esters, cholesterol sulfate, and miscellaneous alkanes. As epidermal cells migrate superficially and transform into the cells of the stratum corneum, the lipid content surrounding these cells changes from polar to more neutral in nature. Specifically, phospholipids and triglycerides tend to decrease while fatty acids, cholesterol, cholesterol sulfate, ceramides, and sphingolipids increase as the epidermal cells differentiate (Elias 1992). Enzymes are also present within this matrix of lipid. These lipids organize themselves into a lipid bilayer structure, with the hydrophobic ends of the molecules orienting themselves with other hydrophobic ends, and the hydrophilic ends orienting themselves in a similar fashion. More than one lipid bilayer can be formed within the intercellular matrix, leading to the formation of hydrophilic and hydrophobic channels, as illustrated in Fig. 53.4. One might assume that this complex lipid barrier would result in very low absorption profiles for hydrophilic (water soluble) compounds since these molecules would have difficulty crossing a hydrophobic barrier, but some studies have shown that many hydrophilic compounds penetrate the epidermis in much higher quantities than predicted, implying that there are other mechanisms whereby hydrophilic compounds permeate the stratum corneum. The primary mechanism by which this is accomplished is for hydrophilic molecules to penetrate through fluctuations, or "kinks," in the lipid alkyl chains (Potts and Francoeur 1992; Potts et al. 1992). Further, the permeation of hydrophilic molecules (such as water, methanol, ethanol, etc.) through the lipid matrix is due to their small size and molecular weight, which aid them in traveling through the lipid matrix through passages established by the lipid alkyl chains. This view is supported by the observation that larger hydrophilic molecules have lower percutaneous absorptions than their smaller molecular weight counterparts. Alternatively, penetration may also occur through the aqueous channels formed between the polar head groups of the lipid layers.

Chemicals may also permeate the skin using the skin appendageal route, mostly by way of hair follicles and sweat ducts. The importance of the transappendageal route on percutaneous absorption is controversial, but some studies indicate that the importance of this route tends to be species specific (Pitman and Rostas 1981). Generally, those animals possessing a sparse number of hair follicles per area of skin (humans, pigs) are considered to have little, if any, absorption of topically applied compounds via this route when compared to animals having a high density of hair follicles (cattle, sheep). In these latter animals, the stratum corneum barrier is just as impermeable to drugs as that of their less-haired counterparts, but the drug permeates the skin barrier via the hair follicles, sweat ducts, or other openings in the stratum corneum, increasing the percutaneous absorption of the chemical. It has been demonstrated that transappendageal absorption is high initially, then becomes insignificant, due to the small surface area of follicles and glands in relation to the total surface area of the stratum corneum. Topical delivery of pesticides to domestic livestock has been used for many years for the control of external as well

condition causing the disease and/or (2) applying agents that will increase the hydration of the stratum corneum by slowing transepidermal water loss. Applying keratolytics (discussed later in this chapter) is also of use. This discussion should point out that selecting a vehicle that increases the amount of water in the stratum corneum will most likely result in more permeation of drug to the underlying affected tissues, an important factor in successful dermatologic therapy. In diseases involving dry skin, returning the stratum corneum to its normal hydration state should also be a goal of dermatologic therapy.

In summary, the vehicle, not just the choice of drug, plays a crucial role in determining the success or failure of dermatologic therapy. No "ideal vehicle" exists; the veterinary clinician must evaluate the patient's skin lesion and should determine what drug is indicated and which vehicle would best augment that therapy. Both factors may markedly influence the success of therapy.

Other Factors Affecting Percutaneous Absorption. Other factors that may enhance or hinder percutaneous absorption are the molecular weight of the chemical, temperature, blood flow, and skin age. Increasing the blood flow through the dermis would suggest a more rapid removal of drugs absorbed from the epidermis (Riviere and Williams 1992). Vasoconstriction of these vessels has been shown to significantly decrease percutaneous absorption of 6-methylprednisolone and testosterone (Malkinson 1958). The temperature of the air surrounding the skin plays a role in blood flow, with warmer environmental temperatures or skin showing one of the cardinal signs of inflammation (heat) increasing the blood flow to the skin and cooler temperatures decreasing cutaneous blood flow. An inverse relationship appears to exist between absorption rate and the molecular weight of the drug (Idsen 1975). Although smaller molecules tend to increase total topical dose absorbed through the skin, there is considerable variability in the amounts percutaneously absorbed among compounds of similar molecular weights (Idsen 1975; Tragear 1966).

Penetration Enhancers. The stratum corneum has been portrayed as a formidable and almost impenetrable barrier to the absorption of lipophilic, hydrophilic, and amphoteric xenobiotics. Many efforts have been made to adjust the barrier of the stratum corneum to increase the percutaneous absorption of topically applied xenobiotics, for the most part with only limited success. The barrier function of the stratum corneum can be structurally modified using a relatively small class of compounds, collectively known as penetration enhancers or penetration accelerants, that increase the percutaneous absorption of many compounds.

Many reports exist in the human and veterinary literature of various agents that have been shown to accelerate penetration of compounds through the skin, but few describe the precise mechanism by which an individual penetration enhancer performs this function. One theory, the lipid-protein-partitioning concept, has been proposed for the mechanism of action of all the known penetration enhancers, including penetration via the intercellular as well as the intracellular routes (Barry 1991). For both routes, this theory acknowledges that polar (hydrophilic) molecules permeate the skin via polar channels (either by aqueous pores or by alkyl group modulation), which are different from the channels used by nonpolar (hydrophobic) molecules. After application to the skin surface, the drug molecules diffuse out of the vehicle and into the stratum corneum and begin to traverse the many aqueous and lipid barriers found in the intercellular matrix (see Fig. 53.4) in order to reach the rest of the body via the systemic circulatory system. Penetration enhancers are hypothesized to modify these lipid and aqueous bilayers of the intercellular lipid matrix and allow topically applied compounds to penetrate the stratum corneum more readily by disrupting the normally very organized structure of the lipid layers.

It is convenient to organize the known penetration enhancers into four common subgroups: azone and its derivatives, urea and its derivatives (1-dodecylurea, 1,3 didodecylurea, 1,3 diphenyl urea, propylene glycol, dimethylisosorbide), the terpenes (carvone, pulegone, piperitone, menthone, cyclohenene oxide, terpinen-4-ol, and others), and the aprotic solvents (dimethylsulfoxide, demethyl formamide, decylmethyl sulfoxide, 2-pyrrolidone, and others). At the present time, the first three groups are used almost exclusively in human pharmaceutical products and research and will not be discussed here. The most extensively used penetration enhancer in veterinary medicine is dimethylsulfoxide (DMSO).

DMSO is a product from the processing of wood pulp and is a dipolar and aprotic solvent. DMSO is also produced by phytoplankton and is present in many foods (Herschler 1982). DMSO has been used to treat a myriad of skin ailments, including otitis externa, interdigital cysts, lick granulomas, superficial burns, skin grafts, and snakebites, and to reduce the engorgement of the mammary glands of the nursing bitch (Knowles 1982). Other less common veterinary uses for DMSO have also been described (Jacob et al. 1965; Jacob 1982; Knowles 1982). In addition to penetration enhancement, DMSO is also bacteriostatic, vasodilatory, fibrinolytic, and anti-inflammatory and produces some degree of topical analgesia. DMSO produces a thermal effect after direct application to the skin, which may function to alleviate pain in the skin and in the underlying muscle and bone. The transient erythema that is induced after topical administration of DMSO is due to the release of histamine (Jacob et al. 1965). These effects are considered transient and reversible and will not generally increase in severity after multiple treatments, indicating no need to discontinue therapy. Potential skin irritation occurs at concentrations of greater than 70% (see the 6th edition of this text for more information on DMSO).

DMSO has the potential to enhance the percutaneous absorption of a number of topically applied compounds.

structure of the epidermis by forming a protective barrier against the surrounding environment. They differ from protectives in that they inherently reduce the irritation from these external stimuli. This group comprises a large and diverse number of chemicals, including mucilages, gums, dextrins, starches, polymeric polyhydric glycols, glycerin, gelatin, hydroxypropyl cellulose, hydroxypropyl methylcellulose, hydroxyethyl cellulose, methyl cellulose, and polyvinyl alcohol. The dried gum extracts from the acacia and tragacanth plants can readily dissolve in water to form mucilages (see the 6th edition of this text for more detail). The most commonly used demulcents in veterinary dermatology today are glycerin, propylene glycol, and the polyethylene glycols.

Glycerin is a hygroscopic, trihydric alcohol prepared from propylene and has been used for many years as a suppository, with high concentrations of this vehicle relieving constipation by drawing water from the body and into the colon. Glycerin is a clear, colorless liquid that is miscible with water and alcohol and has been used neat to reduce corneal edema and to facilitate ophthalmoscopic examinations. Used in high concentrations topically on the skin, glycerin may dehydrate and irritate the skin, thereby increasing transepidermal water loss. Lower concentrations of glycerin absorbed into the skin hydrate the stratum corneum because of glycerin's hygroscopic nature. Despite its side effects, glycerin makes an excellent vehicle for topical drug delivery when used at lower concentrations.

Propylene glycol (1,2 propanediol) is a hygroscopic, colorless, odorless water-soluble liquid that is miscible with many compounds (water, alcohols, acetone, many volatile oils) and is also bacteriostatic, fungistatic, and nonocclusive. It was first considered for use in 1932 to be used with a drug to treat human syphilis and has since been used as a nontoxic antifreeze in dairies and beer breweries (Catanzaro and Smith 1991). Propylene glycol is an ideal medium for the topical delivery of many drugs in animals and humans, as well as for many oral and parenteral drug formulations, such as antitussives and shampoos. Propylene glycol spreads evenly onto the skin's surface and has a very low evaporation rate; it is not greasy to the touch, does not stain clothing or hair, and has some effect on slowing transepidermal water loss, thereby hydrating the stratum corneum to some extent. Topical hypersensitization and other toxicities are rare but have been reported (Catanzaro and Smith 1991).

Polyethylene glycols are a group of structurally similar compounds that differ in molecular weight. The larger the number, the higher the molecular weight and the more viscous the formulation becomes. At ambient temperature, polyethylene glycols 200, 300, 400, and 600 are clear viscous liquids; polyethylene glycols 900 to 9000 are semihard waxy solids at room temperature. As a group, the polyethylene glycols do not easily hydrolyze and are nontoxic, bland, highly water soluble, and nonvolatile.

TABLE 53.2—Emollients in use today

Official vegetable oils	Animal fats	Hydrocarbons
Olive oil	Lanolin (wool fat with water added)	Paraffin
Cottonseed oil	Anhydrous wool fat (no water added)	Petrolatum
Corn oil	Lard	White petrolatum (vasoline)
Almond oil	Whale oil	Mineral oil
Peanut oil		White/yellow waxes (beeswax)
Persic oil		Spermaceti
Cocoa butter		

Emollients. Emollients are bland, fatty materials often used to soften or moisten the skin. Emollients are particularly useful when treating skin conditions resulting from water-soluble irritants and airborne bacteria because of their ability to act as a protectant, sequestering the damaged skin away from these noxious stimuli. When used topically, emollients soften skin by decreasing transepidermal water loss, or transpiration, and increasing the hydration of the stratum corneum. A recent addition to this class are silicone-based polymers such as dimethicone. Therefore, this is a useful group of compounds for treating dermatologic conditions involving dry, crusty, or flaky lesions of the epidermis. Emollients are used today as vehicles for many lipid-soluble drugs. Examples of commonly used emollients are listed in Table 53.2.

Astringents. Astringents precipitate protein, toughen the skin, promote healing, and dry the skin when applied topically. When used to coagulate blood, astringents are said to be styptic and elicit a mildly uncomfortable sensation when applied to small open wounds. Most of the chemicals in this group are inorganic salts of aluminum, zinc, potassium, and silver and include aluminum chloride, aluminum sulfate, calamine (a combination of Fe_2O_3 and ZnO_2), potassium permanganate, silver nitrate, zinc chloride, zinc oxide, zirconium chlorhydrate, and tannic acid. There are many germicidal agents that also have astringent activity. Other astringents are of vegetable origin, most of these preparations owing their activity to tannic acid (gallotannic acid). Astringents in the vegetable-derivative group include gallic acid, kino, krameria, and rubus (blackberry). Astringents have limited uses in veterinary medicine today.

Rubefacients, Irritants, and Vesicants. Chemicals in this class are used to induce hyperemia (rubefacients), hyperemia and inflammation (irritants), or cutaneous blisters (vesicants). Heat applied to the skin via a hot-water bottle, heat lamp, moist hot pack, or an electric heating pad are acceptable rubefacients and are extensively used in human medicine. Chemical rubefacients are more commonly used in veterinary medicine, mainly due to the difficulty in applying the heat sources

skin diseases. The use of vitamin A was limited, however, as the levels needed to induce a clinical improvement of the lesions often induced signs of hypervitaminosis A. This side-effect dilemma prompted research into vitamin A substitutes, which led to the discovery and testing of over 1500 retinoids. Three retinoids—tretinoin, isotretinoin, and etretinate—are available for clinical use today.

The retinoids, like vitamin A, act as growth and differentiation regulators in the skin when administered orally or topically. Although the exact mechanism by which the retinoids exert these effects is not completely understood, it is theorized that retinoids alter RNA synthesis within the cell, in turn altering protein synthesis and prostaglandin production, and also affecting some enzymes, such as ornithine decarboxylase and collagenase (Power and Ihrke 1990). The overall effect of the retinoids is to "normalize" the epithelium in those diseases responsive to these drugs.

In humans, the retinoids are used to treat severe recalcitrant cystic acne, psoriasis, Darier's disease, pityriasis rubra pilaris, and various other disorders of keratinization. Retinoids also have an ability to control malignant transformations in some tissues that are caused by chemical carcinogens, ionizing radiation, growth factors, and viruses. Naturally occurring retinoids have been shown to protect animals against skin papillomas and carcinomas of the skin and other organs (Griffiths and Vorhees 1994; Kwochka 1989). Numerous side effects have been associated with retinoid use in humans, including cheilitis, xerosis of the skin, pruritus, dryness of mucous membranes, epistaxis, thinning of the hair, palmoplantar desquamation, conjunctivitis, headache, ataxia, fatigue, psychologic changes, and visual disturbances. Teratogenicity is a serious problem in women who take isotretinoin during pregnancy. Symptoms of hypervitaminosis A may also occur, which is characterized by demineralization and thinning of the long bones, cortical hyperostosis, periostitis, and premature closure of the epiphyses (Kwochka 1989).

As of this date, retinoids are not used to a great extent in veterinary medicine (Werner and Power 1994). Reported uses of any of the retinoids in dogs and cats are few, and the recommendations for use and possible toxicities and side effects are based on a very small number of animals. Indications for veterinary use remain rather vague, in part because the skin diseases that retinoids may be efficacious in treating humans do not have exact analogs in domestic animals. There is also a lack of formal studies conducted on large populations of dogs or cats. Reported uses for the retinoids in domestic animals are in disorders of keratinization, which may include primary idiopathic seborrhea in Cocker Spaniels, sebaceous adenitis, canine lamellar ichthyosis, Schnauzer comedo syndrome, and epidermal inclusion cysts, among others (Power and Ihrke 1990; Kwochka 1989). The use of retinoids in cats with neoplastic disorders, specifically squamous cell carcinoma and epidermal dysplasia, has been investigated and found to be of limited value (Evans et al. 1985). Toxicities to the retinoids in animals seem to be few, but it should be made clear that the reported side effects and toxicities are based on a small population of clinically ill animals treated for short periods of time with these compounds, and these observations may prove to be inaccurate if the use of these compounds increases. Out of 29 dogs treated with isotretinoin in one study (Kwochka 1989), 4 dogs developed conjunctivitis that was observed to be reversible after treatments ended. There is no formal information available as to the existence of skeletal anomalies in dogs given retinoids for long periods of time (Power and Ihrke 1990). Birth defects involving the central nervous system, skeleton, thymus, and heart do occur, as seen with high doses of vitamin A during pregnancy. Cats appear to have a higher incidence of side effects associated with retinoid treatment. Cats treated with isotretinoin were observed to develop periocular erythema, periocular crusting, epiphora, and blepharospasm (Kwochka 1989).

Tretinoin (*trans*–retinoic acid), also known as Retin-A, is an oxidation product of vitamin A. Applied topically, tretinoin causes inflammation, thickening of the epidermis, and localized intercellular edema. This edema leads to epidermal cell separation and an increase in exfoliation of the epidermal cells, resulting in an overall keratolytic action of the treated area. Used systemically, tretinoin will induce hypervitaminosis A (Power and Ihrke 1990).

Isotretinoin (Accutane, Roche; 13-*cis*-retinoic acid) and etretinate (Tegison, Roche) are two systemically used retinoids that also have potential veterinary applications. Power and Ihrke (1990) describe several cases where these two retinoids have been used to treat several skin diseases in dogs, with variable success. Isotretinoin is the most effective inhibitor of sebum production known (Kwochka 1989), making it potentially useful in treating primary idiopathic seborrhea and comedo syndromes. Although retinoids are associated with less toxicity than vitamin A, toxicities can occur. Etretinate may be associated with fewer toxic side effects than isotretinoin. Insufficient data are available for dogs or cats to determine its efficacy or toxicity.

Coal tar is another pharmaceutical that has keratolytic as well as keratoplastic and antiseborrheic activity. Its mechanism of action and general uses have been discussed previously. Coal tar products should not be used in the feline due to frequent irritant and allergic reactions.

Urea is a product of protein metabolism that, when used topically, acts as a protein denaturant, promoting the hydration of keratin. Once the treated areas of keratin swell, mild keratolysis ensues. The use of urea alone as a keratolytic agent is not common in veterinary dermatology today.

Selenium sulfide is an externally applied antiseborrheic, keratolytic, and keratoplastic compound that also has some antidandruff activities. Selenium sulfide exerts these actions by its antimitotic activity, slowing cell proliferation and sebum production, and tends to be irritating (especially if used in long-term treatment protocols) and also stains hair. It also causes irritation of the mucous membranes, so care should be taken to avoid contact with these tissues. Percutaneous absorption is minimal if applied to intact skin.

CLASSES OF MEDICATED APPLICATIONS. Pharmaceuticals can also be classified by the type of base they are formulated in. There are eight classes of medicated applications (Harvey 1985a; Block 1985; Rippie 1985; Swinyard 1985; Swinyard and Lowenthal 1985; Nairn 1985).

Ointments. Ointments are semisolid preparations that usually (but not always) contain drugs used to treat dermatologic diseases. There are five classes of ointments commonly used in veterinary medicine.

HYDROCARBON BASES. These emollient ointment bases usually are composed of vegetable oils and animal fats. Common members of this subset include spermaceti, cetyl esters wax ("synthetic spermaceti"), oleic acid, olive oil, paraffin, petrolatum, white petrolatum, white wax, and yellow wax. Hydrocarbon base ointments are emollient and generally hydrophobic and occlusive, causing an increase in the hydration of the stratum corneum and underlying epidermal cell structure by decreasing transepidermal water loss, making them useful in rehydrating or softening the skin. Disadvantages include greasiness and their ability to stain clothing; also, they cannot be washed off in water, making them difficult to completely remove from the skin.

ANHYDROUS ABSORPTION BASES. This type of ointment base contains very little (if any) water after preparation but differs from the hydrocarbon bases in that it will readily accept any water molecules it comes in contact with. Absorbent ointment bases can absorb large quantities of water and still keep their thick consistency. Examples of this subgroup include hydrophilic petrolatum and anhydrous lanolin, both of which are emollient, occlusive, and greasy.

WATER-OIL EMULSION BASES. Emulsions, by definition, are oil and water combinations. Water-in-oil emulsion bases (creams) are water-washable bases that are easily removed from the skin surface and contain more oil than water on a percentage basis. The oil phase usually consists of petrolatum or liquid petrolatum and perhaps an alcohol (cetyl or stearyl alcohol). The aqueous phase may consist of water; however, other aqueous vehicles may be used, such as propylene glycol, polyethylene glycol, or glycerin, to which various preservatives (such as paraben derivatives) are usually added. Water-in-oil bases are emollient (due to the higher percentage of oil than aqueous phase), occlusive, greasy, and may absorb some water, but not to the same degree as the anhydrous absorption bases. Other common components of water-in-oil emulsion bases include glyceryl monosterate and stearic acid.

OIL-WATER EMULSION BASES. Oil-in-water emulsions are manufactured in the same manner as the water-in-oil bases, with the exception that the aqueous phase is in a higher percentage than the oil component. The same ingredients are also used to make the oil-in-water bases. Because of the higher water (or other aqueous phase) content, oil-in-water bases are water-washable, nongreasy, and nonocclusive.

WATER-SOLUBLE BASES. As the name implies, these bases have lost their hydrophobic lipid base components. These demulcent bases are primarily composed of polymers that are completely water soluble and usually anhydrous, do not easily hydrolyze, do not support mold growth, and are nongreasy, nonocclusive, and nonvolatile. If the components of a preparation contain water-soluble bases in a gelled medium, they are referred to as gels. Gels are a combination of propylene glycol, propylene gallate, disodium ethylenediaminetetraacetic acid (EDTA), and carboxypolymethylene that results in a clear, water-miscible, and relatively greaseless formulation. A commonly used drug in a gel formulation is DMSO (Domoso, Diamond). Glucocorticosteroids may also be formulated in this way.

Poultices. A poultice (or cataplasm) is a soft moist mass of materials applied locally to an affected area and was historically composed of roots, herbs, seeds, and even mud in a gruel-like base. The poultice was intended to be a topical wound treatment serving as a counterirritant and absorptive/adsorptive sink. Poultices are rarely used in veterinary medicine today.

Pastes. Pastes are absorptive powders placed in a gelatinous base, usually petrolatum or hydrophilic petrolatum. Pastes have been used to adhere to the skin and thereby act as a "sponge" to absorb exudates and moisture and also as a physical barrier to protect the skin from the external environment. Pastes are easily removed from the skin and can be used on moist lesions of the skin.

Powders. Powders have been discussed earlier in this chapter as a class of vehicle for the delivery of topical drugs to the skin. Powders are commonly used in veterinary medicine to deliver pesticides (carbaryl, permethrins, etc.) for the control of external parasites (mainly fleas) and in large-animal veterinary dermatology to deliver antibiotics, such as nitrofurazone, to wounds.

Dressings. Dressings are external applications of some previously discussed compounds (petrolatum, ointments) on an application device such as plastic wrap or sterile gauze and are placed over wound sites to protect the skin lesion from external environmental trauma. Dressings may also contain antimicrobial agents, such as nitrofurazone.

Plasters. Plasters are similar to dressings; however, they are attached to the skin via some adhesive material. They protect skin lesions from the external environment and provide an occlusive environment. Plasters have limited use in veterinary medicine today.

Suspensions. A suspension is a two-phase system composed of a finely divided solid that is dispersed in a liquid, usually water. Suspensions are not utilized to any great degree in veterinary dermatology today. They are more commonly used in oral drug preparation schemes. The most common type of suspension currently used topically is captan (Orthocide, Chevron Chemical), which is used to treat some types of superficial fungal infections and which also has some limited bacteriostatic properties.

Lotions. Lotions are powders dissolved in a liquid, usually water or an alcohol. Lotions, like powders, tend to be cooling, drying, and somewhat mildly antipruritic. Lotions have limited applications in veterinary medicine but are used extensively in human over-the-counter skin-care products.

ANTIMICROBIALS. Bacterial skin infections are a frequent cause of dermatitis in animals. Antimicrobial therapy is thus a mainstay to treat bacterial skin disease. Like other tissues, healthy skin is associated with normal microbial flora. By and large, this group causes no adverse effects unless the skin is in some way compromised, that is, by trauma, parasitism, or iatrogenic intervention (surgery). There are two approaches to treating bacterial skin disease: systemic administration of antibiotics or application of topical agents to the affected skin site. The drugs used for systemic treatment are the same as those fully discussed in the antimicrobial chapters of this text and will not be discussed further. The requirement for successful systemic treatment includes use of a drug with an appropriate spectrum of activity coupled with a favorable distribution to the skin.

Topical Antibiotics. A select few of the antibiotics used in systemic therapy are also used in topical preparations to treat bacterial skin infections, including sulfonamides, chloramphenicol, polymyxins, and neomycin. Agents that are only used topically include bacitracin, mupromycin, nitrofurazone, povidone iodine, and chlorhexidine (Harvey 1985b; Block 1985; Rippie 1985; Swinyard 1985; Swinyard and Lowenthal 1985; Nairn 1985; Bennett 1995).

When used topically, the percutaneous absorption of the aminoglycosides may be slowed by their large molecular structure, positive charge, and binding to pus. When topically administering any antibiotic combination containing an aminoglycoside, cleaning the affected area of exudate before application will increase efficacy. Nephrotoxicity and ototoxicity are rarely observed when aminoglycosides are applied topically because of the minimal absorption of these large hydrophilic molecules.

Polymyxin B and polymyxin E (colistin) are gram-negative bactericidal antibiotics that labilize the cellular membrane of susceptible bacteria, in particular *Pseudomonas* spp. and *Proteus* spp. Both are used in topical formulations only, since systemic use of these antibiotics is not recommended due to the high incidence of nephrotoxicity and respiratory paralysis. Oral doses may induce "sterile bowel" syndrome. Polymyxins are safe for topical use (no appreciable side effects) and are found in many topical prescription and over-the-counter preparations to control mainly gram-negative bacterial skin infections. Bacitracin is another large polypeptide antibiotic that is used safely in many topical preparations but is toxic if administered systemically. The protective barrier offered by the stratum corneum allows large charged drugs such as polymyxins and bacitracin to be safely used in topical formulations.

Nitrofurans—mainly nitrofurazone (5-nitro-2-furaldehyde semicarbazone) and furazolidone (*N*-(5-nitro-2-furfurylidene)-3-amino-2-oxazolidone)—are a class of broad-spectrum antimicrobials that presumably inhibit the conversion of pyruvate to acetyl coenzyme A by blocking oxidative decarboxylation at this step of energy metabolism. Nitrofurans can be bactericidal or bacteriostatic, depending on the concentration used. Used topically, nitrofurans are not significantly absorbed through the intact skin unless formulated in an oil, ointment, or organic solvent base, making them ideal for treating superficial bacterial infections. Nitrofurazone has been reported to have no effect on wound contraction and reepithelialization when topically applied to open wounds, but other studies show that nitrofurazone slows this process by as much as 30% in pigs, and yet other studies show a more efficient wound-healing process (St. Omer 1978). In spite of this controversy, the nitrofurans, in particular nitrofurazone, remain a popular, safe, and effective class of antibiotic to topically prevent or treat bacterial skin infections in a variety of species.

Iodine is one of the oldest and most widely used topical antimicrobials. Iodine is bactericidal, sporicidal, fungicidal, viricidal, and protozoacidal. Elemental iodine is only slightly soluble in water, resulting in the use of other vehicles to increase its solubility. Tincture of iodine contains 2% iodine and 2.4% sodium iodide diluted in 50% ethanol; Lugol's solution contains 5% iodine and 10% potassium iodide in water. It should be noted that the highest concentration of elemental iodine (the "active" form) that can be obtained in a water base is 0.15%. Addition of sodium iodide or potassium iodide to water containing elemental iodine causes the formation of I^{3-}, which functions as a reservoir for I^{2}. Iodines are used to treat a variety of skin infections, are highly efficacious, and have a very low toxicity to animal skin. Disadvantages include staining of the skin and clothing that iodine comes in contact with and some pain when iodine comes in contact with raw and abraded skin surfaces (tincture more so than aqueous). In order to circumvent these disadvantages and preserve the high efficacy and safety of iodine, povidone-iodine was formulated.

Povidone-iodine is elemental iodine coupled with a polyvinylpyrrolidone molecule. This particular complex serves as a sustained-release form for elemental iodine while simultaneously preventing staining of the skin and clothing it may come in contact with. A 10% povidone-iodine solution contains approximately 1% "available" or total iodine, with free iodine (dissociated from the povidone complex) being 0.001%. As the povidone-iodine solution is diluted, more free iodine dissociates from the polyvinylpyrrolidone molecules, increasing the free iodine content in the solution. Bactericidal activity tends to increase as the dilution increases. Many povidone-iodine preparations are commercially available for preventing and treating topical microbial infections, wounds, abscesses, and other skin injuries. Povidone-iodine solutions are also used to prepare skin prior to surgical procedures. A potential for systemic absorption exists (*see* Chap. 39).

Chlorhexidine is another commonly utilized topical antimicrobial used in veterinary dermatology. Chlorhexidine is highly bactericidal, is not virucidal, and is relatively unaffected by organic debris (blood, pus, necrotic tissue, etc). Chlorhexidine gluconate has a sustained residual activity; when applied to the surface of the skin, it binds to the protein portion of the stratum corneum and cannot be removed with ethanol treatment. Systemic absorption and toxicity of chlorhexidine are minimal, and it can be used as an effective antimicrobial to treat skin wounds and to flush abscesses, and as a presurgical antiseptic scrub. It is in shampoos for treating bacterial pyodermas.

Thiostrepton is an antibiotic produced by a strain of *Streptomyces aureus*. A polypeptide antibiotic, thiostrepton is not absorbed from the gastrointestinal tract and is used in some topical antibiotic preparations. It has activity against both gram-positive and gram-negative bacteria and is usually found in combination with another antibiotic, an antifungal, and a glucocorticosteroid in an ointment or cream formulation.

Antifungal Agents. Fungal infections in domestic animals are commonly encountered in veterinary dermatology. The systemic treatment of fungal infections is discussed in greater detail in Chap. 46. Cutaneous mycotic infections, like bacterial infections, can be treated by both topical and systemic routes, depending on the location and severity of the lesions. Common antifungal drugs used topically include benzalkonium chloride, zinc, miconazole, copper naphthanate, povidone-iodine, nystatin, tolnaftate, clotrimazole, and thiabendazole. The 7th edition of this text should be consulted for an in-depth discussion of these drugs.

GLUCOCORTICOSTEROID USE IN DERMATOLOGY. Glucocorticosteroids are inflammatory modulators found in many topical skin preparations, either alone or in combination with antibiotics or antifungal preparations. Glucocorticosteroids have definite indications for treating many dermatologic disorders in domestic animals. Glucocorticosteroids are indicated for the treatment of many allergic dermatoses, notably allergies ("fleabite" dermatitis, food allergies), contact dermatitis, autoimmune diseases manifesting themselves with cutaneous lesions (pemphigus, pemphigoid, lupus erythematosus, eosinophilic granuloma complex), and pyotraumatic dermatitis ("hot-spots").

Glucocorticosteroids have functions other than controlling inflammation and inducing immunosuppression. Many skin diseases have neutrophil infiltration in the dermis and/or epidermis. Glucocorticosteroids have a marked ability to stabilize lysosomal membranes within neutrophils, thereby inhibiting the release of enzymes that result in dermatitis. Fibroblast inhibition also occurs, which may retard healing of the skin if high doses are used frequently and for extended periods of time. Many endogenously produced compounds, such as histamine (and its metabolite *N*-methyl histamine) and complement, have their production inhibited in the presence of glucocorticosteroids. In addition, phospholipase A_2, which is responsible for liberating arachidonic acid from epidermal cells and vascular endothelial cells, is also blocked, resulting in decreased production of the many prostaglandins and leukotrienes discussed previously. Prolonged use in humans results in thinning of the viable epidermal layer. Use of these immunosuppressive compounds may also potentiate secondary bacterial infections. Glucocorticosteroids often increase thirst and appetite and have other systemic side effects. It is beyond the scope of this chapter to review all the physiologic and biochemical effects of all the glucocorticosteroids available to the veterinarian (see Chap. 33). However, because glucocorticosteroids have effects on other body systems when being used to treat skin diseases, we offer some general guidelines here for their use in dermatology:

1. *Be sure of the diagnosis.* Glucocorticosteroids are generally used to relieve the symptom of pruritus. This symptom has an underlying cause, and it is important to make the effort to determine it. Not performing the routine measures to determine the underlying cause of pruritus may lead to more serious systemic side effects.

2. *Use the least amount of steroid to achieve the clinical effect.* The dose of steroid cannot be specified for each skin disease. Rather, the dose of steroid must be adjusted for the individual animal, taking into account individual biological variability, the severity of the disease, the overall improvement in the clinical condition of the animal when treated, and the intensity of side effects observed at that dose of steroid. Steroid use above the clinical effect threshold will not improve the animal's overall condition or speed the recovery but may increase the chances of deleterious side effects (i.e., Cushing's disease). This caveat refers not only to the orally administered glucocorticosteroids but also to

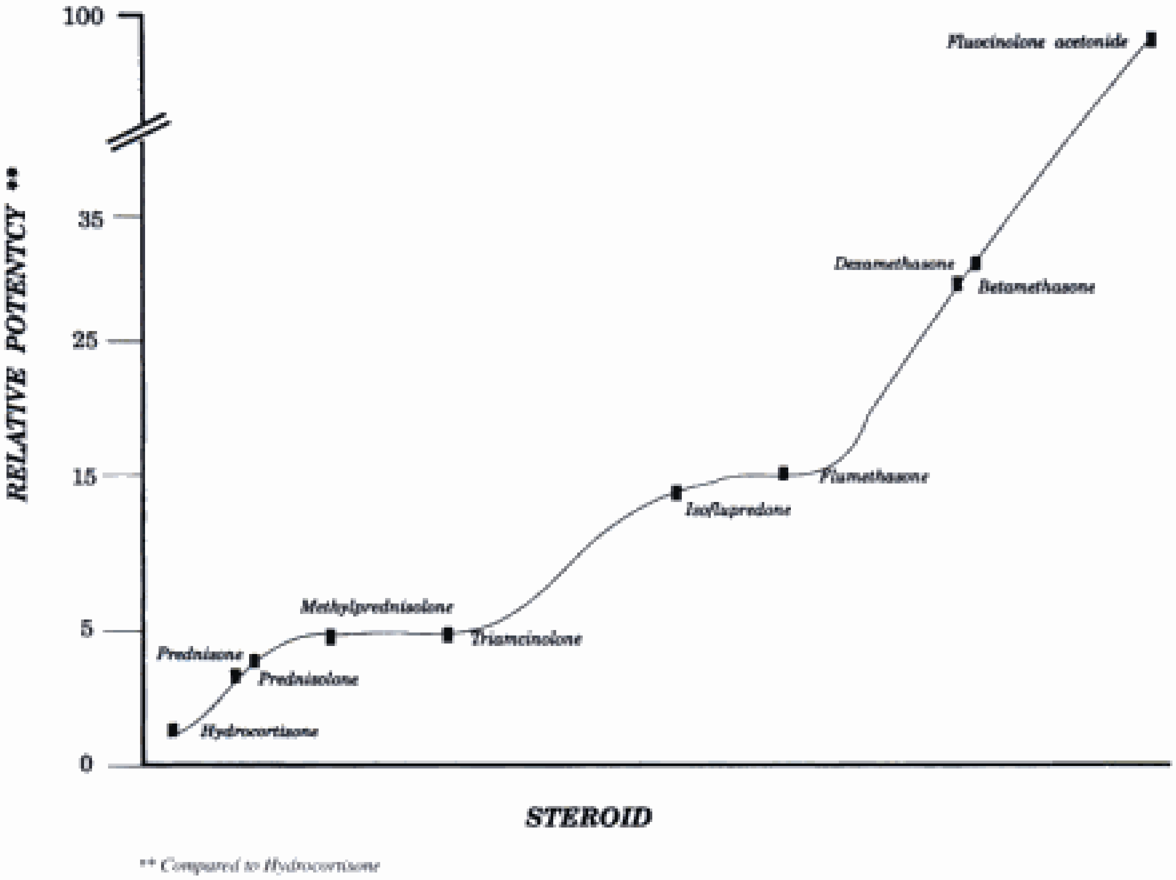

FIG. 53.6—Comparison of the relative potencies of some glucocorticosteroids (compared with hydrocortisone) used in veterinary dermatology.

the topically administered glucocorticosteroids. Glucocorticosteroids applied topically can be absorbed through damaged, as well as normal, skin.

3. *Use the least potent steroid to achieve the clinical effect.* As shown in Fig. 53.6, there is a wide range of potency among the topical glucocorticosteroids, ranging from hydrocortisone (which has the same potency as the endogenously produced cortisol) to the extremely potent fluocinolone acetonide (100 times the potency of hydrocortisone). The more potent glucocorticosteroids should be reserved for the more severe cases of skin disease requiring steroid therapy, while milder cases should be treated with the less potent forms. The least amount as well as the least potent topical steroid should be used to control the symptoms of the disease being treated.

4. *Choose the route of steroid administration according to the type and severity of the lesion being treated.* The route of administration will depend greatly on the skin disease being treated, temperament of the animal, owner compliance, severity of the lesion(s), and whether the lesions are focal or multifocal. Oral or injectable steroid therapies are generally used when lesions are multifocal and/or involve the deeper layers of skin, cover large areas of skin (hot-spots), or involve moderate to severe pruritus, or when immunosuppression is indicated (pemphigus, lupus, eosinophilic granulomas, indolent ulcers, etc.). Topical therapy alone is usually efficacious when a few superficial lesions are present, if mild pruritus is present, and if an anti-inflammatory effect is required.

Antihistamines and nonsteroidal anti-inflammatory drugs have also been used to treat pruritic conditions. Chapters 19–22 of this text should be consulted for further details.

PESTICIDES. Pesticides are widely used in agriculture and home gardening and in the control of many internal and external parasites in both humans and domestic animals. Pesticide use today is important for three reasons: (1) the toxicity that they may induce in the host animal, (2) residues that may accumulate in the food animal and then later be consumed by humans, and (3) environmental effects. All three areas have a formidable literature data base. Chapter 50 of this text should be consulted for a detailed discussion of these agents.

Most pesticides, like many of the drugs and vehicles discussed previously in this chapter, are able to permeate the skin. The skin is the primary route of exposure for pesticides, followed closely by inhalation and

NORMAL RESPIRATORY PHYSIOLOGY

Airway Caliber Changes. Nervous innervation to the smooth muscle of the respiratory tract is complex. The parasympathetic system provides the primary efferent innervation, with acetylcholine as the primary neurotransmitter (Moses and Spaulding 1985; Slonim and Hamilton 1987). These fibers are responsible for the baseline tone of mild bronchoconstriction which characterizes the normal respiratory tract. The sympathetic system balances these effects by stimulating through β_2 receptors to induce bronchodilation (Scott et al. 1991; Gustin et al. 1989; Chand and Deroth 1979). In contrast, α-adrenergic stimulation can contribute to bronchoconstriction (Moise and Spaulding 1981; Slonim and Hamilton 1987; Gustin et al. 1989). A third, largely understood nervous system, referred to as the nonadrenergic-noncholinergic (NANC) system, or purinergic system, also innervates bronchial smooth muscle (Inque et al. 1989; Moses and Spaulding 1985). This system mediates bronchodilation via vagal stimulation. The afferent fibers of this system are probably irritant receptors, and although the neurotransmitter has not yet been conclusively identified, vasoactive intestinal peptide has been implicated in the cat (Altiere and Diamond 1984; Altiere et al. 1984). Malfunction of this system has been associated with bronchial hyperreactivity, which often characterizes asthma (Inque et al. 1989).

The intracellular mechanisms which transmit signals from the nervous system to smooth muscle depend, in part, upon changes in the intracellular concentration of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) (Fig. 54.1). The effects of these two secondary messengers are reciprocal: increased intracellular concentrations of one are associated with decreased concentrations of the other. Cyclic AMP is decreased by α-adrenergic stimulation and increased by β_2-receptor stimulation (Scott et al. 1991). In contrast, cGMP is increased by stimulation of muscarinic (cholinergic) and, indirectly, histaminergic receptors (Fig. 54.1). The relative sensitivity of bronchial smooth muscle to histamine- and acetylcholine-induced bronchoconstriction varies with the location and species (Chand and Deroth 1979; Derksen et al. 1985; Downes et al. 1986). Peripheral airways in dogs are more susceptible than those in cats to acetylcholine. Cat airways, in general, are more sensitive to acetylcholine than to histamine (Colebatch et al. 1966). Airways of horses suffering from chronic obstructive pulmonary disease (COPD) are hyperreactive to histamine (Derksen et al. 1985) and acetylcholine (Chand and Deroth 1979). Smooth muscle receptors are also susceptible to stimulation by a variety of chemical mediators (Fig. 54.1) which may also modulate cAMP and cGMP (Townley et al. 1989; Soler et al. 1990; Gray et al. 1989).

Control of bronchial smooth muscle tone is very complex and depends upon input from sensory receptors. At least five types of sensory receptors have been identified in cat lungs, all of which can be classified as either irritant (mechanoreceptor), stretch, or J receptors (Inque et al. 1989). All appear to be innervated by the parasympathetic system. Irritant receptors, located beneath the respiratory epithelium, occur in the upper airways (Slonim and Hamilton 1987) and, in cats, as far peripherally as the alveoli (Moses and Spaulding 1985). Physical, mechanical, or chemical stimulation of these receptors results in tachypnea, bronchoconstriction, and/or cough. Airflow velocity appears to be the most critical factor determining stimulation of irritant receptors in the upper airways (Moses and Spaulding 1985). Airway constriction sufficient to cause air-

TABLE 54.2—Doses of drugs used to treat respiratory diseases

Drug	Route[a]	Dose[b] (mg/kg)	Frequency (hr)
β agonists[c]			
Epinephrine	IM, IV, SC	20 μg/kg of .01% solution	
	SC	0.01 mL/kg of 0.1 solution	0.5[d]
Ephedrine	IM, PO	2–5 mg total (C)	
		5–15 mg (total) (D)	
Isoproterenol	PO	0.44	6–12
	IM, SC, IV	0.1–0.2 mg total	6
	Aerosol	0.5 cc of 1:200 dilution	4 × 3
Metaproterenol	PO	0.5	6
	Aerosol		4 × 3
Albuterol	Aerosol	200 μg[e]	
Terbutaline	PO	1.25 mg total	12
Isoetherine	Aerosol	0.5–1.0 mL of 1:3 saline dilution	8
Anticholinergics			
Atropine	IV, IM, SC	0.02–0.04	Prn
Glycopyrrolate	IV, IM, SC	0.01–0.02	Prn
Methylxanthines		10 (D)	6–8 (D)
Aminophylline	PO	5–6 (C)	12 (C)
	IV infusion[f]	2–5	8–12
			Over 0.5–1 hr
Theophylline base	PO	4 (C)[g]	12 (C)
		5–10 (D)	6–8 (D)
		5 (H)	12 (H)
		20 (C)	12 (C)
Oxytriphylline	PO	10–15[h]	8–12
Glucocorticoids			
Prednisolone	PO	1–2	6–12[i]
Prednisolone sodium succinate	IV, IM[i]	2–4	4–6
Dexamethasone	IV, IM[i]	0.2–2.2	
Triancinolone	PO	0.25–0.5 mg total	24[j]
Beclomethasone dipropionate	Inhalant	200 μg total[e]	6–8
Megestrol acetate	PO	5 mg total	24 × 4, then weekly × 4
Antitussives			
Codeine	PO	1–2	8
		0.2–2 g (H)	
		15–60 mg (P)	
Hydrocodone	PO	0.22	6–12
Butorphanol tartrate	SC, IM	0.055–0.11	Prn
	PO	0.5–1.0	6–12
	SC	0.55	
Dextromethorphan	PO	1–2	6–8
Morphine	IM, SC	0.1	6–12
Decongestants			
Chlorpheniramine	PO	0.22 mg/kg (D)	8
	PO	2–4 mg total (C)	24
		1/4 to 1/2 slow release (C)	24
Diphenhydramine	PO	2–4	8
Dimenhydrinate	PO	12.5 mg total (C)	8
	PO	8 (D)	
Hydroxyzine	PO	2 (D)	6–8

[a] IV = intravenous, IM = intramuscular, SC = subcutaneous, PO = orally.
[b] C = cat, D = dog, H = horse, P = pig.
[c] Use cautiously in cats with cardiac disease.
[d] Up to a total dose of 0.5 mL.
[e] Human dose.
[f] Emergency treatment.
[g] Based upon 80% theophylline.
[h] Based upon 65% theophylline.
[i] Taper doses to minimum effective dose.

(Bauer 1986; Papich 1986a). Concentrations between 10 and 15 µg/mL have been recommended in horses (Button et al. 1985; Errecalde et al. 1984).

Adverse effects, including central nervous stimulation, sweating, and tremors, occur in horses if serum concentration surpasses 15 µg/mL (Larsson et al. 1989). The application of therapeutic drug monitoring (TDM) to guide therapy will assist in identifying the most appropriate dosing regimen. Although a therapeutic range has not been established in small animals, the range recommended in people (10-20 µg/mL) can be extrapolated until a more definitive range has been established. Dogs are apparently more tolerant of theophylline toxicity than people. In one study, toxicity manifested as tachycardia, central nervous stimulation (restlessness and excitement), and vomition did not occur until plasma theophylline concentrations reached 37-60 µg/mL. Doses of 80-160 mg/kg of a sustained-release preparation were required to induce toxicity (Munsiff et al. 1988b). In cats, concentrations as high as 40 µg/mL do not induce adverse reactions (Love et al. 1981), although salivation and vomiting are common following administration of more than 50 mg/kg and seizures may occur at doses greater than 60 mg/kg (Persson and Ergefalt 1982).

The side effects of theophylline are dose dependent and might be avoided to a large degree by appropriate dosing. TDM should facilitate design of proper dosing regimens to prevent toxicity.

Anticholinergics

PHARMACOLOGIC EFFECTS. Anticholinergic drugs compete with acetylcholine at muscarinic receptor sites (Gross and Skorodin 1984). In the respiratory tract, they reduce the sensitivity of irritant receptors and antagonize vagally mediated bronchoconstriction. In horses, atropine IV appears to minimally affect resting bronchomotor tone but has a major effect on tone in horses suffering from clinical signs of COPD (Broadstone et al. 1988). The site of action of these drugs in the respiratory tract is controversial. In some studies, bronchodilation is reported throughout the airways in asthmatic human patients and cats, but other investigators feel the effects are confined to large airways (Gross and Skorodin 1984). The route by which anticholinergics are administered influences their bronchodilatory effects. Despite their effect on bronchial airways, the anticholinergics have not proven clinically effective in the treatment of bronchial diseases in animals. The lack of clinical efficacy of anticholinergics may reflect nonselective drug-receptor interaction (Barnes 1989, 1988). Thus far, three types of muscarinic receptors have been identified in airways. M_3 receptors release acetylcholine, and M_2 receptors block its release. Nonselective blockade of muscarinic receptors by atropine and ipratropium may actually potentiate acetylcholine release by antagonizing the effects of M_2-receptor stimulation. Drugs specific for M_3 receptors may ultimately lead to successful treatment of bronchial disease with anticholinergics (Barnes 1989, 1988).

ATROPINE. Aerosolized atropine, a prototype anticholinergic drug, affects predominantly the central airways, whereas both central and peripheral airways are affected if the drug is administered intravenously (Barnes 1989, 1988). Because atropine is highly specific for all muscarinic receptors, it causes a number of systemic side effects, including tachycardia, mydriasis, and altered gastrointestinal and urinary tract function (McKiernan et al. 1981). In the respiratory tract, atropine reduces ciliary beat frequency, mucus secretion, and electrolyte and water flux into the trachea. The net effect is decreased mucociliary clearance, which is undesirable in patients with chronic lung disease (McKiernan et al. 1981). Aerosolization of atropine does not reduce the incidence of adverse reactions. Atropine is well absorbed (in humans) following oral administration. In humans, atropine has proven most useful for treatment of chronic bronchitis and emphysema, diseases which are characterized by increased intrinsic vagal tone (Gross and Skorodin 1984). However, its adverse effects on respiratory secretions and ciliary activity negate its benefits to bronchial tone during long-term administration in animals. The primary indication of atropine in small animals is facilitation of bronchodilation in acutely dyspneic animals. It is the treatment of choice for life-threatening respiratory distress induced by anticholinesterases. Combining atropine with either β-adrenergic agonists or glucocorticoids causes better bronchodilation than using either of the latter drugs alone (Gross and Skorodin 1984).

IPRATROPIUM BROMIDE. This synthetic anticholinergic is pharmacodynamically superior to atropine. While the two drugs are equipotent, ipratropium does not cross the blood-brain barrier. It is not well absorbed following aerosolization, which limits the likelihood of adverse effects. Ipratropium has been studied in the dog but not in the cat (Gross and Skorodin 1984). Of the anticholinergics studied in dogs, ipratropium appears to cause the greatest bronchodilation (twice as much as atropine) with the least change in salivation (Gross and Skorodin 1984). Unlike atropine, it does not alter mucociliary transport rates.

GLYCOPYRROLATE. Glycopyrrolate can be used as a bronchodilator in small animals. Although its onset of action is slower than that of atropine (Bauer 1986; Papich 1986a), its half-life is 4-6 hours compared to 1-2 hours for atropine. The potency of the two drugs following systemic therapy has apparently not been compared, although glycopyrrolate is twice as potent when aerosolized. Systemic side effects of glycopyrrolate are minimal.

Mast Cell Stabilizers. Drugs that stabilize mast cells are most effective in syndromes associated with marked mast cell activity. The stabilizing effects of β-adrenergic agonists, methylxanthines, and glucocorticoids on inflammatory cells have been discussed.

codeine. It can be used safely in cats. Studies in humans have shown that the combination of dextromethorphan with a bronchodilator is superior to dextromethorphan alone (Tukianinen et al. 1986).

NOSCAPINE. Noscapine is a nonaddictive opium alkaloid (benzylisoquinolones) which has antitussive effects similar to codeine (Brain 1983). Its use in small animals appears to be limited.

Peripheral Bronchodilators. Bronchodilators (previously discussed) are powerful peripheral antitussives because they relieve irritant-receptor stimulation induced by mechanical deformation of the bronchial wall during bronchoconstriction. Ephedrine peripherally induces bronchodilation, and as both a bronchodilator and decongestant is a common constituent of over-the-counter cough preparations. Theophylline and isoproterenol are also common ingredients found in some preparations. Other peripheral antitussives include mucokinetic agents and hydrating agents (Roudebush 1982).

MUCOKINETICS. Mucokinetic drugs facilitate the removal of secretions from the respiratory tree. They are indicated in conditions associated with viscous to inspissated pulmonary secretions such as are commonly associated with chronic bronchial diseases. Mucokinesis can be induced by drugs which improve ciliary activity (e.g., β-receptor agonists and methylxanthines) or by drugs that improve the mobility of bronchial secretions by changing viscosity. Viscosity of bronchial secretions can be decreased by hydration (e.g., sterile or bacteriostatic water or saline), increasing pH (e.g., sodium bicarbonate), increasing ionic strength (sodium bicarbonate and saline), or rupturing sulfur (S-S) linkages in the mucus (e.g., acetylcysteine or iodine). Hydrating agents can be administered parenterally (i.e., isotonic crystalloids) or by aerosolization. Home aerosolization can be easily achieved with a humidifier or steamed bathroom or with a commercially available aerosolizer. The efficacy of aerosolization in liquefying airway secretions is controversial (Wanner and Rao 1980), with greatest benefit occurring in upper airways. Bland aerosols such as water and saline can actually be detrimental to mucociliary function (Wanner and Rao 1980). The efficacy of ionic solutions or alkaline solutions, compared to water, on enhanced mucus mobility is controversial (Wanner and Rao 1980).

N-Acetyl-L-Cysteine

PHARMACOLOGIC EFFECTS. Acetylcysteine (*N*-acetyl-L-cysteine) is the most widely used mucolytic drug in humans (Wanner and Rao 1980; Ziment 1988). While it appears to be efficacious following aerosolization, more recently oral administration has become the preferred route (Ziment 1988). In Europe, the drug is available in solid and powder dosing forms. Unfortunately, only the solution, which is unpalatable and malodorous, is approved for use in the United States. Regardless of the route of administration, the mechanism of acetylcysteine reflects destruction of mucoprotein of the disulfide bonds by a free sulfhydryl group. Smaller molecules are less viscid and not able to efficiently bind to inflammatory debris. In addition, *N*-acetylcysteine serves as a precursor to glutathione, a major scavenger of free oxygen radicals associated with inflammation. The drug also appears to induce respiratory tract secretions, probably via a gastropulmonary reflex. At higher oral doses, acetylcysteine will also induce vomition (Ziment 1986). Acetylcysteine is often used in combination with aerosolized antimicrobials because it may improve antibacterial penetration of infected mucus (Ziment 1988). Acetylcysteine improved gas exchange in a study of dogs with experimentally induced methacholine bronchoconstriction (Ueno et al. 1989).

DISPOSITION. In humans, acetylcysteine is rapidly absorbed from the gastrointestinal tract and extensively distributed to the liver, kidneys, and lungs, where it may accumulate. It is rapidly metabolized by the liver to the natural amino acids cysteine and cystine (Ziment 1986, 1988). The indications for oral acetylcysteine therapy in people include toxic inhalants (including tobacco smoke), bronchitis, COPD, cystic fibrosis, asthma, tuberculosis, pneumonia, emphysema, and the adult respiratory distress syndrome. Installation of a 10-20% solution has also been used to clean and treat chronic sinusitis (Ziment 1988). Similar uses are indicated in veterinary patients. Physiotherapy will enhance the efficacy of acetylcysteine.

ADVERSE EFFECTS. Acetylcysteine therapy is associated with few adverse affects. In humans, doses as high as 500 mg/kg are well tolerated (Ziment 1986), although vomition and anorexia can occur. The median LD_{50} in dogs following oral use is 1 g/kg, and parenterally 700 mg/kg. Because it is metabolized to sulfur-containing products, it should be used cautiously in animals suffering from liver disease characterized by hepatic encephalopathy. Aerosolization of *N*-acetylcysteine can cause reflex bronchoconstriction due to irritant-receptor stimulation and should be preceded by administration of bronchodilators.

EXPECTORANTS. Expectorants such as potassium iodide are common ingredients in over-the-counter cough preparations. Expectorants increase the fluidity of respiratory secretions through several possible mechanisms and are often used as adjuvants for the management of cough because they facilitate removal of the inciting cause. Bronchial secretions are increased by vagal reflex following gastric mucosa irritation (iodide salts), and directly through sympathetic stimulation or by volatile oils which are partially

tion. In contrast to other causes of rhinitis, topical decongestants may be more of a risk in patients with allergic rhinitis because of the risk of drug reaction (rhinitis medicamentosa). This side effect is avoided with systemic therapy. Since the antihistamines are safer than sympathomimetic drugs following oral administration, this may be the preferred route for antihistamines (Hendeles 1993).

Formulations of topical preparations can influence drug efficacy. Controlled-release polymers can decrease the rate of drug dissolution (and thus its ability to reach cellular targets). Although these differences may not be clinically relevant, it is important to realize that bioequivalency of the topical decongestant products containing older drugs may vary. The major disadvantage of topical agents is their short duration of action.

Hidden page

anesthesia lasts between 10 and 20 minutes. To anesthetize the conjunctiva, 4-5 administrations over 2-3 minutes are usually necessary to achieve adequate analgesia. During the anesthetic period, tear production and blink reflex will be suppressed. Therefore, a lubricant ointment should be applied to the eye at the conclusion of the procedure. Topical anesthetics should not be used continuously for treating ocular pain since these agents are damaging to the corneal epithelium and may delay corneal wound healing. Excessive applications should also be avoided since cardiac and respiratory toxicities, although unlikely, are possible with these lipid-soluble agents.

Injectable Local Anesthetics. Injectable agents may be used for local (eyelid) or regional (orbital) anesthesia in ophthalmic patients and are particularly useful in large herbivores. *Lidocaine* (1-2%), *bupivacaine* (0.25-0.75%), and *mepivacaine* (1-2%) are most commonly used for infiltration anesthesia of the periocular area. The duration of action is the major difference between these agents, with lidocaine having the shortest duration of action (40-60 min), mepivacaine an intermediate duration (2 hr), and bupivacaine the longest duration (4-6 hr). Epinephrine is sometimes added to cause local vasoconstriction, which prolongs absorption and delays the action of the local anesthetic agent. Epinephrine can prolong the duration of action of lidocaine up to 2 hours. Hyaluronidase may also be added to enhance diffusion of local anesthetic. Injectable local and topical agents are frequently used concurrently to achieve the desired degree of local anesthesia.

DIAGNOSTIC AGENTS. *Fluorescein* dye is used extensively in veterinary ophthalmology, with its most frequent and important use being its application to the ocular surface for detecting corneal ulceration. To ensure sterility of topical ophthalmic dyes, individual sterile strips are moistened with sterile eyewash solution or physiologic fluid. This liberates the dye from the sterile strips and allows its instillation onto the eye.

Since the corneal stroma is hydrophilic, water-soluble fluorescein has a marked affinity for exposed stroma. Positive staining is noted as an area of yellow-gold stain retention with room light or when a focal white light is used. A cobalt blue filter or an ultraviolet light source will excite the fluorescein, and any area(s) of positive staining will appear bright green. Topically applied fluorescein will not stain intact epithelial surfaces or Descemet's membrane. Topical fluorescein solution is also useful for determining patency of the nasolacrimal drainage system.

Injectable sodium fluorescein solution may be given intravenously to study intraocular circulation. Anterior segment fluorescein angiography allows evaluation of conjunctival, scleral, and iridal blood vessels. Retinal and choroidal circulation may also be studied following intravenous injection of sodium fluorescein. Breakdown of either the blood-aqueous or the blood-retinal barrier will allow leakage of fluorescein, which can be quantified or photographed.

Rose Bengal is useful in ophthalmic diagnostics because it is retained by abnormal ocular surface cells in the absence of overt ulceration. Although a more sensitive indicator of surface pathology than topical fluorescein, it may cause mild ocular discomfort in some animals. Because devitalized corneal or conjunctival epithelial cells will stain a deep red, subtle surface cell abnormalities such as occur in early cases of keratoconjunctivitis sicca (KCS) are detectable with Rose Bengal. It is also used to detect dendritic epithelial defects in feline corneas resulting from acute herpesvirus keratitis. Like fluorescein, Rose Bengal is best utilized as individual sterile strips moistened with sterile physiologic fluid.

Phenol red has recently been described for tear measurement by placing a small thread impregnated with this dye into the ventral conjunctival fornix for 15 seconds. A normal range of 30-38 mm of wetting per 15 seconds has been determined (Brown et al. 1996).

OCULAR IRRIGATING SOLUTIONS

Ocular Surface Irrigants. Irrigants are used to rinse away ocular surface debris and to reduce numbers of conjunctival bacteria. Only low-pressure lavage should be used for the ocular surface; therefore, an adequate volume of irrigating solution is important. Sterile physiologic saline is a commonly used and acceptable irrigant. Commercially prepared eyewashes are available and also frequently used to flush the ocular surface. These products are polyionic and buffered for ocular use but also have preservatives, which, with repeated use, may cause minor irritation in the eyes of some patients. Sterile distilled water is not recommended as an ocular irrigant because of its hypotonicity.

Adding an antiseptic or antibiotic to the irrigating solution may be useful in further reducing surface bacteria. The efficacy of this practice is dependent on the susceptibility of the resident or contaminating organisms to the specific agent. Also, the choice of agent and the concentration used should be such that the lavage solution has antimicrobial effects without causing tissue damage. A potentially serious error is the addition of an excessively high concentration of the active agent to the irrigating fluids, thereby causing tissue toxicity.

Antiseptic Solutions. Povidone-iodine antiseptic solutions are widely used in veterinary medicine. The advantage of povidone-iodine is its broad spectrum of activity and its wide range of safety to surface tissues. For cutaneous use, a concentration of 1% or less is recommended; a 1:10 dilution of a stock solution results in a 1.0% solution of povidone-iodine. More of the active-free iodine occurs in lower concentrations of povidone-iodine. Roberts et al. studied the effectiveness of various dilute povidone-iodine solutions in eliminating resident bacterial flora from eyes of dogs when used as a presurgical irrigant (Roberts et al. 1986). Disinfection with 1:2, 1:10, and 1:50 povidone-iodine dilutions was effective in eliminating bacteria from canine eyes. The use of a 1:50 povidone-iodine solution was as effective as more concentrated solutions without causing appreciable tissue reactions. Disadvantages of povidone-iodine antiseptics include acidity, possible influence on thyroid function, reduced residual activity, and reduced efficacy in the presence of organic matter. Therefore, povidone-iodine may not be the best choice for heavily contaminated wounds or where devitalized tissue is present.

Chlorhexidine is another effective antiseptic solution. A 1:40 dilution in water of the 2% concentrate is used (final concentration of 0.05%) for cutaneous antisepsis. In a light microscopy study, 2% chlorhexidine was nontoxic to rabbit corneal epithelium or endothelium when applied topically (Gassett and Ishii 1975). Advantages of chlorhexidine are that bacterial resistance has not been documented, it is affected less by organic material than povidone-iodine, and good initial kill of bacteria occurs with excellent residual activity. A disadvantage of chlorhexidine is its potential for irritating the cornea and conjunctiva when higher than recommended strengths contact the ocular surface (MacRae et al. 1984). Chlorhexidine is also unstable in saline solution.

Soaps and detergents are damaging to ocular surface tissues and should *not* be used around the eyes. An exception to this generalization is the possible use of commercial infant hair shampoos as a surgical scrub for the eyelids.

Intraocular Irrigation. Intraocular irrigation is necessary to maintain integrity of the eye during surgery and to flush unwanted material such as lens fragments or blood cells from intraocular compartments. It is essential that intraocular irrigating fluid be isotonic (290-300 mOsm), have a physiologic pH (7.4), and be nonirritating to intraocular tissues, particularly the corneal endothelium. Calcium, bicarbonate, and glutathione are important components of intraocular irrigant solutions for maintaining corneal endothelium health particularly in instances where surgery is prolonged (Glasser et al. 1985; Araie et al. 1990). Polyionic solutions such as lactated Ringer's solution or balanced salt solution are satisfactory solutions for short-term irrigation (Nasisse et al. 1986). Normal physiologic saline (0.9%), when used intraoperatively to irrigate the anterior chamber, has been associated with postoperative corneal edema resulting from loss of corneal endothelium (Edelhauser et al. 1976). Therefore, physiologic saline is not recommended for routine use as an intraocular irrigant.

ANTI-INFLAMMATORY AND ANTIMETABOLITE AGENTS. Steroidal or nonsteroidal anti-inflammatory agents are frequently indicated for treating noninfectious and infectious eye diseases of domestic species. Inflammatory processes of the eye and adnexa may cause progressive deterioration of the eye with loss of vision. Spontaneous immune-mediated diseases affecting the eye may be particularly serious and require short- or long-term anti-inflammatory therapy. In these immune-mediated processes, ocular damage may be controlled or prevented only with appropriate use of topical and/or systemic anti-inflammatory agents.

Corticosteroids

TOPICAL CORTICOSTEROIDS. Topical corticosteroids are used to treat both ocular surface and intraocular inflammatory diseases. The choice of a specific agent depends on penetrability, combination with antibiotic(s), and cost. Because of its lipid solubility, *prednisolone acetate* penetrates the cornea quite effectively and, therefore, is used extensively in therapy of intraocular diseases, particularly for treating anterior uveitis. Prednisolone acetate is commercially available as 0.125% or 1.0% suspensions and is also available as an ointment in combination with antibiotics. The combination of prednisolone acetate and chloramphenicol is often chosen for topical therapy in cases of septic uveitis because of the solubility properties of each drug. Neonatal ophthalmitis resulting from bacterial septicemia and rickettsial disease-associated uveitis are examples of infectious uveitides that respond to this topical combination administered concurrently with appropriate systemic therapy.

Dexamethasone suspension formulated in combination with neomycin and polymyxin also penetrates the cornea well and is effective in treating uveitis of domestic species. However, the antibiotics in this particular combination do not penetrate the eye well. Although *dexamethasone sodium phosphate* is commercially available as an uncombined product, dexamethasone suspension penetrates the cornea more effectively and, therefore, is preferred in therapy of uveitis. Combination solutions of gentamicin and *betamethasone* or neomycin, polymyxin, and *flumethasone* are available commercially. These are effective and less expensive alternatives for treating ocular surface inflammation. However, prednisolone and dexamethasone with or without accompanying antibiotics are generally preferred in the treatment of uveitis. A comparison of different forms of some topical corticosteroids in corneal epithelial penetration and suppression of corneal inflammation is given in Table 55.1.

In the topical treatment of diseases of the external eye, such as blepharitis, conjunctivitis, or keratitis, antibiotic-corticosteroid combinations are commonly administered. A less potent corticosteroid such as *hydrocortisone acetate* may be an effective, economical alternative that may be less likely to cause systemic side effects. Hydrocortisone is also available as an ointment in combination with triple antibiotic or in combination with chloramphenicol and polymyxin B.

TABLE 55.1—Comparison of different topical corticosteroids in suppressing rabbit corneal inflammation

	Corneal epithelium	
Corticosteroid	Intact (% decrease)	Absent (% decrease)
Prednisolone acetate 1%	51	53
Dexamethasone alcohol 0.1%	40	42
Prednisolone sodium phosphate 1%	28	47
Fluoromethalone alcohol 0.1%	31	37
Dexamethasone sodium phosphate 0.1%	19	22
Dexamethasone sodium phosphate ointment 0.05%	13	—

Source: Modified from Leibowitz and Kupferman 1980.

TABLE 55.2—Corticosteroids for topical ophthalmic use

Agent	Dosage form	Concentration
Dexamethasone	Suspension	0.1%
	Sodium phosphate solution	0.1%
	Sodium phosphate ointment	0.05%
Prednisone	Acetate suspension	0.125%, 1.0%
	Sodium phosphate solution	0.125%, 1.0%
Betamethasone	Acetate solution	0.1%
Flumethasone	Solution	0.01%
Hydrocortisone	Acetate ointment	1.0%
Fluorometholone	Suspension	0.1%, 0.25%
	Ointment	0.1%
Medrysone	Suspension	1.0%
Rimexolone	Suspension	1.0%

Medrysone 1.0% is a synthetic corticosteroid marketed for topical ophthalmic anti-inflammatory use in humans. It has less anti-inflammatory potency than 0.1% dexamethasone. Studies in human patients with increased intraocular pressure (IOP) and in those susceptible to a rise in IOP indicate that there is less effect on pressure with medrysone than with either dexamethasone or betamethasone.

Fluorometholone is a progesterone-like corticosteroid developed as an anti-inflammatory agent for human patients who respond adversely to conventional topical corticosteroid therapy by developing an increased IOP. When compared to topical dexamethasone, topical fluorometholone decreases the tendency for increased IOP in human steroid-responders. Although clinical experience indicates that fluorometholone is an effective anti-inflammatory agent when used in animals, there is no evidence that animals treated with topical corticosteroids develop ocular hypertension or glaucoma.

Rimexolone is a recently marketed ophthalmic corticosteroid with the manufacturer's claim of few side effects, including low risk of IOP increase. In clinical trials rimexolone has been similar to fluorometholone in percentage of human patients who demonstrated a significant IOP rise. Produced as a 1% suspension, rimexolone carries a label indication for postoperative inflammation following ocular surgery and for the treatment of anterior uveitis. Topical ophthalmic corticosteroids are summarized in Table 55.2.

The primary contraindication for topical corticosteroid therapy is in the presence of ulcerative keratitis, where topical corticosteroid may delay corneal healing by impairing fibroblastic and keratocytic activity, predispose to infection, and enhance activity of degradative proteases, including collagenases. Topical corticosteroids also are contraindicated for ocular surface viral infections.

SYSTEMIC CORTICOSTEROIDS. Systemic corticosteroids may be used alone or in combination with topical corticosteroids. Common indications for systemic corticosteroids in ophthalmology are for treatment of blepharitis, scleritis/episcleritis, uveitis, chorioretinitis, optic neuritis, and orbital inflammatory diseases. Systemic corticosteroids can be used following traumatic rupture or laceration of the globe when topical corticosteroids are contraindicated because of corneal damage. Systemic corticosteroids may also be used to treat severe uveitis which may be present concurrently with ulcerative keratitis. It is important to remember that both topically and systemically administered corticosteroids may cause adrenal suppression (Roberts et al. 1984; Glaze et al. 1988; Murphy et al. 1990; Moore et al. 1992). Therefore, gradual reduction of systemic corticosteroid therapy is recommended to reduce the likelihood of adrenal complications while preventing recurrence of the ocular condition. For further information on systemic corticosteroids, refer to Chap. 33.

Nonsteroidal Anti-inflammatory Drugs. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin-mediated inflammation by inhibiting the cyclooxygenase (COX) enzymes, also referred to as prostaglandin endoperoxide synthases, responsible for converting arachidonic acid to eicosanoids and subsequently prostanoids. Two COX enzymes occur in tissues. COX-1 is most common and promotes release of prostaglandins that regulate normal cell activity, while COX-2 is found in resting cells and is only released in response to noxious stimuli (Vane and Botting 1995). As a result of their action on the inflammatory cascade, NSAIDs have antipyretic and analgesic properties. The primary indication for NSAIDs in ophthalmology is for the treatment of uveitis, although administration of NSAIDs may reduce symptoms of other inflammatory diseases such as blepharitis, conjunctivitis, or keratitis. Since NSAIDs interfere with platelet aggregation, they are contraindicated in cases of hyphema or when systemic bleeding disorders are present.

animals at a frequency of 3 times daily when signs of chronic conjunctivitis would not improve with other therapy. A topical, selective histamine antagonist is available for human use and is reported to be effective and well tolerated by children with allergic conjunctivitis (Wultrich and Gerber 1995).

Cromolyn sodium is a mast cell stabilizer that has been used topically and systemically in human patients to prevent signs of allergic conjunctivitis. Because it is most effective when used just prior to exposure to offending allergins rather than after clinical signs are already present, it has not been widely used in veterinary ophthalmology.

Megestrol acetate is a progesterone analog which has been effective in treating feline eosinophilic and proliferative keratopathies. The precise mechanism of its anti-inflammatory action is undetermined. The dosage is 5 mg orally daily for 5 days, then 5 mg every other day for one week, followed by 5 mg weekly as maintenance therapy. Megestrol acetate is not FDA approved for cats, and caution is advised when administering to cats since known side effects include endometritis, pyometra, diabetes mellitus, weight gain, adrenocortical suppression, and behavioral changes.

The combination of *tetracycline* and *niacinamide* has been used to successfully treat sterile granulomatous ocular adnexal diseases in dogs. Tetracycline (500 mg PO q8h) and niacinamide (500 mg PO q8h) are administered until remission of granulomatous swelling is noted. Then, frequency of treatment is tapered to q12h and finally to q24h over several weeks. Eventually all treatments are discontinued. Although the specific mechanism is not understood, the combination of these agents is known to have immunomodulating and anti-inflammatory effects (Rothstein et al. 1997).

ANTIMICROBIAL AGENTS. Antimicrobial drugs are routinely used for treating ophthalmic diseases of domestic animals. Selection of a particular therapeutic agent is based on the known antimicrobial spectrum for a given drug, knowledge of likely offending organisms, and results of specific susceptibility tests. Selection may also be influenced by physiologic barriers and the desired site(s) of action, drug compatibilities, potential toxicity, and specific formulations available (i.e., solution, suspension, ointment).

In cases of ulcerative keratitis where the corneal epithelial barrier is lost, corneal penetration becomes possible for drugs that would not typically move across the epithelium. However, if the primary objective is treatment of deep intraocular or orbital infection, then systemic therapy is indicated. Unique properties of the normal blood-aqueous barrier may limit the intraocular penetration of many antimicrobial agents given systemically. Antimicrobial therapy is frequently warranted in cases of uveitis, whereby intraocular inflammation enhances penetration of systemically administered drugs. Orbital tissues achieve antibiotic levels of systemically administered drugs comparable to those of other soft tissues.

Subconjunctival injection of nonirritating antimicrobials may be used to achieve high local levels of a drug for up to 6 hours for most aqueous-based preparations. Only parenteral antimicrobial preparations should be used for subconjunctival injections. Some injectables, such as oxytetracycline and amphotericin, are extremely irritating and are not recommended for subconjunctival use. Antibiotics which can be safely injected subconjunctivally are given in Table 55.4. Combining antimicrobial therapy may be beneficial in some instances. In therapy of deep corneal disease or uveitis, it is common to combine topical, subconjunctival, and systemic therapy. Alternatively, to enhance antimicrobial activity, more than one drug may be delivered by the same route. If more than one antimicrobial is applied to the eye at one dosing, some minimal amount of time (e.g., 5 min) should be allowed between each instillation to avoid dilution or chemical incompatibility.

Because of the limited availability of antimicrobials approved for topical ophthalmic use in animals, extra-label use of human ophthalmic products or compounding topical preparations from injectable formulations is often necessary to adequately treat animal eye diseases.

Aminoglycosides. Gentamicin, neomycin, tobramycin, kanamycin, and amikacin are aminoglycoside antibiotics commonly used in ophthalmology. Although aminoglycosides penetrate the intact eye poorly, they are extremely useful for treating ocular surface infections that cause or complicate conjunctivitis and ulcerative keratitis. They are particularly effective when used to treat serious gram-negative infections of the eye, specifically those caused by *Pseudomonas aeruginosa*. Aminoglycosides have a broad antibacterial spectrum against a variety of gram-positive and gram-negative bacteria; however, streptococci are notoriously resistant to these drugs. When injected subconjunctivally at recommended doses, the aqueous humor concentrations of aminoglycosides are sufficient to achieve bactericidal levels. Although renal and auditory toxicities are important side effects of systemically administered aminoglycosides, these side effects have not been observed with local ocular administration.

Topical *gentamicin* is recommended as initial therapy when gram-negative bacterial infections are suspected or confirmed. Gentamicin is generally highly effective against *Pseudomonas aeruginosa* and *Staphylococcus* spp. (Moore et al. 1983; Gerding et al. 1988). Gentamicin is commercially available as a 0.3% topical ophthalmic solution and as an ophthalmic ointment. Fortified solutions of gentamicin can be prepared by adding gentamicin injectable to artificial tear solution. For example, 2 mL of gentamicin injectable (50 mg/mL) may be added to 13 mL of artificial tears to make a final concentration of 0.67% gentamicin (6.7 mg/mL); or, alternatively, 5 mL of the same injectable may be added to 12.5 mL of artificial tears to make a

TABLE 55.4—Use of antimicrobial solutions for topical ophthalmic and subconjunctival use

	Topical concentration	Reference	Subconjunctival dose	Reference
Antibacterials				
Gentamicin	10–20 mg/mL	Hyndiuk and Snyder 1987	20–40 mg	Regnier 1991
Tobramycin	10–20 mg/mL	Hyndiuk and Snyder 1987	20–40 mg	Nasisse and Nelms 1992
Amikacin	10 mg/mL	Regnier and Toutain 1991	25 mg	Hyndiuk and Snyder 1987
Kanamycin	10 mg/mL	Moore 1995	10–20 mg	Hyndiuk and Snyder 1987
Cefazolin	50 mg/mL	Hyndiuk and Snyder 1987	100 mg	Hyndiuk and Snyder 1987

Nystatin	50,000 U/mL	Forster 1987	—	—
Miconazole	10 mg/mL (1%)	Forster 1987	5–10 mg	Forster 1987
Ketoconazole	10–20 mg/mL	Forster 1987	—	—
Flucytosine	10 mg/mL (1%)	Forster 1987	—	—
Clotrimazole	1% in peanut oil	Davidson 1991	—	—
Itraconazole	1% in 30% DMSO ointment	Ball 1997	—	—

final concentration of 1.4% gentamicin (14 mg/mL) (Kern 1990). A subconjunctival dose of 10-12.5 mg of gentamicin may be given for small animals or 25 mg for large animals. For subconjunctival use, the 40 mg/mL or 50 mg/mL injectable solutions of gentamicin are preferred over the 100 mg/mL solution, which contains the preservative benzyl alcohol, which may cause local irritation. Gentamicin is incompatible with sulfonamides and chloramphenicol.

Neomycin is an aminoglycoside commonly applied to the eye in combination with bacitracin (or gramicidin) and polymyxin B. This triple antibiotic combination maximizes the spectrum of antibacterial activity against both gram-positive and gram-negative organisms. Triple antibiotic is an excellent first choice for acute external ocular infections or for prophylaxis against surface infection. Neomycin hypersensitivity may occur with chronic therapy and manifests as persistent conjunctival hyperemia in the absence of infection. If neomycin hypersensitivity is suspected, the drug is discontinued and it is replaced with a non-aminoglycoside antibiotic.

Tobramycin has been suggested to be 4 times more effective against *Pseudomonas* organisms than gentamicin (Havener 1983) and, like gentamicin, is effective against penicillinase-producing staphylococci. Tobramycin is available commercially as an ophthalmic ointment or solution and may be used as an alternative to gentamicin, particularly in cases of resistant *Pseudomonas* spp.

Kanamycin is an aminoglycoside that is active against many gram-negative pathogens and is particularly useful when treating coliform or *Klebsiella* spp. infections of the equine eye. Kanamycin has been demonstrated to be highly active against *Moraxella bovis* (minimum inhibitory concentration less than 0.5 µg/mL) (George et al. 1986). *Amikacin* is an acetylated kanamycin and is an alternative aminoglycoside for use against gentamicin- or tobramycin-resistant *Pseudomonas* spp. The acetyl moiety renders amikacin more resistant to bacterial enzyme inactivation. Solutions for topical ophthalmic use may be prepared by adding 3 mL (50 mg/mL) of injectable amikacin or kanamycin to 12 mL of artificial tears for a final concentration of 1.0%. Kanamycin or amikacin injectable (50 mg/mL) can each be given subconjunctivally (Table 55.4). Subconjunctival injections of 100 mg of kanamycin in calves produced local levels exceeding 1 µg/mL for 4 hours, resulting in successful treatment of infectious bovine keratoconjunctivitis (IBK) (George et al. 1986).

Cephalosporins. Cephalosporins are β-lactam bactericidal antibiotics similar in spectrum to penicillins except that this group of agents is generally effective against penicillinase-producing organisms. Local

effective intraocular levels for 48 hours (Havener 1983). Although Allen et al. (1995) reported that all 333 *Moraxella bovis* isolates recovered from cattle with infectious keratoconjunctivitis (IBK) were susceptible to 0.3 U of penicillin/mL, subconjunctival treatment with procaine-penicillin G, alone or in combination with dexamethasone, did not significantly affect the outcome of naturally developing IBK.

Penicillin G may be mixed with artificial tears for topical administration; however, its potency is reduced to 74% in 3 days and to 25% after 7 days (Osborn et al. 1976). Therefore, penicillin G in artificial tear solution should be replaced after 3 days at room temperature. *Ampicillin* has broad-spectrum antibacterial activity and may be reconstituted as a 100 mg/mL solution and administered topically after adding 1.75 mL to 15 cc artificial tears (10 mg/mL) or injected subconjunctivally directly (100 mg/mL) as prophylaxis or definitive therapy for streptococcal keratitis or IBK. Ampicillin may be administered parenterally when broad-spectrum systemic therapy is desired. Amoxicillin, which is comparable in spectrum to ampicillin, is often prescribed when prophylaxis or empirical broad-spectrum systemic therapy is desired because of its availability and convenient oral dosage forms. Amoxicillin or amoxicillin-clavulanate combination are excellent first choices for therapy of orbital infections.

Carbenicillin, a semisynthetic penicillin effective against gram-negative infections, including *Pseudomonas, Proteus,* and *Escherichia coli,* is therapeutically synergistic with gentamicin, tobramycin, and amikacin but is no longer commercially available. *Ticarcillin* has a comparable antibacterial spectrum to carbenicillin and is available as a reconstitutable powder in sterile 1 g vials. Although therapeutically synergistic, ticarcillin should not be mixed with aminoglycoside solutions. Therefore, when used simultaneously, these agents should be administered separately.

Methicillin, unlike penicillin, ampicillin, amoxicillin, and ticarcillin, is resistant to destruction by penicillinase and is, therefore, effective against resistant staphylococci. However, methicillin is very unstable and must be used immediately after reconstitution. Like methicillin, *cloxacillin* is also active against staphylococci and other penicillinase-producing bacteria. Benzathine cloxacillin has been documented to be effective against *Moraxella bovis,* the cause of IBK. A single topical administration of an intramammary preparation of benzathine cloxacillin has been used to successfully treat IBK (Daigneault and George 1990). The concentration of cloxacillin in tears should exceed 2 μg/mL for 12 hours to be effective. An apparent affinity of benzathine cloxacillin for cornea and conjunctiva may contribute to its efficacy in treating IBK (Daigneault et al. 1990).

Polypeptide Antibiotics. *Bacitracin* and *polymyxin B* are bactericidal polypeptide antibiotics commonly used in ophthalmology in combination with neomycin. Inclusion of bacitracin in the triple antibiotic combination enhances its spectrum against streptococci, while inclusion of polymyxin B expands efficacy against gram-negative organisms. Like neomycin, bacitracin and polymyxin B do not penetrate the intact cornea. Bacitracin has a range of activity similar to penicillin, but bacterial resistance and allergic reactions against it are much less common than with penicillin. Bacitracin is too toxic for systemic use and, therefore, is used only topically. Bacitracin is water soluble and a 10,000 IU/mL solution may be injected subconjunctivally (up to 1 mL) (Regnier and Toutain 1991).

Polymyxin B is effective against most gram-negative bacteria, including many *Pseudomonas* spp. The presence of polymyxin B makes the triple antibiotic combination preferable to chloramphenicol in therapy of uncomplicated corneal ulcers because of its expanded efficacy against *Pseudomonas* infection. Although *Proteus* spp. are typically resistant to polymyxin B, the neomycin present in the triple antibiotic combination generally is effective against *Proteus.* Polymyxin B has recently been combined with trimethoprim, producing a broad-spectrum preparation for topical ophthalmic use. Polymyxin B should not be injected subconjunctivally since it may cause severe chemosis and conjunctival necrosis.

Like polymyxin B, *colistin* (polymyxin E) is a polypeptide antibiotic which is highly effective in inhibiting gram-negative organisms, including *Pseudomonas aeruginosa,* but has little effect against gram-positive organisms or *Proteus* spp. Colistin is nonirritating when topically applied to the cornea or conjunctiva and, unlike polymyxin B, may be given subconjunctivally without irritation. When administered systemically, both colistin and polymyxin B may produce severe renal and neural toxicity.

Sulfonamides. Sulfonamides are relatively broad-spectrum bacteriostatic antimicrobial agents that demonstrate activity against most gram-positive and a variety of gram-negative organisms, including some *Pseudomonas* spp. *Sulfacetamide* and *sulfisoxazole* are available as human ophthalmic preparations but are not commonly used in veterinary ophthalmology because of more effective and more readily available topical alternatives. In human patients, sulfacetamide is effective therapy for ocular surface infections caused by *Staphylococcus.*

The combination of *trimethoprim-sulfadiazine* is frequently used systemically as an adjunct to topical therapy for ocular infections. Trimethoprim-sulfadiazine is reported to be effective against ocular toxoplasmosis. In the presence of uveitis, the aqueous concentration following systemic administration of trimethoprim-sulfadiazine approximates that in the blood stream. Sulfonamides also show some activity against chlamydia, and therefore, trimethoprim-sulfadiazine may be an effective alternative to systemic tetracycline therapy in young cats with conjunctivitis and respiratory disease. Prolonged systemic therapy with sulfonamides may cause dry eye in the dog due to

activity against gram-positive bacteria. Ceftazidime and aztreonam are commercially available as sterile powders for reconstitution and injection in 500 mg, 1 g, and 2 g vials. The principal advantage of these new-generation antibiotics is their decreased vulnerability to hydrolysis by β lactamase and their lack of nephrotoxicity. The potential usefulness of these and other newer generation antibiotics for treating eye infections of animals merits in vitro and clinical investigations.

Imipenem is a β-lactam antibiotic that is highly resistant to all β-lactamase enzymes and can penetrate most gram-negative bacteria. It has been used primarily for serious, resistant infections that would otherwise require multiple drugs, including animoglycosides. Imipenem has the broadest antibacterial action in comparison to other β lactams, even surpassing many third-generation cephalosporins. It is one of the newest and most expensive antibiotics currently available.

Fusidic acid, or fusidin, is a steroidal antibiotic chemically related to cephalosporin P. It is effective against a wide range of gram-positive organisms, especially against staphylococci (both β-lactamase positive and negative) and some gram-negative bacteria. It is marketed as a 1% viscous topical agent in Europe and Great Britain for treatment of bacterial conjunctivitis of dogs. The sustained-release vehicle allows it to be used effectively with once- or twice-daily administration. Although it is not presently licensed for use in cats, it is reportedly well tolerated in cats and is undergoing investigation as a possible treatment for feline conjunctivitis.

Antifungals

POLYENE ANTIBIOTICS. *Natamycin,* a tetraene polyene antibiotic, is the only antifungal agent presently FDA approved for topical ophthalmic use in humans. It is available commercially as a 5% suspension, which is well tolerated by the mammalian eye and may be safely applied topically as frequently as every 1-2 hours for several days in cases of keratomycosis. Natamycin has a broad antifungal spectrum against both filamentous fungi and yeast and is the preferred treatment for *Fusarium* infections of the cornea (Beech and Sweeney 1983). Use of natamycin in veterinary medicine has been limited somewhat by the cost of the product. However, this should not be considered a major deterrent given other expenses incurred in treatment of serious corneal infections of animals, particularly in equids.

Amphotericin B may be used as a topical solution (0.10-0.25%) in cases of keratomycoses when there is known or suspected resistance to other antifungal agents. Only sterile water or 5% dextrose solution should be used as diluents since amphotericin B is incompatible with saline or other electrolyte solutions. Amphotericin B is extremely irritating when injected, and therefore, subconjunctival administration is not recommended. Reconstituted amphotericin B solution should be stored in a dark container and refrigerated to prevent photodegradation.

Nystatin, a polyene antibiotic with high efficacy against yeasts, is widely used in the treatment of localized candidiasis in humans. Nystatin is available in nonocular forms, including tablets, creams, and ointments. Tablets must be dissolved to formulate a solution containing 50,000 U/mL for topical application (Forster 1987). Dermatologic or mucous-membrane creams or ointments may be applied directly to the eye. Although nystatin is relatively nontoxic to ocular surface tissues, its use is somewhat limited because of its limited antifungal spectrum.

IMIDAZOLE AGENTS. *Miconazole* is an imidazole derivative with broad antifungal activity against common fungal infections. Miconazole is often used as the initial treatment for cases of confirmed or suspected fungal keratitis in the horse. A 1% miconazole intravenous solution was historically used directly on the eye 4-6 times daily or even more frequently in severe or rapidly progressive cases of keratomycoses. Miconazole solution *should not* be mixed with artificial tears or other ophthalmic preparations. Unfortunately, 1% miconazole intravenous solution is presently not commercially available. Miconazole 2% creams, available for human and veterinary use, are well tolerated by the equine eye. The author has applied the veterinary dermatologic cream to equine eyes affected with fungal keratitis up to 4 times daily for 3 weeks without adverse effects. Miconazole dermatologic lotions or sprays containing ethyl alcohol *should not* be applied to the eye. Miconazole and amphotericin B are antagonistic and should not be used concurrently.

Fluconazole is a synthetic broad-spectrum imidazole agent with demonstrated fungistatic activity against *Aspergillus flavus* and *A. fumigatus* infections in laboratory animals (Troke et al. 1987). Fluconazole is available as a 0.2% (2 mg/mL) injectable solution, which the author has applied topically to the equine eye and injected subconjunctivally (1 mL) without adverse reaction. As with most antifungal drugs, it should not be mixed with other solutions. *Clotrimazole,* used as a 1% dermatologic cream, has been well tolerated by the equine eye. An anthelmintic paste form of *thiabendazole* has been applied to infected equine eyes and was reportedly effective in treating fungal keratitis (Joyce 1983). *Ketoconazole* and *econazole* are available as 2% and 1% dermatologic creams, respectively; however their tolerance by the equine eye has not been established. *Itraconazole* is commercially available in 100 mg capsules and has been compounded in an ointment with dimethyl sulfoxide and applied topically as effective treatment for equine keratomycosis (Ball et al. 1997) infected with fungi. Oral itraconazole may be useful in treating canine ocular blastomycosis (Brooks et al. 1991). See Table 55.4 for a summary of extralabel formulations of antifungal solutions for local ophthalmic administration.

MISCELLANEOUS ANTIFUNGAL AGENTS. *Flucytosine* (5 fluorocytosine, 5-FC) is an antifungal antimetabolite most commonly used in combination with amphotericin B to treat systemic mycoses in humans. When dictated by in vitro susceptibility testing, flucytosine may be formulated for topical use in the equine eye by dissolving contents of oral capsules in sterile water to form a 1% solution. *Silver sulfadiazine* is a bactericidal dermatologic cream used to treat human burn patients. It also has antifungal properties and has been reported to be safe and effective for treatment of human keratomycosis (Mohan et al. 1988). Silver sulfadiazine has also been used to treat equine keratomycoses; it is well tolerated and appears to be effective. Lower cost and ready availability are the primary reasons for its use as an antifungal agent for treatment of equine eyes. *Iodines,* organic solutions or 7% tincture, are used to treat infectious keratitis in horses. Although more irritating than organic iodine, 7% tincture penetrates the cornea more effectively and serves as a stimulus for fibrovascular infiltrates (Moore et al. 1995). However, iodine tincture must be applied with discretion, as it is capable of causing moderately severe epibulbar hyperemia and chemosis if it inadvertently contacts the conjunctiva.

Antiviral Agents. Antiviral agents applicable to treatment of animal eye disease may be categorized as pyrimidine nucleoside analogs, cytokines, or amino acid (lysine).

Pyrimidine nucleoside analogs include the antiviral drugs *idoxuridine, trifluridine, vidarabine,* and *acyclovir.* These drugs act by substitution reactions within the viral DNA molecule to render the virus ineffective. In veterinary ophthalmology, these antiviral agents are most commonly used for therapy of herpesvirus infections, especially feline herpesvirus 1 (FHV-1) conjunctivitis and keratitis. An in vitro study of FHV-1 sensitivity to a number of antiviral agents indicated the relative potency to be trifluridine > idoxuridine > vidarabine > acyclovir (Nasisse et al. 1989). Although clinical studies to corroborate these in vitro efficacy results are not available, anecdotal accounts indicate trifluridine is the drug of choice for treating feline herpesvirus ocular disease. However, because trifluridine is relatively expensive and available only as a topical solution, idoxuridine is often used as the initial therapy.

Historically, idoxuridine has been commercially available as an ointment or solution. However, it is currently unavailable commercially but may be specially compounded. Vidarabine, available commercially as an ophthalmic ointment, demonstrated some efficacy in Nasisse's in vitro herpesvirus study. Acyclovir, an effective drug for treatment of human patients suffering from herpesvirus infections, appears to have little in vitro efficacy against the FHV-1. *Valacyclovir,* given orally to experimental cats, causes toxicity characterized by bone marrow suppression and renal insufficiency (Nasisse et al. 1997).

When administering topical antiviral agents for ocular herpesvirus infections, solutions are applied every 2-4 hours the first day of therapy and then 4-5 times daily thereafter until clinical improvement is noted. Ointments should be applied a minimum of 4 times daily to be effective.

Interferons (IFNs) are cytokines produced by lymphoid cells and serve as the principal source of macrophage activation. As part of the natural immune system, IFNs offer potential for treating viral diseases. Preparations of recombinant human IFN-α (5-25 U/day) may be administered orally or topically to cats with FHV-1 infections; when given empirically in such cases, this treatment appears to reduce the severity of FHV-1 infections. Recombinant IFN-α has been administered orally in combination with topical antiviral agents in the management of feline herpesvirus ocular disease (Stiles 1995); however, beneficial effects could not be documented.

The amino acid L-lysine, given orally at a dose of 250 mg/day, has been suggested as adjunctive treatment for persistent or severe feline herpesvirus ocular infections (Collins et al. 1995). An in vitro increase in the lysine/arginine ratio reduces herpesvirus replication.

Antiparasiticides. Thelaziasis is a common ocular parasitic condition of large domestic herbivores. Avermectins have been demonstrated to be effective in eliminating organisms from the eye. In experimentally infected cattle, a single dose of ivermectin was 100% effective in eliminating *Thelazia skrjabini* (Kennedy 1992). In a similar study, doramectin was highly effective in treating two *Thelazia* spp., *T. skrjabini* and *T. gulosa* (Kennedy and Phillips 1993). Each drug was administered subcutaneously at a dosage of 200 μg/kg. Ivermectin was also effective against *T. rhodesii* (Soll et al. 1992). Lyons et al. found that oral levamisole was effective against *T. skrjabini* and *T. gulosa:* however, the injectable formulation was not effective against *T. skrjabini* (Lyons et al. 1981).

AUTONOMIC OCULAR PHARMACOLOGIC RESPONSES

Cholinergic Responses. Parasympathomimetic, or cholinergic, agents work either by mimicking endogenous acetylcholine or by binding acetylcholine esterase, which allows endogenous acetylcholine to accumulate and to stimulate cholinoreceptive sites. Therefore, cholinergic agents are divided into direct-acting agents and indirect-acting agents (cholinesterase inhibitors).

Whether direct or indirect acting, the ocular effects of cholinergic stimulation are increased tearing, miosis, and reduction of intraocular pressure (IOP). These effects result from stimulation of lacrimal glands, iris sphincter muscle, and ciliary body muscles, respectively. Additional ocular effects are vasodilation and increased capillary permeability of iris and ciliary vessels with resultant increase in permeability of the blood-aqueous barrier. Myopia (nearsightedness) may be induced or augmented by cholinergic drugs.

temic organophosphate parasiticide drugs, because systemic toxicity may result. Systemic side effects of cholinesterase inhibitors include salivation, vomiting, diarrhea, and abdominal cramps. Following long-term use of indirect-acting parasympathomimetic ophthalmic agents in human patients, ocular side effects include cataracts, iris cysts, disrupted blood-aqueous barrier, and retinal separation.

Adrenergic Drugs

ADRENERGIC AGONISTS. *Epinephrine*, an α- and β-adrenergic agonist, both reduces the production of aqueous humor (early effect) and increases the outflow facility (prolonged effect). Reduced aqueous production results from α_2-receptor stimulation and reduced intracellular cAMP (Erickson et al. 1994). The α-receptor effect also causes vasoconstriction of ciliary vessels. The effect on outflow has been associated with an increase in aqueous cAMP, probably a β-mediated effect.

Epinephrine is used clinically as a 1% or 2% solution which may be used concurrently with other hypotensive agents such as pilocarpine, timolol, and carbonic anhydrase inhibitors. Ocular side effects of epinephrine include formation of rust-colored deposits on the cornea, conjunctiva, and eyelids, and mydriasis. Rust discoloration and facial tear staining is due to accumulation of adrenochrome pigment, an oxidative product of epinephrine. Systemic cardiovascular effects reported in human patients after topical administration of epinephrine include arrhythmias, tachycardia, and hypertension.

Dipivefrin hydrochloride is an epinephrine prodrug produced by the addition of two pivalic acid groups to the parent epinephrine molecule. This configuration results in increased lipophilicity of the dipivefrin molecule, allowing it to penetrate the cornea more readily. Once absorbed, dipivefrin is converted by tissue esterases to epinephrine, which produces the observed hypotensive effects. In Beagle dogs, topical 0.5% dipivefrin has hypotensive and mydriatic effects similar to those of 2% epinephrine (Gwin et al. 1978). Topical administration of the 0.5% solution will cause local irritation, mild conjunctivitis, and tearing in some animals.

Dipivefrin is commercially prepared as a 0.1% topical solution. Twice-daily administration of 0.1% dipivefrin in human patients produces hypotensive effects equivalent to those of 4-times-daily topical 2% pilocarpine. Infrequent ocular side effects in humans include slight discomfort (burning or stinging), mild mydriasis, and rare allergic reactions.

Apraclonidine hydrochloride, a clonidine derivative, is an α agonist approved for use in human patients prior to laser iridotomy and laser trabeculoplasty to prevent postoperative rises in IOP (Brown et al. 1988). Apraclonidine reduces IOP by reducing aqueous humor formation (Gharagozloo et al. 1988). Although the mechanism by which it decreases aqueous humor production is presumably through α_2-receptor agonist activity, the precise mechanism is unknown. Vasoconstriction of afferent arterioles supplying the ciliary body may also contribute to its hypotensive effect. Ocular side effects of apraclonidine in human patients are infrequent but include conjunctival blanching, upper eyelid elevation, mydriasis, and allergic responses.

Effects of topical administration of 0.5% apraclonidine have been studied in clinically normal dogs and cats. In cats, apraclonidine reduced IOP, pupil size, and resting heart rate while causing miosis (Miller and Rhaesa 1996). By contrast, this drug resulted in mydriasis in dogs while also lowering IOP and exhibiting less predictable depressant effects on heart rate (Miller et al. 1996). No information is currently available on the efficacy or safety of apraclonidine in treating spontaneous glaucomas of animal patients.

Brimonidine is an α_2-adrenergic receptor agonist that reduces intraocular pressure probably both by reducing aqueous humor production and by increasing uveoscleral outflow. In human patients, the recommended dose is one drop 3 times daily, whereby the ocular hypotensive effects are generally equivalent to those of timolol. Local ocular irritation is the most common side effect and occurs in 3-9% of human patients receiving this drug. Fatigue or drowsiness has also been reported.

ADRENERGIC ANTAGONISTS. Beta-blocking agents effectively lower IOP in human and animal glaucoma patients. There are a number of β-blocking drugs approved for human antiglaucoma therapy, including *timolol, betaxolol, carteolol, metipranolol,* and *levobunolol.* In veterinary medicine timolol is the most widely used ophthalmic β-blocking agent, blocking both β_1 and β_2 receptors. Two concentrations are available, 0.25% and 0.50% solutions. Experimentally in rabbits, cats, and dogs, timolol produces a relatively short duration, dose-dependent lowering of the IOP (Potter 1981; Svec and Strosberg 1986). In multiple-dose studies in glaucomatous Beagles, timolol significantly reduced IOP, with increasing concentrations yielding more profound reduction in IOP (Gum et al. 1991).

Timolol is used to treat both primary and secondary glaucomas. Timolol reduces IOP by inhibiting aqueous humor formation rather than by any effects on aqueous humor outflow. The β-blocking effect diminishes cAMP production and thereby reduces aqueous humor formation. In experiments performed in rabbits, timolol also reduced the blood flow to the ciliary body, which resulted in a decrease in aqueous humor production (Watanabe and Chiou 1983). In humans, the acute effect of timolol on aqueous humor production diminishes when the drug is used chronically. The mechanism of adaptation in the chronically β-blocked eye is unclear. The hypotensive effects of timolol are additive with parasympathomimetic and carbonic anhydrase inhibitors.

Effects of topical administration of a single dose of timolol maleate on IOP and pupil diameter were evaluated in normal cats (Wilkie and Latimer 1991b).

as a mydriatic in horses has been questioned (Hacker et al. 1987). It has been used as an adjunct to atropine therapy in cases of anterior uveitis with severe miosis. In cats, phenylephrine is ineffective by itself as a mydriatic agent.

Phenylephrine is used in the diagnosis of sympathetic denervation syndromes, e.g., Horner's syndrome, whereby an affected eye exhibits a denervation hypersensitivity due to functional destruction of postganglionic sympathetic neurons. In such cases, instillation of low concentrations of phenylephrine, such as 0.1-1.0%, will stimulate pupillary dilation. In cases of conjunctival hyperemia, topical phenylephrine causes blanching of conjunctival vessels and, therefore, may be used to differentiate between conjunctivitis and uveitis. In cases of sympathetic denervation, application of phenylephrine will result in symptomatic improvement by stimulating retraction of the third eyelid. Repeated administration of 10% phenylephrine to an eye may cause conjunctival irritation and corneal epithelial damage.

Topical ophthalmic *epinephrine,* used mainly as an antiglaucoma agent, has limited clinical application as a mydriatic in animals. Similar to phenylephrine, dilute epinephrine (0.10-0.01% solution) will result in mydriasis in cases of Horner's syndrome. A positive response confirms a postganglionic lesion of the sympathetic neuron. Concentrations of epinephrine normally used to treat glaucoma (1-2% solutions) produce moderate mydriasis in dogs given a single dose but have no apparent effects in cats. During intraocular surgery, intracameral solutions of 0.01% epinephrine aid in maintaining mydriasis and controlling minor bleeding. Intracameral epinephrine solution should not be used with halothane anesthesia.

Adrenergic Antagonist (Mydriasis Reversal). *Dapiprazole* is a recently synthesized α-adrenolytic agent which produces miosis by blocking the α receptors of the dilator muscle of the iris. Dapiprazole has been used to reverse the effects of diagnostic mydriatics. A topical solution containing 0.5% dapiprazole has been demonstrated to safely and effectively reverse mydriasis induced by 1% tropicamide and 2.5% phenylephrine in human patients (Allinson et al. 1990). Although dapiprazole caused short-term conjunctival vascular injection in some patients, no effects on IOP, visual acuity, blood pressure, or heart rate were noted (Allinson et al. 1990).

Contraindications and Cautions with Use of Topical Autonomic Agents. *Miotics* are contraindicated when constriction of the pupil is undesirable, such as with acute iritis or anterior lens luxations. In inflamed eyes, cholinergic agents may exacerbate signs of inflammation. Indirect-acting cholinergic drugs should not be used concurrently with topical or systemically administered organophosphates.

Adrenergic agents must be used cautiously in patients with cardiac arrhythmias. Timolol is contraindicated when bradycardia or hypotension is present or in patients with bronchospasm. Timolol should be used cautiously in cases with metabolic disease, such as diabetes mellitus or hyperthyroidism. Epinephrine or propine should not be used in animals with tachycardia or hypertension.

Anticholinergic *mydriatic drugs,* e.g., atropine, should not be used in instances where the IOP is elevated. Topical atropine will exacerbate aqueous tear deficiency and is, therefore, contraindicated in cases of KCS. Systemic absorption of topically administered atropine may potentiate preexisting gastrointestinal hypomotility and result in gut stasis, particularly in horses.

NONAUTONOMIC HYPOTENSIVE AGENTS

Carbonic Anhydrase Inhibition. Carbonic anhydrase, present in both pigmented and nonpigmented layers of the ciliary epithelium, is an enzyme essential to the production of aqueous humor. The reversible carbonic anhydrase reaction produces bicarbonate, which binds to sodium and results in the secretion of both ions into the posterior chamber. Sodium molecules osmotically attract water from the vessels of the ciliary stroma, contributing to aqueous humor formation. Carbonic anhydrase inhibitor (CAI) diuretics suppress bicarbonate formation by ciliary epithelium and, therefore, prevent transport of sodium from ciliary stroma to aqueous humor. The net effect of CAI administration is lowering of the IOP. Systemic acidosis induced by CAIs may also inhibit aqueous humor formation and enhance the pressure-lowering effect of these drugs.

For additive hypotensive effects in managing primary or secondary glaucomas, CAIs are usually administered in combination with other agents. CAIs may be used both for short-term treatment to control acute increases in IOP and for long-term therapy of chronic glaucoma. Reduced response to CAI drugs may occur with prolonged use. In some cases systemic side effects, such as metabolic acidosis, gastrointestinal signs, panting, hypokalemia, and behavioral changes, may limit the use of these agents. Therefore, dosage alterations or changes in combination therapy may be needed in the course of glaucoma treatment.

Selection of a systemic CAI diuretic is based on familiarity with a given product, relative side effects, individual patient tolerance, and cost. *Acetazolamide,* a first-generation CAI, is available in oral and injectable forms. An intravenous dose of 5-10 mg/kg is recommended for emergency treatment of acute glaucoma. Oral dosage forms include 125 mg and 500 mg tablets and 500 mg time-released capsules. A dose of 10-25 mg/kg 2-3 times daily is the usual dose for canine glaucoma. In glaucomatous Beagles the effect of a single dose of acetazolamide lasts 8 hours. In cats the hypotensive effect of a single dose lasts about 5 hours.

Although acetazolamide is the least expensive of the CAI drugs, adverse side effects are common, especially

drugs. It does not significantly delay healing of corneal epithelial wounds. *Polyvinyl alcohol* is a synthetic hydrophilic resin that is less viscous than methylcellulose but has good corneal adhesive properties. Available as a 1.4% solution, polyvinyl alcohol is the primary ingredient in a number of artificial tear products.

MUCINOMIMETICS. Linear polymers, such as dextran and polyvinylpyrrolidone, have mucomimetic properties. Patented polymers are often combined with buffered solutions of substituted cellulose esters to form preparations for treating deficiencies of aqueous and mucin components of the preocular tear film.

Viscoelastic substances that have mucinomimetic properties include sodium hyaluronate, chondroitin sulfate, and methylcellulose. Sodium hyaluronate is a naturally occurring, high-molecular-weight glycosaminoglycan that has excellent viscoelastic and lubricating properties. Sodium hyaluronate has been diluted with artificial tear to make a 0.04% solution that may be applied topically every 4 hours initially and then reduced to 2-4 times daily in treating eyes of patients with KCS (Schadler 1987). Treated eyes were markedly improved, although Schirmer tear test values were not improved with this treatment. A hyaluron-derivative viscoelastic tear supplement is available commercially in Canada as either a 0.15% or a 0.40% drop. This product has been particularly useful in managing severe cases of KCS in dogs. Chondroitin sulfate is a glycosaminoglycan polymer made up of disaccharide units. Chondroitin sulfate is not as viscous as sodium hyaluronate. Hydroxypropylmethylcellulose in concentrations of 1-2% has been proposed as a less expensive substitute for sodium hyaluronate and chondroitin sulfate.

LIPOPHILIC AGENTS. *Lanolin* and *petrolatum* are commonly used as bases for ophthalmic lubricant ointments. These ingredients mimic the function of naturally occurring meibomian lipids by preventing evaporation and preserving existing tears. Nonmedicated ophthalmic ointments containing lanolin and/or petrolatum are used to lubricate and protect eyes in instances where corneal exposure is a problem, i.e., during anesthesia and surgery or in cases of eyelid paresis or eyelid swelling. Lanolin and petrolatum vehicles provide prolonged corneal and conjunctival contact for other agents, such as corticosteroids and antibiotics.

MISCELLANEOUS AGENTS. A variety of therapeutic agents have recently been developed for ophthalmic use. Because these agents do not fit into established categories of ophthalmic pharmaceutical agents, they are discussed separately here.

Adhesives. *Cyanoacrylate* adhesives have the unique property of rapidly solidifying by anionic polymerization at room temperature without catalysts, solvents, or application of pressure. Corneal uses of tissue adhesive include sealing of perforations, covering epithelial erosions, and inhibiting progression of noninfectious stromal ulceration. Although cyanoacrylates have been shown to possess bactericidal properties, corneal infections may be masked by these adhesives (Cavanaugh and Gottsch 1991). Adverse effects of cyanoacrylates are related to rapid degradation rate and release of irritating breakdown products, such as formaldehyde. Local tissue toxicity may compromise the host's immune barriers, enhancing development of infections.

Aldose Reductase Inhibitors. Aldose reductase inhibitors, such as *sorbinil*, have been shown to prevent and reverse cataracts in galactosemic rats (Tsuju et al. 1990). However, effective use of aldose reductase inhibitors to prevent or reverse spontaneous cataracts in domestic animals has not been reported. Aldose reductase inhibition has been demonstrated to prevent retinal capillary basement membrane thickening in galactosemic rats, and therefore, use of inhibitor agents may prove to be beneficial in prevention of diabetic retinopathy (Das et al. 1990).

Anticoagulants. By activating antithrombin, *heparin* can minimize intraocular fibrin formation and the associated undesirable sequelae of synechiae, i.e., anterior capsular lens opacities and fibrin in the trabecular meshwork of the drainage angle. Heparin is frequently diluted to 2-5 U/mL in irrigating solutions used for intraocular procedures. Heparin has a half-life of 5 hours, and its action can be stopped by protamine sulfate. Aspirin and other nonsteroidal anti-inflammatory agents often used to treat uveitis in animals suppress the aggregation of platelets and reduce the adherence of platelets to the vascular wall, interfering with plug formation. Therefore, for patients receiving nonsteroidal anti-inflammatory therapy preoperatively, it may be prudent to discontinue administration several days prior to planned intraocular surgery (Moll et al. 1989).

Anticollagenases and Antiproteases. Because *N-acetylcysteine* has both anticollagenase and mucinolytic properties, it has been commonly used in veterinary ophthalmology to treat ulcerative keratitis and KCS. Excessive collagenase, produced by epithelial and stromal tissue, inflammatory cells, and ocular surface bacteria, is destructive to stromal collagen and can contribute to progressive ulceration and perforation. Acetylcysteine inhibits collagenase activity by chelating available free calcium cations essential for enzyme activation. Other agents used topically for their protease-inhibiting activity include cysteine, sodium ethylenediaminetetraacetic acid (Na-EDTA), heparin, and serum.

Denatured mucous harbors microorganisms and surface debris and loses it viscoelastic properties, becoming tenacious and inhibiting normal ocular cleansing and lubrication. Since free sulfhydryl groups reduce the viscosity of mucoproteins, increasing concentrations of acetylcysteine decrease the viscosity of mucus.

The first viscoelastic material introduced commercially was sodium hyaluronate, and therefore, it is generally the standard to which other similar products are compared. Sodium hyaluronate is a large polysaccharide molecule that is present in nearly all vertebrate connective tissues. It is also a component of the capsular material surrounding streptococcal organisms. Sodium hyaluronate is extracted from a number of natural sources, including the dermis of rooster combs, umbilical cords, and cultures of streptococcal organisms. Sodium hyaluronate has also been produced using genetic engineering techniques.

Sodium hyaluronate is used widely in cataract surgery and intraocular lens implantation. Because autoclaving causes depolymerization and a change in viscosity, preparation of a sterile and stable compound is technologically demanding. This accounts for its relatively high cost. After intraocular use, a transient postoperative increase in IOP frequently occurs.

Highly purified hydroxypropylmethylcellulose (HPMC), commonly referred to simply as methylcellulose, has long been used as a 2% solution for ocular surface lubrication in gonioscopic solutions and as a base for eyedrops. A newer use has been to lubricate intraocular lenses for implantation following cataract removal. Although methylcellulose products have excellent viscoadherent properties, they have relatively poor viscoelasticity, requiring larger cannulas and higher pressures for injection.

Medical-grade methylcellulose is manufactured from raw wood pulp; production processing to form ophthalmic HPMC includes multiple filtration steps that result in a highly purified synthetic nonprotein substance which is nontoxic. The potential advantages of HPMC over other viscoelastic materials are the availability of raw materials, relative ease in manufacturing, ability to withstand autoclaving, and low cost. However, production procedures necessary to purify the material prior to intraocular use can substantially increase the cost. Also, since it is not a natural animal product, the fate of HPMC in the body is unknown.

Chondroitin sulfate is a polysaccharide, similar to sodium hyaluronate, that is harvested from shark fin cartilage. It differs from sodium hyaluronate by being sulfated. This results in an extra negative charge per repeating unit that may allow it to coat the positively charged tissue or implant surface and thus decrease the electrostatic interaction between the implant and the endothelium. A product with one part 4% chondroitin sulfate and three parts 3% sodium hyaluronate is commercially available. The manufacturer believes this product combines the advantages of each compound, i.e., the higher viscosity and chamber-maintaining properties of sodium hyaluronate with the coating and cell protection properties of chondroitin sulfate.

The effects of intracameral injection of viscoelastic solutions on IOP and corneal endothelium have been evaluated in dogs. Following anterior chamber injection of sodium hyaluronate 1%, combined sodium chondroitin sulfate 4% and sodium hyaluronate 3%, and HPMC 2%, IOP, corneal endothelial integrity, and corneal thickness were evaluated (Gerding et al. 1989; Gerding et al. 1990). These studies revealed that the viscoelastic products evaluated caused relatively minor transient effects on IOP and corneal thickness, suggesting that these substances may be used safely in canine patients undergoing intraocular surgery.

Besides their use in cataract surgery and intraocular implant procedures, other ophthalmic uses of these viscoelastic substances include trauma repair, corneal transplantation, glaucoma filter surgery, and vitreoretinal surgery. Viscoelastic substances are also used in the medical therapy of tear-deficient states. Human placental collagen, synthetic polyacrylamide, and other viscoelastic polymers are being investigated for general medical and ophthalmic uses.

were just beginning to have an impact on infectious diseases. Milk was still unpasteurized and cows were not tested for tuberculosis. Thousands of so-called patent medicines such as Kickapoo Sagwa Renovator for Stomach, Liver, and Kidney, Dr. Shreve's Anti-Gallstone Remedy, and Hamlin's Wizard Oil—Cures All Pain in Man or Beast flooded the marketplace. "Medicine-men" competed with circuses, minstrel shows, and "Wild West" shows to entertain the public and sell their products. Medicines containing opium, morphine, heroin, and cocaine were sold without restriction and without even any indication of the presence of the drugs in the product. Preparations that were otherwise harmless, other perhaps than being alcohol-based, were labeled for the cure of every disease or symptom of man and beast. Labels did not list ingredients, and warnings against misuse were virtually nonexistent. Of course, such practices were by no means universal, and many firms were producing reliable and wholesome products. However, there was no lack of material for investigation and disclosure by Dr. Wiley's chemists. In order to generate support for his cause, Dr. Wiley took their findings to the public, speaking frequently at women's clubs and civic and business organizations. Crusading reporters (muckrakers), organized women's clubs, and farsighted businessmen became his strong supporters. In 1903, Dr. Wiley captured the attention of the public by establishing his now famous volunteer "poison squad" of young men who agreed to eat only foods treated with measured amounts of chemical preservatives, in order to evaluate the safety of such products. Thanks to the publicity engendered by Dr. Wiley's work, public concern began to build. It reached a climax with the publication of Upton Sinclair's book *The Jungle*, a brutally graphic novel which focused national attention on the unsanitary conditions in US meatpacking plants. As a result the first federal food and drug law, the Food and Drugs Act of 1906, was passed by Congress and signed into law by President Theodore Roosevelt on June 30, 1906.

Basically the law banned from interstate commerce any traffic in adulterated or misbranded food or drugs. The act defined "drug" to include all medicines and preparations recognized in the *US Pharmacopeia* or *National Formulary* for internal or external use and any substance or mixture of substances intended to be used for the cure, mitigation, or prevention of disease in either humans or other animals.

Drugs were to be deemed "adulterated" if they were sold under or by a name recognized in the official compendia (the *US Pharmacopeia* and the *National Formulary*) but failed to meet the standards set forth therein, except that a recognized drug not meeting the official standard would not be deemed adulterated if it met its own standard of strength, quality, and purity as stated on the container. A drug was deemed "misbranded" if the label bore any statement, design, or device regarding the contents which was false or misleading, or if the drug was falsely branded as to the state, territory, or country in which it was manufactured. Drugs would also be misbranded if they were an imitation of, or offered for sale under the name of, another article or if the original contents had been removed in whole or in part and/or other contents added. Drugs would also be misbranded if their labels failed to disclose any quantities of alcohol, narcotics, and other specified substances present in the product.

Although the 1906 law represented a great step forward, there were obvious weaknesses. In 1911, the Supreme Court ruled that the labeling provisions of the act prohibited *only* false statements about the identity of the drug product but not false therapeutic claims. The Congress responded by passing the Shirley Amendment of 1912, which outlawed false *and fraudulent* curative or therapeutic claims. Under the Shirley Amendment, the government was required to prove that a false claim was also fraudulent, that is, that the promoter *intended* to deceive the purchaser. A defendant had only to show that he personally believed in his patent medicine to escape prosecution. This remained a major weakness in the law for 26 years.

The USDA's Bureau of Chemistry enforced the law until 1927, when the bureau was reorganized in order to separate law enforcement functions from agricultural research and development. The Food, Drug, and Insecticide Administration was formed. It was renamed the Food and Drug Administration (FDA) in 1931, and in 1940 the FDA was transferred from the USDA to the Federal Security Agency, in order to eliminate recurring conflicts between consumer interests and producer interests. In 1953, the Federal Security Agency became the Department of Health, Education, and Welfare—now the Department of Health and Human Services (DHHS).

An interesting side note, FDA's budget (appropriations), because of its origins in the USDA, comes through the House and Senate Agricultural Appropriations committees. Amendments to the Federal Food, Drug, and Cosmetic Act, however, come under the jurisdiction of the Senate Committee on Labor and Human Resources and the House Committee on Energy and Commerce.

By the early 1930s it was evident that there were serious shortcomings in the 1906 act. False advertising in print and on the radio was blatant, and manufacturers had found many ways to circumvent the law. Technological advancements were revolutionizing the production and marketing of foods, drugs, and related products, making the 1906 law obsolete.

In 1933, Walter Campbell, then chief of the FDA, seized an opportunity to work with Rexford Tugwell, a member of newly elected president Franklin D. Roosevelt's "brain trust" who had been appointed assistant secretary of agriculture, in developing a complete revision of the Food and Drugs Act. When the resulting "Tugwell bill" was introduced in Congress, it was a legislative disaster. Opposition to this New Deal legislation by industry and advertising interests was total. This was due in part to Rexford Tugwell's reputation in the business community and to some extent in Con-

tion of therapeutic antimicrobial agents, are classified as over-the-counter, whereas most drugs approved for companion animals are classified as prescription.

This focus on OTC drugs (and the attendant need to be able to provide labeling that can be reasonably followed by laypersons) has led to the approval of OTC drugs that are labeled for very specific and limited indications and that have directions for use which provide little or no flexibility in how the product can be used. As a result, there are many animal species for which there are no drugs approved, and for others the number of approved drugs is very limited and does not include drugs such as anesthetics, anti-inflammatory agents, or other drugs with low market potential.

Faced with an insufficient armamentarium of drugs approved for all of the various animal species-disease combinations encountered in veterinary practice, veterinarians historically have exercised considerable judgment in utilizing therapeutic agents, often going beyond the limits of approved labeling. Prior to 1994, veterinarians who engaged in extra-label drug use technically were in violation of federal law, unlike their physician counterparts, who were not prohibited by the act from using or prescribing drugs for use in humans as they deemed appropriate. In spite of the fact that the act clearly specifies that an animal drug must be used in strict accordance with the indications and directions for use contained in its labeling, FDA policy was very permissive in this regard.

During the late 1970s and early 1980s the FDA recognized the need for a more structured policy regarding such use, one that would define the conditions under which such use would not ordinarily result in regulatory action while at the same time drawing attention to the responsibilities incurred by the veterinary practitioner electing to use a drug in an extra-label fashion, especially in a food-producing animal. The policy took the form of a Compliance Policy Guide (CPG). CPGs are used to provide guidance regarding regulatory initiatives and enforcement priorities to FDA field and headquarters personnel. CPG 7125.06, titled "Extra-Label Use of New Animal Drugs in Food-Producing Animals," communicated the FDA's recognition that the extra-label use of a drug in food-producing animals may be considered by a veterinarian when the health of animals is immediately threatened and suffering or death would result from failure to treat the affected animal(s). In instances of this nature, regulatory action would not ordinarily be considered provided that several criteria were met (see Chap. 58).

The FDA also recognized that in the case of companion animals (non-food animals) veterinarians had become reliant on a number of drugs approved for use in humans but for which no counterparts were approved for use in animals. Examples of human drugs widely used in companion animals include digitalis derivatives, insulin, and anticancer drugs. CPG 7125.35, "Human Drugs Distributed to Veterinarians for Use in Animals," basically provides that as long as such distribution of a human drug is initiated (ordered) by a licensed veterinarian and is *not* intended for use in food-producing animals, the FDA would *not* ordinarily consider regulatory action. However, it should be noted that the manufacturers are *not* permitted to advertise or otherwise promote the use of human-labeled drugs for use in animals.

Although CPGs generally discourage the use of human drugs in food animals, certain exceptions are recognized. These include certain poison antidotes, insulin for use in the treatment of ketosis, and certain anesthetics and analgesics for use in surgical cases and for relief of pain and suffering.

Despite the efforts of the FDA to establish policies that recognized the needs of animals while protecting the public's health, such policies were based on the agency's authority to exercise discretion in deciding whether or not to enforce certain provisions of the act. The fact that the FDA elected not to take enforcement actions against veterinarians who administered drugs in an extra-label manner in no way conferred legal status to such practices. Concerned by the notion that veterinarians, unlike the members of any other licensed profession, were forced to repeatedly break the law in order to responsibly carry out their professional duties, the American Veterinary Medical Association actively petitioned Congress to amend the act.

In 1994, Congress, in an effort to decriminalize the everyday practice of veterinary medicine, passed the Animal Medicinal Drug Use Clarification Act of 1994. This legislation allows licensed veterinarians to use and prescribe, under specified conditions, animal and human drugs for extra-label purposes. In general the legislation is intended to codify in law and regulations the conditions and restrictions for extra-label use provided in CPG 7125.06 and CPG 7125.35 as outlined above. It also recognized compounding of animal drugs from FDA-approved human or animal drugs as a form of extra-label drug use. Such compounding is permissible by a veterinarian or a pharmacist on the order of a veterinarian provided that (1) there is no approved new animal or new human drug that, when used as labeled and in the available dosage form and concentration, appropriately treats the condition diagnosed; (2) the compounding is performed by a licensed pharmacist or veterinarian within the scope of a professional practice; (3) adequate procedures and processes are followed that ensure the safety and effectiveness of the compounded product; (4) the scale of the compounding operation is commensurate with the established need for compounded products (e.g., similar to that of comparable practices); and (5) all relevant state laws relating to the compounding of drugs for use in animals are followed. Compounding from a human drug for use in food-producing animals is not permitted if an approved animal drug can be used for compounding. Compounding from bulk drugs is not permitted under the act; however, the FDA on occasion has exercised regulatory discretion in allowing compounding from bulk drugs where the need was great and the risk to animals and the public was small. Additional information on

comply with the Schedule III requirements of the CSA and must register with the DEA.

DRUG COMPENDIA. It is critically important to the veterinarian, pharmacist, and physician and their patients and clients that the drugs they employ are of uniform potency, purity, and quality. Without such standardization, rational pharmacotherapy would be impossible. Such assurance is a basic objective of the laws and regulations described above and is the purpose of the *US Pharmacopeia* (USP)-*National Formulary* (NF). The USP-NF is the legally recognized drug compendium for the United States. The USP was originally compiled and first published in 1820 and has been regularly and continuously revised by the US Pharmacopeial Convention, which is composed of elected delegates representing human medicine, pharmacy, veterinary medicine, dentistry, and nursing. The *National Formulary* was a separate official compendium published by the American Pharmaceutical Association to serve the need of pharmacists for standardization of certain pure drugs that were not used widely enough to be included in the USP. During the 1975-80 USP revision period these two official compendia were "unified" into a single USP-NF compendium. At that time the scope of the two components was changed in that the USP covered all drug substances and drug products, while the NF was devoted exclusively to pharmaceutic ingredients.

In addition to USP and NF designations, a drug may be given an International Nonproprietary Name (INN).

The USP and NF derive their official status from the FFD&C Act. Standards promulgated by the Committee of Revision of the USP Convention are enforceable by the FDA.

medium with acacia, lecithin, or methylcellulose added to stabilize the dispersion.

Two types of dosage forms are available for parenteral administration: injections and implants. Injections are sterile solutions or suspensions in an aqueous (sometimes an oil) vehicle. Most injections are heat sterilized or, if unstable to heat, are sterilized by filtration or irradiated. Some drugs are unstable in solution and are packaged aseptically in vials. These products are reconstituted with sterile water immediately before use for injection. A somewhat similar situation is that of tablet triturates, which are small, loosely packed tablets to be dissolved in water immediately before injection. Injections must be free of particulate foreign substances and pyrogens and should be nearly isotonic. They may be supplied in ampules, multiple-dose vials, or large-volume capped bottles or IV bags to which an intravenous infusion set may be attached. Syringes and needles for parenteral administration of drugs must be clean and sterile and the needles must be sharp. One may use either glass or disposable plastic syringes. However, it is best to use disposable needles since they are convenient, economical, and always sharp. Injections should not be stored in syringes for any length of time prior to use unless instructed to do so by the manufacturer, as some drugs will adsorb to either the glass (insulin) or plastic (diazepam) walls of the syringe and inadequate doses will be delivered. Disposable syringes and needles should be promptly destroyed and disposed of after use, and syringes and needles should be kept out of sight to keep them out of the hands of people who would use them for self-abuse for administration of addictive drugs. Specific regulations now exist for proper disposal of biohazard material.

Repository forms of drugs are designed to prolong effective drug concentration in the body by providing for sustained release from the dosage form. Sustained-release forms of injections are prepared by modifying the chemical nature of the drug to decrease its solubility, altering its physical form, or modifying its vehicle. Implants are very hard, sterile pellets inserted under the skin where they dissolve very slowly. Oral sustained-release preparations have not been as reliable because of individual differences in GI absorption and transit times. Capsules are available in which drug particles are coated with materials having different dissolution rates. Other methods are layered tablets and incorporation of ion exchange resins with the drug in tablets or capsules.

Several external dosage forms can be applied to the skin surface for various purposes. Liniments or braces are liquid or semisolid preparations to be applied to the skin with inunction (rubbing). These generally contain counterirritants to relieve muscle or tendon pain. Lotions are solutions or suspensions of soothing substances to be applied to the skin without friction (calamine lotion). Ointments are semisolid greasy preparations in which the drug is dissolved or dispersed in a suitable base, the nature of which may vary from an oleaginous substance such as petrolatum to a completely water-soluble base such as polyethylene glycol. Creams incorporate a drug in a water-oil emulsion; water will evaporate following application, leaving the drug and a thin film of oil on the skin. Dusting powders are mixtures of drugs in powder form for application to external surfaces. These may be applied for their adsorbent (cornstarch) or lubricant (talcum) properties. Aerosols are drugs incorporated in a suitable solvent and packaged under pressure with a propellant such as fluorinated hydrocarbon or nitrogen. Topical insecticides and wound dressings are frequently prepared as aerosols.

NOMENCLATURE. Names of drugs are often a source of confusion to the novice, partly because most drugs have at least three different names: a chemical name, a nonproprietary name, and one or more proprietary names. The chemical name provides scientific and technical personnel with a precise and unambiguous description of the substance in accordance with rules of chemical nomenclature established by the International Union of Pure and Applied Chemistry (commonly abbreviated IUPAC). Generally, such names are too complex and cumbersome to meet the everyday needs of the pharmacist, prescriber, and regulatory bodies. Accordingly, official nonproprietary names (incorrectly termed generic names) are designated to identify particular drug entities. Drug names appearing throughout this text and other discussions in pharmacology are principally nonproprietary names. A given drug entity may have a number of proprietary names that are brand names assigned and possibly trademarked by different manufacturers; e.g., POLYOTIC® Oblets, TET-SOL® 10, SOLUTET® Soluble Powder, TETRABAC® 324, ACHROMYCIN® V Capsules, TOPICYCLINE® for Topical Solution, HELIDAC® Therapy, and PANMYCIN® 500 Boluses are all proprietary names used to describe forms of tetracycline. An example of the complete nomenclature for a single entity is as follows: the nonproprietary, or generic, name for a certain sedative drug is diazepam, one proprietary name for a diazepam product is Valium® Tablets, and the chemical name is 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one. Technically, the proprietary term is an adjective that modifies a dosage form of the drug (e.g., NAXCEL® Sterile Powder, or NAXCEL® brand of Ceftiofur Sodium Sterile Powder).

Some order has been brought to the matter of drug nomenclature by the US Pharmacopeial Convention. A compilation of the United States Adopted Names (USAN) is published annually as the *USAN and the USP Dictionary of Drug Names*. Each entry of the compilation includes the US Adopted Name, the year of publication as a USAN, a pronunciation guide, the molecular formula, the chemical name, the registry number, the pharmacologic and therapeutic activity claim, the proprietary names and manufacturers, and the structural formula. An additional problem for the student is that there may be different nonproprietary names for the same drug in different countries; e.g., an analgesic drug is named meperidine in the United States, pethidine in the United Kingdom (UK), and dolantin in Germany. Similarly, barbiturates have the suffix *-al* in the United States and *-one* in the UK; e.g., pentobarbital is the same compound as pentobarbitone. Sulfamethazine in the United States is sulfadimidine in the UK. These differences are soon learned when practicing in a different country.

PRESCRIPTION WRITING. A prescription is an order to a pharmacist written by a licensed veterinarian, physician, or dentist to prepare the prescribed medicine, affix the directions, and sell the preparation to the client or patient. The prescription is a legally recognized document, and the writer is held responsible for its accuracy. Dispensing, on the other hand, is the preparation and distribution of medicines to those who are to use them. As a licensed practitioner, the veterinarian is entitled by law to dispense, administer, or prescribe medications for animal patients. Veterinarians have tended toward dispensing products rather than prescribing drugs. Knapp (1955) enumerated several good reasons for the veterinarian to become adept at prescription writing and employ the services of a registered pharmacist:

1. The veterinarian can charge just about the same fee as when drugs are dispensed; payment for services and knowledge rather than just payment for the remedy should receive higher priority.
2. Writing a prescription eliminates the cost of the dispensed item so that subtraction from the fee is obviated.
3. Prescribing provides the practicing veterinarian with a supply of pharmaceuticals that might not always be available on the shelves of the clinic.
4. Prescription writing reduces the investment tied up in drug inventory when one dispenses drugs.
5. If a client does not pay the bill, cost of the medicines dispensed are not lost.
6. Prescribing can bring about improved cooperation between the pharmaceutical and veterinary medical professions.
7. The client is frequently more inclined to pay for two smaller fees than one large fee.
8. Prescription writing provides a means for learning, including an appreciation of drugs and their actions, indications, and dosages; individuals adept in prescription writing usually have more detailed information at their command than those who are not.

The veterinarian should weigh the relative advantages between dispensing and prescribing and do what is best for the particular circumstances. In any case, every veterinarian should be able to write a prescription.

Form of the Prescription. The essential parts of a classic prescription consist of the following:

1. The *date* of writing the prescription.
2. The *identity* and *address* of owner and patient.
3. The *superscription,* Rx, is an abbreviation of the Latin word *recipe* meaning "take thou of." A portion of this superscription is the symbol of the Roman god Jupiter and is a relic of the times when all prescriptions were begun with a prayer to Jupiter asking his help in making them effective in the cure of disease.
4. The *inscription* lists the names and amounts of drugs to be incorporated in the prescription. Names of the drugs should be written in English and the total amounts required should be written in the metric system, which is preferred and official in the USP-NF. (In the past, the apothecaries' system of measurement and Latin terminology were preferred for prescription writing.) The modern tendency in therapeutics is to employ as few drugs as possible and strive for specific therapy. The complicated and useless mixtures ("shotgun" prescriptions) of earlier decades have been discarded in favor of single drugs or simple combinations of drugs. Most of the drugs needed by the practitioner are listed in the USP-NF.
5. The *subscription* gives the instructions to the pharmacist. These instructions may be entirely in English or with Latin abbreviations.
6. The *signa* (Sig. or S.) consists of instructions for administration of the medicine, which the pharmacist writes or types on the label.
7. The *signature* of the practitioner must appear on the prescription to make it a legal document.

Abbreviations. Names of drugs to be included in the prescription should not be abbreviated but should be written out in full to avoid possible errors. Chemical formulas must not be used in prescription writing because of the greatly increased probability of error.

Abbreviations of Latin words are commonly used in writing a prescription because they save time and are readily understood by the pharmacist. Commonly used abbreviations that should be memorized are provided in Table 57.1.

Dosage regimens have been expressed in a number of ways that have caused confusion and misunderstanding; e.g., dosage may be recommended as 22 mg/kg t.i.d., 22 mg/kg to be divided for t.i.d. administration, 66 mg/kg to be divided for t.i.d. administration, or 22 mg/kg q8h. As you can see, serious misunderstandings can arise if a drug is employed with a low margin of safety; e.g., if you gave 66 mg/kg three times between 0800 and 2200. It has been recommended (Aronson 1980) that dosage regimens be expressed as mg/kg and the time interval be expressed in hours, e.g., q4h, q8h, q12h. Thus abbreviations of s.i.d., b.i.d., t.i.d. and q.i.d. would be abandoned. This makes good sense, because three doses of a drug could be given within an hour and technically the animal would have received t.i.d. medication.

Metrology. Metrology is the study of weights and measures. The use of different or mixed systems of

TABLE 57.1—Abbreviations commonly used in prescribing

Abbreviation	Latin	Meaning
ad lib.	*ad libitum*	freely as wanted
ā ā	*ana*	of each
ā	*ante*	before
a.c.	*ante cibum*	before meals
aq.	*aqua*	water
b.i.d. (or BID)	*bis in die*	twice a day
cap.	*capula*	capsule
c̄	*cum*	with
div.	*divide*	divide
dos.	*dosis*	a dose
eq. pts.	*equalis partis*	equal parts
ft.	*fiat*	make
gtt.	*gutta*	a drop
haust.	*haustus*	drench
h.	*hora*	hour
M.	*misce*	mix
n.r.	*non repetatur*	not to be repeated
no.	*numero*	number
O.	*octarius*	pint
o.d.	*omne die*	every day
p.c.	*post cibum*	after meals
p.r.n.	*pro re nata*	as occasion requires
Q.R.	*quantum rectum*	correct quantities
q.s.	*quantum sufficiat*	sufficient quantity
q4h	*quaque 4 hora*	every 4 hours
q6h	*quaque 6 hora*	every 6 hours
q.i.d. (or QID)	*quater in die*	four times a day
s.i.d. (or SID)	*semel in die*	once a day
s̄ s̄	*semisse*	half
Sig., S.	*signa*	write on the label
s̄	*sine*	without
s.o.s.	*si opus sit*	if necessary
sol.	*solutio*	solution
stat.	*statim*	immediately
tab.	*tabella*	a tablet
t.i.d. (or TID)	*ter in die*	three times a day

metrology should be avoided, and the metric system is preferred worldwide. Appendix Table A57.1 lists commonly used weights and measures.

In the United States the weight/volume method (W/V) of measuring solids and liquids is employed; i.e., the masses of solids are weighed and the volumes of liquids are measured. The weight/weight method (W/W) is employed in continental Europe; i.e., both liquids and solids are weighed in prescription compounding. The completely gravimetric method is more accurate because it compensates for differences in specific gravity of liquids. However, for most purposes the weight by volume method employed in this country proves satisfactory.

The metric system uses Arabic numerals to indicate the quantities of drug required. The Arabic numeral is followed by the unit of measurement. A single vertical line may be substituted for aligned decimal points on successive lines. The figures to the left of the line are whole numbers, while those to the right are decimal fractions. In the metric system the quantities automatically indicate grams (g) for solids and milliliters (mL) for liquids without specific designation.

The veterinarian must be familiar with basic apothecary units in the United States for conversion to the metric system because a number of older dosage forms are still provided in the apothecaries' system of weights and measures by pharmaceutical companies. Conversion factors can be found in Appendix Table A57.2.

Writing the Prescription. Several examples of prescription writing are given in this section. The prescription is often very simple and requires little writing and calculation. In the one shown in Fig. 57.1, dosage is not important because the lotion would be applied by the owner in quantity sufficient to cover the lesions on the skin. The amount of 480 mL of lotion was chosen for dispensing because this volume exactly fills a 16-oz prescription bottle. The veterinarian should know that prescription bottles are available in the following volumes in fluid ounces: 1, 2, 3, 4, 6, 8, 12, 16, and 32. Bottles are also available calibrated in the metric system (i.e., mL). The veterinarian should prescribe appropriate volumes because the client is often better satisfied when paying for a full bottle.

Some drugs are not soluble in the common solvents and must be administered as solids. Powders may be administered as such when sprinkled on the animal's solid feed. Many powders are distasteful and must be masked by some flavoring agent or administered in a more palatable form. A common way of administering powders is by packing into a hard gelatin capsule. The capsule is tasteless, readily swallowed, and disintegrates rapidly in the stomach. Hard gelatin capsules are available in two series of sizes. The smallest is known as No. 5. In order of increasing size, capsules are numbered as 5, 4, 3, 2, 1, 0, 00, 000. Another numbering scheme is used for the next series of hard gelatin capsules, which increase in size from the last mentioned. In order of increasing size they are 13, 12, 11, and 10. In addition, there are infrequently used sizes 9, 8, and 7. The weight of drug contained in a capsule varies too widely with the ingredient to be of significance, but the No. 10 gelatin capsule is commonly referred to as the 1-oz size, the No. 11 as the 1/2-oz, the No. 12 as the 1/4-oz, and the No. 13 as the 1/8-oz capsule.

Assume that you have examined a toy poodle weighing 11 lb and have decided that the patient will benefit from a drug that will dilate the bronchioles. You elect to write a prescription for aminophylline tablets. You find that the dosage rate is 10 mg/kg to be given every 8 hours. Furthermore, you consult a reference to learn that aminophylline is available in 100- and 200-mg scored tablets. You want to prescribe enough medication for 2 weeks, after which you want to reexamine the patient. Your calculations would be as follows: the dog weighs 11 lb or 11 ÷ 2.2 = 5 kg; the dose is 10 mg/kg × 5 kg = 50 mg; this is to be given every 8 hours for 14 days. The nearest-sized tablet is 100 mg, so each dose would be one-half tablet. The number of 100 mg tablets needed is 21. You would write:

from low solubility of drug in a given solvent, immiscibility of liquids mixed together, and precipitation. One can readily avoid these problems by thoroughly understanding the actions of drugs used in therapy, using the services of a pharmacist, refraining from mixing different medicaments in the same syringe prior to administration, and being parsimonious in use of drugs.

CHEMICAL RESIDUES IN TISSUES OF FOOD ANIMALS

JIM E. RIVIERE AND STEPHEN F. SUNDLOF

The Concern over Residues in Food
Regulation of Drug Residues in Animals
  The Veterinarian and Extra-Label Drug Use
Pharmacokinetics and Residues
Drugs Prohibited from Extra-Label Use
Residue Prevention

Most of this textbook has focused on describing the pharmacodynamics and pharmacokinetics of drugs in animals. In both human medical and companion-animal veterinary practices, the primary concern in drug selection and use is the therapeutic end point, whether or not the drug is efficacious against the disease being treated. Doses are usually administered at label recommendations, and if greater than label doses are administered, only potential toxicity is of concern. While this line of reasoning is also true to a large degree in food-animal production, veterinarians and producers involved in the treatment of disease in food animals bear the additional concern of the persistence of drug residues in the edible tissues after the disease process has been treated. Adulteration of the food supply with antimicrobial agents, pesticides, environmental contaminants, and other chemicals has been a growing source of concern to the general public and special-interest groups in recent years.

The importance of chemical residues in the edible tissues of food-producing animals has been thoroughly reviewed elsewhere (Sundlof 1989; Riviere 1991, 1992a; Van Dresser and Wilcke 1989; Mercer 1990; Kindred and Hubbert 1993; Bevill 1989). The purpose of this chapter is to acquaint the veterinarian with the legal and regulatory issues concerning the control of drug and other chemical residues in the United States, and to review some of the pharmacokinetic parameters used to determine withdrawal times for drugs and other chemicals in food animals. The primary parameter used by veterinarians to prevent violative tissue residues is the length of the withdrawal time, or the time required for a drug to be depleted from the animal before the animal's meat can be marketed for human consumption. In dairy practice, this is the milk discard time. Recently, government regulation and control have necessitated more stringent adherence to withdrawal times, and on-site monitoring for many drugs has been instituted. This may have an economic impact on production costs. Unlike in previous editions of this text, withdrawal times will not be tabulated, because they are subject to constant regulatory revision. Extensive tables of tissue depletion pharmacokinetic data are published elsewhere (Riviere et al. 1991; Craigmill et al. 1994).

THE CONCERN OVER RESIDUES IN FOOD. A great deal of concern has been demonstrated over the last 40 years about the presence of chemical adulterants or residues, mainly antimicrobials and pesticides, in the meat, poultry, and milk supplies of the United States. By definition, a chemical residue is either the parent compound or a metabolite of the parent compound that may accumulate, deposit, or otherwise be stored within the cells, tissues, organs, or edible products (e.g., milk, eggs) of an animal following its use to prevent, control, or treat animal disease or to enhance production. Residues can also result from unintentional administration of drugs or food additives. Finally, accidental exposure to chemicals in the environment can also result in tissue residues.

Concerns over food residues are economic as well as public health related. For example, the contamination of milk with antibiotics, most commonly penicillin, can affect starter cultures used to make fermented milk products such as cheeses, buttermilk, sour cream, etc., which can result in economic losses to those processors. From a public-health viewpoint, both the US government and producer associations have taken active roles in minimizing antibiotic residues in meats and milk. Penicillin, for example, is known to induce allergic reactions in some sensitive people, and therefore, penicillin-tainted milk poses a health risk for these individuals. Similarly, chloramphenicol has been reported to induce blood dyscrasias that may lead to death; hence, its use in food-producing animals has been prohibited by the Food and Drug Administration (FDA). The FDA has also prohibited the use of nitrofurans in food-producing animals because recent data have shown them to be carcinogenic. Not only therapeutic drugs but pesticides create residue problems. Most pesticides are administered topically, allowing some amount of percutaneous absorption and sequestration in edible tissues (see Chap. 53 of this text). Lindane has been detected in the fat deposits of sheep dipped in a 0.0125% lindane emulsion 12 weeks after topical exposure (Collett and Harrison 1963). Other studies have shown lindane residues in sheep, goats (Jackson et al. 1959), and lactating cows (Oehler et al. 1969). In addition to lindane, many common pesticides (organochlorines, organophosphates, botanicals, pyrethrins, etc.) and herbicides used in agriculture today that are applied topically have been shown to produce residues in food-producing animals. Environmental contaminants (e.g., heavy metals, PCB, mycotoxins) are also of major concern today. Tissue residue violations detected by governmental monitoring programs have been summarized by Sundlof (1989). More information on xenobiotics in food-producing animals is available in Riviere 1992a. Both public-health and economic concerns have been the major driving forces in the United States and in other countries behind the search for ways to minimize the threat of residue contamination of the public food supply.

Contamination of the food supply with chemical residues is rarely an intentional act and usually results either from failure to observe the correct meat withdrawal or milk discard time for a drug after it has been used to treat a disease in food animals or from accidental contamination of feed by chemicals or drugs. A study by Van Dresser and Wilcke (1989) provides some interesting insight on drug residue problems in food-producing animals. In that study, streptomycin, penicillin, sulfamethazine, and oxytetracycline were the four most common antibiotics found in tissues, with sulfamethazine being the most commonly found sulfonamide in animal tissues. Long-acting formulations of these drugs (i.e., penicillin and oxytetracycline) had the highest association with violative residues in the animals involved in the study. Injectable drugs were more likely to be associated with residue problems than were feed additives and boluses. Most of these residues were found in veal calves, cows, and market barrows and gilts. The most frequently cited reason for violative residues was failure to observe the correct withdrawal time for the drug. Failure to observe the correct withdrawal time was cited as the most common reason for violative drug residue levels in a study performed by the FDA in the 1970s (Bevill 1984) and continued to be the most common cause of residue violations in the 1990s. Interestingly, in this study the producer was found to be the responsible party in 80% of the cases investigated for violative levels of drug found in edible tissues (when the responsible party could be identified); unapproved drug use (extra-label drugs) is not considered a major cause of drug residues in animals. Ways to prevent drug residues will be discussed later in this chapter.

The FDA and Environmental Protection Agency (EPA) establish tolerances for a drug, pesticide, or other chemical in the relevant tissues of the food-producing animals. The tolerance is the tissue concentration below which a marker residue for the drug or chemical must fall in the target tissue before that animal's edible tissues (meat, milk, or eggs) are considered safe for human consumption (Riviere 1991). The marker residue may be the parent compound or a metabolite and reflects a known relationship to the total residues of the drug or chemical (parent and all metabolites). The target tissue is an edible tissue, frequently liver or kidney, which, when the compound has depleted below the tolerance, assures that all edible tissues are safe for human consumption. Tolerances for different tissues are considered legal end points for which drug withdrawal times are established. Tolerances are established based on extensive toxicologic studies of the potential hazard of consumption to humans. Oral toxicity studies are conducted in animals leading to the determination of an acceptable daily intake (ADI) for the compound in the human diet. These studies consider the compound's carcinogenic potential and its systemic, reproductive, and developmental toxicity and incorporate various safety factors. A safe concentration for human consumption is calculated using an equation that accounts for the amount of a specific food consumed by a person representing a high-consuming population (e.g., 19-year-old males) so that a safe concentration of the drug in this food (e.g., meat, milk, eggs) can be established. Various safety factors and statistical considerations are built into these determinations, and a tolerance for this drug in the specific tissue is established where appropriate and is published. For example, safety factors reflect the duration of exposure and the nature of the toxic effects associated with the chemical. A teratogen requires a larger safety factor than a nonteratogen, and ADIs based on a short-term subchronic study use a larger safety factor than ADIs based on chronic studies. The tolerance is for a specific drug or chemical entity and reflects both the inherent toxicity of the chemical and assumptions about the human consumption of the tissue for which the tolerance is established. Tolerances are determined for the active ingredient (the drug substance or its metabolite) and are not established for the specific formulation of the commercial drug product. A full discussion of this process has recently been reviewed (Baynes et al. 1999) and can be found in toxicology or risk assessment texts. It is important for the veterinarian to realize that the end point for determining withdrawal times, the tolerance, is a combined scientific and legal concept and therefore is ultimately controlled by *regulatory* and not medical practices.

The actual withdrawal time appearing on a drug label is also a function of the experimental design that the manufacturer used in the research studies submitted to the FDA for approval. Thus, although the science governing the withdrawal time is based on the pharmacokinetic principles discussed below, the withdrawal time is actually determined based on experimental data. Generally, a drug is administered to healthy animals, groups of the animals are slaughtered at sequential time intervals, and their edible tissues are analyzed for drug concentrations. The withdrawal time is the time from cessation of treatment to the time it takes for the residues of the drug to deplete below the safe concentration.

A statistical method is used to determine the time at which the marker residue depletes to the tolerance in the target tissue. The method determines the time, rounded to the next whole day, at which the upper bound of the marker residue tissue concentration is below the established tolerance in the target tissue (where the upper bound is statistically determined to represent with 95% confidence the 99th percentile of the population). Withdrawal times for the FDA-approved drugs for use in food animals are only valid for the specified species, dose, route, and frequency of administration. They are also specific to the manufacturer's product and formulation; thus, a drug substance (the active ingredient) may have different withdrawal times when present in the differently formulated drug products. An analogous process occurs in establishing milk discard times and in determining the withdrawal times for drugs administered to egg-laying poultry (although presently, all drugs approved in the United States for use in laying hens have a 0-day withdrawal).

REGULATION OF DRUG RESIDUES IN ANIMALS. Producers, veterinarians, and other persons involved with chemicals and food-animal production should be acquainted with a few terms and the agencies involved in drug residue control in order to better understand the drug residue problem and how withdrawal times are determined.

The use of drugs in veterinary medicine, especially in food-producing animals, is closely regulated in the United States by the FDA under the Department of Health and Human Services. The FDA is charged, through the Federal Food, Drug, and Cosmetic Act of 1938 (amended in 1968), with regulating the use of drugs in humans and in animals as well as requiring that the safety and efficacy of a drug be established before the product can be approved for use in animals, including those products added to animal feeds. The FDA also regulates human biologics, medical devices, drugs, and food safety. The FDA's Center for Veterinary Medicine (FDA-CVM) is responsible for the regulation of drugs, medical devices, and feeds intended for animals. The FDA is charged with the responsibility for establishing withdrawal times of drugs and the tolerances of drugs. The FDA and the EPA share responsibility for establishing tolerances for pesticide residues in animal-derived foods.

Whereas the FDA establishes safety guidelines for drug use in food animals, it is the responsibility of the US Department of Agriculture (USDA) to enforce the standards established by the FDA and the EPA. The USDA, through authorization by the Federal Meat Inspection Act of 1906 and the Poultry Inspection Act of 1967, inspects meat and poultry for sale through interstate commerce. The USDA is also authorized to test the tissues of food-producing animals through provisions in the Federal Insecticide, Fungicide and Rodenticide Act of 1947 in order to determine if violative levels of residues of chemicals and drugs are present. The Food Safety Inspection Service (FSIS), a division of the USDA, monitors these tissues through the National Residue Program (NRP) and identifies problems with drug and chemical residues. The NRP has been in action for over 25 years and has concentrated on individual, as well as population, sampling for monitoring and surveying possible residue problems in slaughter animals. In 1992, the NRP estimated they would collect some 350,000 specimens that year to analyze for antimicrobial and pesticide residues (Kindred and Hubbert 1993). The FSIS is the largest food safety inspection force in the federal government (Norcross and Post 1990).

The FSIS uses several rapid tests for determining contamination of animal products. Among these are the Swab Test on Premises (STOP) for antibiotic and sulfonamide residues, the Overnight Rapid Beef Identification Test (ORBIT) for species identification of meat, the Calf Antibiotic and Sulfa Test (CAST), the Sulfa-on-Site (SOS), and a variety of enzyme-linked immunosorbent assays (ELISAs) (Norcross and Post 1990). Rapid screening tests for residues have been summarized (Sundlof 1989). Milk in bulk tanks and from individual animals is assayed for antibiotic residues using various testing strategies: Charm Tests (Charm Sciences, Inc.), *Bacillus stearmothemophilus* disk assay (Charm Sciences, Inc.), SNAP Beta-lactam (IDEXX Laboratories, Inc.), LakTek tests, and Delvo tests (Gist-Brocades Food Ingredients, Inc.), to name only a few. This area is difficult to adequately summarize because rapid advances in analytical screening methodologies have led to the rapid development of new tests.

Other federal government agencies have defined roles in regulating the sale and use of drugs in animals, including the Drug Enforcement Agency (a division of the Department of Justice), the Animal and Plant Health Inspection Service (a part of the USDA), the EPA (mainly for pesticides), and the Department of Transportation. On a state level, the Department of Public Safety, Department of Health, the Animal Health Commission, Boards of Veterinary Medical Licensing, and Pharmacy Boards all have some regulatory influence over the use of drugs in food-producing, as well as companion, animals.

The Veterinarian and Extra-Label Drug Use. The FDA approves new animal drugs for specific indications in a particular species or subclass of animals (e.g., dairy cattle, weanling pigs). Occasionally, veterinarians may encounter diseases or conditions in animals for which there are no FDA-approved drugs. Under such circumstances, veterinarians often administer drugs that are not approved for use in food animals or they administer approved drugs in nonapproved ways, practices commonly referred to as "extra-label" usage. Extra-label drug use is defined as the use of a drug in a manner that is inconsistent with its FDA-approved labeling, a practice that, until 1994, was technically illegal. Recognizing that the Food, Drug, and Cosmetic

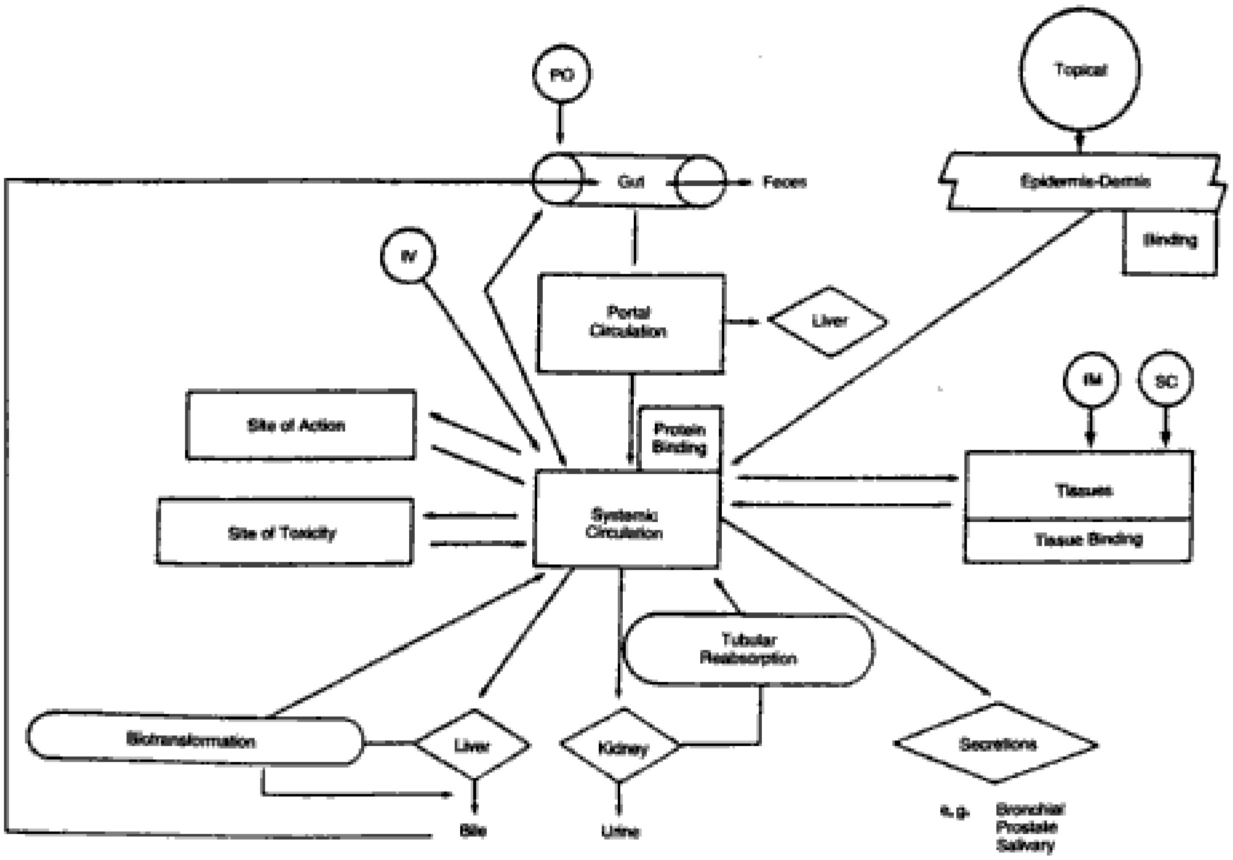

FIG. 58.1—Schematic diagram of how a drug can distribute in the body.

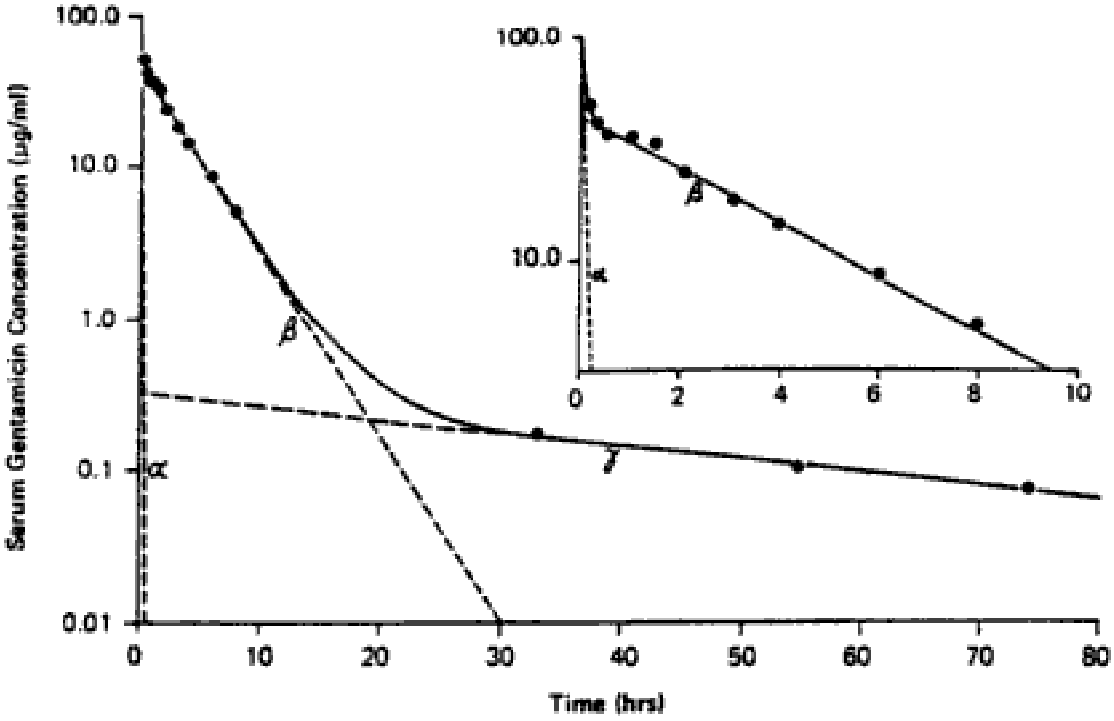

FIG. 58.2—A typical serum concentration-time profile for gentamicin after intravenous administration in a food-producing animal. Note the terminal-phase (γ) half-life of gentamicin, which is useful in predicting tissue withdrawal times. (Reprinted, with permission, from Riviere 1988.)

specific tissue that is of paramount importance. This information is not available to the veterinarian. Additionally, tissue pharmacokinetics is exceedingly complex, and a discussion here of terminal half-lives will be sufficient to illustrate the concepts involved. For more in-depth information on the clinical application of pharmacokinetics and how pharmacokinetic parameters can affect clinical parameters, readers should consult Chaps. 3 and 4 of this textbook.

The half-life of the drug or chemical in the body is the primary biological measurement used to determine withdrawal times of drugs and chemicals in food-producing animals; however, this parameter can be influenced by many biological factors. The $t_{1/2}$ of the γ phase of a drug by definition is the time it takes for 50% of the drug in the animal to be eliminated from the body and is the primary part of the elimination curve shown in Fig. 58.2 used to determine the withdrawal time of a drug. The $t_{1/2}$ is calculated using the equation

$$t_{1/2} = \frac{\ln 2}{\text{slope}} \quad \text{or} \quad t_{1/2} = \frac{0.693}{\text{slope}}$$

If the concentration of a drug in the muscle of a food animal after dosing is 100 parts per million (ppm), then the time it takes for the concentration in the muscle to decrease to 50 ppm would be the biological half-life of the drug in the muscle. Extrapolated out, the amount of drug in the muscle after 10 half-lives would be 0.1 ppm, or, put in other terms, 99.9% of the drug would have been eliminated from the muscle after 10 half-lives. If the dose is doubled and the beginning concentration in the muscle is now 200 ppm, only 1 additional half-life would be required to reach the 0.1 ppm concentration. On the other hand, if the half-life of the drug in the muscle is doubled, perhaps due to a disease state, then the elimination half-life would also double, thereby increasing the risk of violative drug residues in the edible tissues of that animal.

As stated above, the elimination half-life can be influenced by many biological factors. The half-life of a drug or chemical in the body is influenced by how well it distributes in the body and how quickly it is eliminated from the body. The physicochemical properties of a drug can influence its disposition in the body—in particular, how well it distributes into certain tissues or whether or not it penetrates intracellularly or whether it permeates the blood-brain barrier. The volume of distribution (V_d) is the quantitative estimate of the extent of the distribution of the drug in the body and can therefore directly influence the $t_{1/2}$ of the drug. It is a proportionality constant relating the concentration of drug in the serum to the total amount of drug in the body. For an intravenous injection of a drug, the equation for calculating V_d is

$$V_d = \frac{\text{amount of drug in the body}}{\text{serum drug concentration}}$$

It is important to point out that the V_d, typically reported in L/kg, does not actually refer to any specific physiologic space or body area; rather, it gives a good indication of how well a drug in general distributes throughout the body. A drug that has a large V_d typically has good tissue distribution throughout the body (tetracyclines), whereas a drug with a small V_d has less penetration into the body tissues as a whole, perhaps being confined to the extracellular spaces due to one or more of its physicochemical properties (not lipid soluble, fixed charge). While V_d may give an indication of the overall distribution of a drug, some drugs may not be uniformly distributed throughout the body. In this case, a drug may seek specific cells or organs or be bound to tissue macromolecules, resulting in a large V_d measurement and yet a relatively poor overall distribution in a majority of the body's tissues. Some drugs may have prolonged withdrawal times due to a large V_d.

In addition to V_d, the clearance (Cl) of the drug also plays an important part in determining the withdrawal time of the drug. Clearance quantitates the efficiency of the elimination processes and is defined as the rate of drug elimination from the body relative to the concentration of drug in the serum by the equation

$$Cl = \frac{\text{rate of elimination}}{\text{serum drug concentration}}$$

Drugs that have a slow rate of elimination from the body will tend to have protracted half-lives, whereas those that are eliminated quickly will have shorter half-lives.

The $t_{1/2}$ is dependent on two functions: V_d and Cl. By combining terms, an equation can be derived that reflects the influence of V_d and Cl on the $t_{1/2}$ of a drug:

$$t_{1/2} = \ln 2 \times \frac{V_d}{Cl} \quad \text{or} \quad t_{1/2} = 0.693 \times \frac{V_d}{Cl}$$

Several physiologic events can occur to change V_d or Cl and can therefore influence the $t_{1/2}$ of the drug in the body. For example, if renal function is impaired, the drug's clearance may be reduced and the $t_{1/2}$ prolonged by several hours or several days, in turn prolonging the withdrawal time of the drug. If the animal's fluid balance changes, the V_d may change accordingly. Factors such as the age, nutritional status, percentage of body fat, species, presence of other drugs, and extent of protein binding can all have a significant role in determining the V_d and Cl and hence the $t_{1/2}$ of any drug introduced into the body. For more information on the pharmacokinetics, readers are encouraged to consult Chaps. 3 and 4.

The pharmacokinetic behavior and efficacy of the drug or chemical used to treat a disease process are of major concern early on in the successful management of herd health in food animals. For residue control in food-animal species, the primary purpose of knowing the pharmacokinetic behavior of the drug (i.e., the terminal elimination half-life) is to determine the withdrawal time to prevent residue accumulation in those tissues consumed by humans. A knowledge of what physiological processes affect the half-life is thus

Committee on Food Additives (JECFA) has evaluated several drugs and has published monographs that list toxicity, metabolism, acceptable daily intakes, maximum residue levels permitted for different tissues, and biological fate of drugs in food-producing animals. The *United States Pharmacopoeia* (USP) also publishes monographs (similar to the monographs for human drugs) that go into more detail about expanded (extralabel) pharmaceutical usage and pharmacokinetic variables that can alter withdrawal times in food-producing animals (Sundlof 1993).

The prevention of harmful residues in the edible tissues of our food-producing animals is the responsibility of many producers, veterinarians, professional and layperson associations, and governmental agencies. All of these groups must continue to strive to regulate and utilize the drugs used to prevent or cure animal diseases in a responsible manner in order to prevent the accumulation of harmful amounts of residues in the food supply.
